Modularity of Mind

Two influential theoretical positions have permeated cognitive science: (1) that the mind/brain is a general-purpose problem solver (NEWELL and Simon 1972; PIAGET 1971); and (2) that it is made up of special-purpose modules (Chomsky 1980; Fodor 1983; Gardner 1985). The concept of modular organization dates back to KANT (1781/1953) and to Gall's faculty theory (see Hollander 1920). But it was the publication of Fodor's *Modularity of Mind* (1983) that set the stage for recent modularity theorizing and which provided a precise set of criteria about what constitutes a module.

Fodor holds that the mind is made up of genetically specified, independently functioning modules. Information from the external environment passes first through a system of sensory transducers that transform the data into formats each special-purpose module can process. Each module, in turn, outputs data in a common format suitable for central, domain-general processing. The modules are deemed to be hardwired (not assembled from more primitive processes), of fixed neural architecture (specified genetically), domain-specific (a module computes a constrained class of specific inputs bottom-up, focusing on entities relevant only to its particular processing capacities), fast, autonomous, mandatory (a module's processing is set in motion whenever relevant data present themselves), automatic, stimulus-driven, and insensitive to central cognitive goals. A further characteristic of modules is that they are informationally encapsulated. In other words, other parts of the mind can neither influence nor have access to the internal workings of a module, only to its outputs. Modules only have access to information from stages of processing at lower levels, not from top-down processes. Take, for example, the Muller-Lyer illusion, where, even if a subject explicitly knows that two lines are of equal length, the perceptual system cannot see them as equal. Explicit knowledge about equal line length, available in what Fodor calls the "central system," cannot infiltrate the perceptual system's automatic, mandatory computation of relative lengths.

For Fodor, it is the co-occurrence of all the properties discussed above that defines a module. Alone, particular properties do not necessarily entail modularity. For instance, automatic, rapid processing can also take place outside input systems such as in skill learning (Anderson 1980). Task-specific EXPERTISE should not be confounded with the Fodorian concept of a module. Rather, each module is like a special-purpose computer with a proprietary database. A Fodorian module can only process certain types of data; it automatically ignores other, potentially competing input. This enhances automaticity and speed of computation by ensuring that the organism is insensitive to many potential

classes of information from other input systems and to top-down expectations from central processing. In other words, Fodor divides the mind/brain into two very different parts: innately specified modules and the nonmodular central processes responsible for deductive reasoning and the like.

Fodor's modularity theory had a strong impact on researchers in cognitive development. Until the 1980s BEHAVIORISM and Piaget's constructivism had been dominant forces in development. Both these theories maintain that the infant and child learn about all domains—SYNTAX, SEMANTICS, number, space, THEORY OF MIND, physics, and so forth—via a single set of domain-general mechanisms (the actual types of mechanism invoked are very different in the two theories). By contrast, with Chomskyan linguistics and Fodorian modularity, a sizable number of developmentalists opted for an innately specified, modular view of the infant mind. Not only did Chomskyan psycholinguists argue for the innately specified modularity of syntax (e.g., Smith and Tsimpli 1995; see Garfield 1987; but see also Marslen-Wilson and Tyler 1987 for a different view), but developmentalists also supported a modular view of semantics (Pinker 1994), of theory of mind (Anderson 1992; Baron-Cohen 1995; Leslie 1988), of certain aspects of the infant's knowledge of physics (Spelke et al. 1992; but see Baillargéon 1994 for a different view), and of number in the form of a set of special-purpose, number-relevant principles (Gelman and Gallistel 1978).

Data from normal adults whose brains become damaged from stroke or accident seem to support the modular view (Butterworth, Cipolotti, and Warrington 1996; Caramazza, Berndt, and Basili 1983). Indeed, brain-damaged adults often display dissociations where, say, face processing is impaired, while other aspects of visual-spatial processing are spared, or where semantics is spared in the face of impaired syntax, and so forth. On the other hand, several authors have now challenged these seemingly clear-cut dissociations, demonstrating, for instance, that supposedly damaged syntax can turn out to be intact if one uses on-line tasks tapping automatic processes rather than off-line, meta-linguistic tasks (e.g., Tyler 1992), and that a single underlying deficit can give rise to behavioral dissociations (Farah and McClelland 1991; Plaut 1995).

Evidence from idiots savants (Smith and Tsimpli 1995) and from persons having certain developmental disorders (e.g., Baron-Cohen 1995; Leslie 1988; Pinker 1994) has also been used to lend support to the modularity view. There are, for instance, developmental disorders where theory of mind is impaired in otherwise high functioning people with AUTISM (Frith 1989), or where face processing scores are in the normal range but visuo-spatial cognition is seriously impaired, as in the case of people with Williams syndrome (Bellugi, Wang and Jernigan 1994). These data have led some theorists to claim that such modules must be innately specified because they are left intact or impaired in genetic disorders of development. Yet this claim has also been recently challenged. In almost every case of islets of so-called intact modular functioning, serious impairments within the "intact" domain have subsequently been identified (e.g., Karmiloff-Smith 1998; Karmiloff-Smith et al. 1997), and in cases of purported singular modular deficits, more general impairments have frequently been brought to light (e.g., Bishop 1997; Frith 1989; Pennington and Welsh 1995). In other words, abnormal development does not point to isolated, prespecified modules divorced from the rest of the cognitive, motor, and emotional systems. Genetic impairments affect various aspects of the developmental process, in some domains very subtly and in others more seriously.

In normal development, too, new research is also pointing to gradual specialization rather than prespecification. Take the case of syntax, a particularly popular domain for claimants of modularity. Brain imaging studies of infants and toddlers have shown a changing pattern of HEMISPHERIC SPECIALIZATION (Mills, Coffey-Corina, and Neville 1993, 1994). Initially, the infant processes syntax in various parts of the brain across both hemispheres. It is only with time that parts of the left hemisphere become increasingly specialized. This also obtains for other aspects of language and for face processing in which infant imaging studies using high-density ERPs show progressive localization and specialization (Johnson 1997). The human cortex takes time to structure itself as a function of complex interactions at multiple levels: differential timing of the development of parts of cortex, the predispositions each part has for different types of computation, and the structure of the inputs it receives (for detailed discussion, see for example Elman et al. 1996; Johnson 1997; Quartz and Sejnowsky forthcoming). While there may be prespecification at the cellular level, this does not seem to hold for synaptogenesis at the cortical level. Specialized circuitry and the rich network of connections between cells appear to develop as a function of experience, which challenges the notion of prespecified modules.

Although the fully developed adult brain may include a number of module-like structures, it does not follow that these must be innately specified. Given the lengthy period of human postnatal brain development and what we know about the necessary and complex interaction of the genome with environmental influences (e.g., Elman et al. 1996; Johnson, 1997; Quartz and Sejnowsky 1997; Rose 1997), modules could be the product in adulthood of a gradual developmental process (Karmiloff-Smith 1992), rather than being fully prespecified, as Fodorians maintain. This is not a return to a general-purpose, equipotential view of the infant brain. On the contrary, an alternative to representational nativism (the innate knowledge position on which modularity theory is based) has been proposed by several theorists who have formulated hypotheses about what might be innately specified in terms of computational and timing constraints, while leaving ample room for epigenetic processes (Elman et al. 1996; Quartz and Sejnowsky 1997).

While the concept of prespecified modules has been challenged on a number of fronts, it has also become increasingly clear that the general-purpose view of the brain is inadequate. The human mind/brain is not a single, domain-general processing system, either in infancy or in adulthood. Nor is the alternative a return to simple behaviorism. The genome and sociophysical environment both place constraints on development. A different way to conceive of

modularity might therefore be to adopt a truly developmental perspective and acknowledge that the structure of minds could emerge from dynamically developing brains, whether normal or abnormal, in interaction with the environment. The long period of human postnatal cortical development and the considerable plasticity it displays suggest that progressive modularization may arise simply as a consequence of the developmental process. Variations in developmental timing and the brain's capacity to carry out subtly different kinds of computation, together with differential structures in the environmental input, could suffice to structure the brain (Elman et al. 1996; Karmiloff-Smith 1992, 1995; Quartz and Sejnowsky 1997; Rose 1997). Nativists of course recognize that environmental input is essential to trigger developmental processes, but the environment only plays a very secondary role to the genome in such theories. In the alternative framework suggested above, there is no need to invoke innate knowledge or representations to account for resulting specialization, because of variations in developmental timing, different learning algorithms together with information inherent in different environmental inputs would together play a central role in the dynamics of development and in the gradual formation of module-like structures.

Moral Psychology

Moral psychology is a branch of ethics. It concerns the features of human psychology whose study is necessary to the examination of the main questions of ethics, questions about what is inherently valuable, what constitutes human well-being, and what justice and decency toward others demand. Adequate examination of these questions requires an understanding of the primary motives of human behavior, the sources of pleasure and pain in human life, the capacity humans have for voluntary action, and the nature of such psychological states and processes as desire, emotion, conscience, deliberation, choice, character or personality, and volition. The study of these phenomena in relation to the main questions of ethics defines the field of moral psychology.

At the heart of this study are questions about the intellectual and emotional capacities in virtue of which human beings qualify as moral agents. Humans, in being capable of moral agency, differ from all other animals. This difference explains why human action, unlike the actions of other animals, is subject to moral assessment and why humans, unlike other animals, are morally responsible for their actions. At the same time, not every human being is morally responsible for his or her actions. Some like the very young and the utterly demented are not. They lack the capacities that a person must have to be morally responsible, capacities that equip people for understanding the moral quality of their actions and for being motivated to act accordingly. Full possession of these capacities is what qualifies a person as a moral agent, and it is the business of moral psychology to specify what they are and to determine what full possession of them consists in.

In modern ethics the study of these questions has largely concentrated on the role and importance of reason in moral thought and moral motivation. The overarching issue is whether reason alone, if fully developed and unimpaired, is sufficient for moral agency, and the field divides into affirmative and negative positions on this issue. Rationalist phi-

losophers, among whom KANT is foremost in the modern period, defend the former. On their view, reason works not only to instruct one about the moral quality of one's actions but also to produce motivation to act morally. Human beings, on this view, are moved by two fundamental kinds of desire, rational and nonrational. Rational desires have their source in the operations of reason, nonrational in animal appetite and passion. Accordingly, moral motivation, on this position, is a species of rational desire, and reason not only produces such desire but is also capable of investing it with enough strength to suppress the conflicting impulses of appetite and passion. Moral agency in human beings thus consists in the governance of appetite and passion by reason, and the possession of reason is therefore alone ordinarily sufficient to make one responsible for one's actions.

The chief opposition to this view comes from philosophers such as HUME and Mill. They deny that reason is ever the source of moral motivation and restrict its role in moral agency to instructing one about the moral quality of one's actions. On this view, all desires originate in animal appetite and passion, and reason works in the service of these desires to produce intelligent action, action that is well aimed for attaining the objects of the desires it serves. Consequently, the primary forms of moral motivation, on this position, the desire to act rightly, the aversion to acting wrongly, are not products of reason but are instead acquired through some mechanical process of socialization by which their objects become associated with the objects of natural desires and aversions. Moral agency in human beings thus consists in cooperation among several forces, including reason, but also including a desire to act rightly and an aversion to acting wrongly that originate in natural desires and aversions. Hence, because the acquisition of these desires and aversions is not guaranteed by the maturation of reason, the possession of reason is never alone sufficient to make one responsible for one's actions.

This anti-rationalist view is typically inspired by, when not grounded in, the methods and theories of natural science as applied to human psychology. In this regard, the most influential elaboration of the view in twentieth century thought is Freud's. Applying the general principles of personality development central to his mature theory, FREUD gave an account of the child's development of a conscience and a sense of guilt that explained the independence and seeming authority of these phenomena consistently with their originating in emotions and drives that humans like other animals possess innately. His account in this way speaks directly to the challenge that the rationalist view represents, for rationalists, such as Kant, make the independence and seeming authority of conscience the basis for attributing the phenomena of conscience, including their motivational force, to the operations of reason.

A second dispute between rationalists and their opponents concerns the nature of moral thought. Rationalists hold that moral thought at its foundations is intelligible independently of all sensory and affective experiences. It is, in this respect, like arithmetic thought at its foundations. Kant's view again sets the standard. In brief, it is that the concepts and principles constitutive of moral thought are

formal and universal, that their application defines an attitude of impartiality toward oneself and others, and that through their realization in action, that is, by following the judgments one makes in applying them, one achieves a certain kind of freedom, which Kant called autonomy. This view, unlike Kant's view about moral motivation, which has little currency outside of philosophy, deeply informs various programs in contemporary developmental psychology, notably those of PIAGET and his followers, whose work on moral judgment and its development draws heavily on the formalist and universalist elements in Kant's ethics.

Opponents of this view maintain that some moral thought is embodied by or founded on certain affective experiences. In this respect they follow common opinion. Sympathy, compassion, love, humanity, and attitudes of caring and friendship are commonly regarded as moral responses, and in the views of leading anti-rationalist thinkers one or another of these responses is treated as fundamental to ethics. Accordingly, the cognitions that each embodies or the beliefs about human needs and well-being (or the needs and well-being of other animals) that each presupposes and to which each gives force count on these views as forms of foundational moral thought. Such thought, in contrast to the rationalist conception, is not resolvable into formal concepts and principles, does not necessarily reflect an attitude of impartiality toward oneself and others, and brings through its realization, not autonomy, but connection with others. In contemporary developmental psychology, this view finds support in work on gender differences in moral thinking and on the origins of such thinking in the child's capacity for empathy.

Morphology

Morphology is the branch of linguistics that deals with the internal structure of those words that can be broken down further into meaningful parts. Morphology is concerned centrally with how speakers of language understand complex words and how they create new ones. Compare the two English words *marry* and *remarry*. There is no way to break the word *marry* down further into parts whose meanings contribute to the meaning of the whole word, but *remarry* consists of two meaningful parts and therefore lies within the domain of morphology. It is important to stress that we are dealing with meaningful parts. If we look only at sound, then *marry* consists of two syllables and four or five phonemes, but this analysis is purely a matter of PHONOLOGY

and has nothing to do with meaningful structure and hence is outside morphology.

The first part of *remarry* is a prefix (*re-*), which means approximately 'again'; it is joined together with the second component, the verb *marry*, to form another verb with the predictable meaning 'marry again'. The same prefix *re-* occurs in many other words (e.g., *reacquaint, redesign, refasten,* and *recalibrate*) and can also be used to form novel words like *redamage* or *retarget* whose meaning is understood automatically by speakers of English. The additional fact that verbs like **reweep* or **relike* are impossible tells us that there are restrictions on this prefix. It is the morphologist's job to discover the general principles that underlie our ability to form and understand certain complex words but not others.

Languages differ quite greatly in both the complexity and the type of their morphology. Some languages (e.g., Mandarin Chinese and Vietnamese) have very little in the way of morphology. Others (e.g., Turkish, Sanskrit, Swahili, and Navajo) are famous for their complex morphology. English falls somewhere in the middle. It is quite normal for an English sentence to contain no complex words. Even Shakespeare, who is commonly thought of as using complex language, tended to use morphologically simple words. That most famous of Shakespeare's sentences, "To be or not to be, that is the question," is morphologically very simple.

The atomic meaningful units of language are traditionally called *morphemes*. Morphemes are classified into two very basic types: *free morphemes* and *bound morphemes,* the difference between them being that a bound morpheme is defined in terms of how it attaches to (or is bound to) another form (called its *stem*). The most common types of bound morphemes are *prefixes* and *suffixes*. The other major device for forming complex words in English is *compounding,* whereby free morphemes are put together to form a word like *doghouse* or *ready-made*. Although these devices are quite simple, repeated application allows for the formation of fairly complex words by piling one prefix or suffix on another or by successive compounding. The word *unmanageableness* contains three bound morphemes and has been built up in stages from *manage* by first adding the suffix *-able* to produce *manageable*, then the prefix *un-* to form *unmanageable*, and finally the suffix *-ness*, resulting in [[*un*[[*manage*]$_V$*able*]$_A$]$_A$*ness*]$_N$.

Among the world's languages, suffixation is the most common morphological device and there are quite a few languages (including Japanese, Turkish, and the very large Dravidian family of South India) that have no prefixes but permit long sequences of suffixes. Languages with many prefixes and few or no suffixes are quite rare (Navajo is one example). Some languages use *infixes,* which are placed at a specific place inside their stems. In Tagalog, the national language of the Philippines, for example, the infix *-um-* may be added in front of the first vowel of a stem, after any consonants that may precede it, to mark a completed event. Alongside *takbuh* 'run' and *lakad* 'walk,' we find *tumakbuh* 'ran' and *lumakad* 'walked'. Another internal morphological device is to change a sound in the stem. A fairly small number of English verbs form their past tenses by changing the vowel: *write/wrote, sing/sang, hold/held.* These are irregular in English, because the vast majority of English

verbs form their past tense by suffixation, but in some languages, most prominently the Semitic languages, this type of vowel substitution is normal. Consonants as well as vowels may be altered in a meaningful way. One example of this in English is the relation between nouns like *cloth* that end in voiceless fricatives (in which there is no vibration of the vocal folds) and corresponding verbs like *clothe*, which end in the corresponding voiced fricative sound. Bound morphemes thus modify the sound shape of the words to which they attach, either by adding something to the stem or by changing it. In the limiting case, known as *conversion,* there is no change at all in the shape of the word. This device is very common in English, where basic nouns like *ship* and *sand* are routinely turned into verbs, and verbs like *run* can similarly be turned into nouns.

Linguists distinguish *derivational morphology* from *inflectional morphology*. Derivational morphology, as just discussed, deals with how distinct words (*lexemes*) are related to one another; inflectional morphology is concerned with the different forms that a word may take, depending on its role in a sentence. English is quite poor inflectionally. Nouns have at most a singular and a plural form, and only pronouns have special *case* forms that depend on the role of the word in a sentence; regular verbs have only four distinctive forms, and the different tenses, aspects, and moods are formed by means of auxiliary verbs. But in many other languages, all nouns have distinct case forms, adjectives must often agree with the nouns that they modify, and verbs may have not only distinct forms for each TENSE AND ASPECT, *voice* and *mood,* but may also agree with their subject or object. In Classical Greek, each noun will have 11 different forms, each adjective 30, and every regular verb over 300. Other languages are even more complex in their inflection.

An important difference between morphology and SYNTAX is that morphological patterns vary greatly in their *productivity,* the ease with which new words can be created and understood. If we compare the three English noun-forming suffixes *-ness*, *-ity*, and *-th*, we find that there are many existing nouns ending in *-ness*, a somewhat smaller number ending in *-ity*, and only a dozen or so nouns ending in *-th*. The numbers correlate roughly with the productivity of new words: experiments show that a new noun ending in *-ness* will be more readily accepted as English than a new noun ending in *-ity*, and no new noun in *-th* has been added to the language since about 1600.

The study of productivity shows that the distinct lexemes and their forms comprise a complex network. A major research focus for the experimental study of morphology has been the nature of this network. The prevailing model is that speakers each have a mental LEXICON in which is stored every word of their language, inflected or derived, that has any unpredictable feature. Completely regular words are produced on the fly by productive patterns as they are needed and then discarded. Less productive patterns may also be used, but the words formed in these patterns are less predictable in their meaning and are more likely to be stored once they have been used.

Morphology lies at the heart of language. It interacts with syntax, phonology, SEMANTICS, PRAGMATICS, and the lexicon. Through this interaction, it also relates to numerous

aspects of NATURAL LANGUAGE PROCESSING and cognition. Morphology can thus provide a window onto detailed aspects of language and cognition. The more we discover about the rest of language and cognition, the more important the study of morphology will become.

Motion, Perception of

The visual environment of most animals consists of objects that move with respect to one another and to the observer. Detection and interpretation of these motions are not only crucial for predicting the future state of one's dynamic world—as would be necessary to escape an approaching predator, for example—but also provide a wealth of information about the 3-D structure of the environment. Not surprisingly, motion perception is one of the most phylogenetically well conserved of visual functions. In primates, who rely heavily on vision, motion processing has reached a peak of computational sophistication and neuronal complexity.

The neuronal processes underlying perceived motion first gained widespread attention in the nineteenth century. Our present understanding of this topic is a triumph of cognitive science, fueled by coordinated application of a variety of techniques drawn from the fields of COMPUTATIONAL NEUROSCIENCE, ELECTROPHYSIOLOGY, ELECTRIC AND MAGNETIC EVOKED FIELDS, PSYCHOPHYSICS, and neuroanatomy. Most commonly the visual stimulus selectivities of individual neurons are assessed via the technique of SINGLE-NEURON RECORDING, and attempts are made to link selectivities to well-defined computational steps, to behavioral measures of perceptual state, or to specific patterns of neuronal circuitry. The product of this integrative approach has been a broad perspective on the neural structures and events responsible for visual motion perception.

Motion processing serves a number of behavioral goals, from which it is possible to infer a hierarchy of computational steps. An initial step common to all aspects of motion processing is detection of the displacement of retinal image features, a process termed "motion detection." In the primate visual system, neurons involved in motion detection are first seen at the level of primary VISUAL CORTEX (area V1; Hubel and Wiesel 1968). Many V1 neurons exhibit selectivity for the direction in which an image feature moves across the retina and hence are termed "directionally selective." These V1 neurons give rise to a larger subsystem for motion processing that involves several interconnected regions of the dorsal (or "parietal") VISUAL PROCESSING STREAMS (Felleman and Van Essen 1991). Most notable among these cortical regions is the middle temporal visual area, commonly known as area MT (or V5)—a small visual-otopically organized area with a striking abundance of directionally selective neurons (Albright 1993).

Several detailed models have been proposed to account for neuronal motion detection (Borst and Egelhaaf 1993). The earliest was developed over forty years ago to explain motion sensitivity in flying insects. According to this model and its many derivatives, motion is computed through spatiotemporal correlation. This COMPUTATION is thought to be achieved neuronally via convergence of temporally staggered outputs from receptors with luminance sensitivity profiles that are spatially displaced. The results of electrophysiological experiments indicate that a mechanism of this type can account for directional selectivity seen in area V1 (Ganz and Felder 1984).

While motion detection is thus implemented at the earliest stage of cortical visual processing in primates, a number of studies (Shadlen and Newsome 1996) have demonstrated a close link between the discriminative capacity of motion-sensitive neurons at subsequent stages—particularly area MT—and perceptual sensitivity to direction of motion. Using a stimulus in which the "strength" of a motion signal can be varied continuously, Newsome and colleagues have shown that the ability of individual MT neurons to discriminate different directions of motion is, on average, comparable to that of the nonhuman primate observer in whose CEREBRAL CORTEX the neurons reside. In a related experiment, these investigators found that they could predictably bias the observer's perceptual report of motion direction by electrically stimulating a cortical column of MT neurons that represent a known direction. Finally, direction discrimination performance was severely impaired by ablation of area MT. In concert, the results of these experiments indicate that MT neurons provide representations of image motion upon which perceptual decisions can be made.

Once retinal image motion is detected and discriminated, the resultant signals are used for a variety of purposes. These include (1) establishing the 3-D structure of a visual scene, (2) guiding balance and postural control, (3) estimating the observer's own path of locomotion and time to collision with environmental objects, (4) parsing retinal image features into objects, and—perhaps most obviously—(5) identifying the trajectories of moving objects and predicting their future positions in order to elicit an appropriate behavioral response (e.g., ducking). Computa-

tional steps and corresponding neural substrates have been identified for many of these perceptual and motor functions.

Establishing 3-D scene structure from motion and estimating the path of locomotion, for example, both involve detection of complex velocity gradients in the image (e.g., rotation, expansion, tilt; see STRUCTURE FROM VISUAL INFORMATION SOURCES). Psychophysical studies demonstrate that primates possess fine sensitivity to such gradients (Van Doorn and Koenderink 1983) and electrophysiological evidence indicates that neurons selective for specific velocity gradients exist in the medial superior temporal (MST) area, and other higher areas of the parietal stream (Duffy and Wurtz 1991).

Establishing the trajectory of a moving object—another essential motion-processing function—is also an area of considerable interest. This task is fundamentally one of transforming signals representing retinal image motions, such as those carried by V1 neurons, into signals representing visual scene motions. Computationally, this transformation is complex (indeed, the solution is formally underconstrained), owing, in part, to spurious retinal image motions that are generated by the incidental overlap of moving objects. Contextual cues for visual scene segmentation play an essential role in achieving this transformation. This process has been explored extensively using visual stimuli that simulate retinal images rendered by one object moving past another (Stoner and Albright 1993). A variety of real-world contextual cues, including brightness differences (indicative of shading, transparency, or differential surface reflectance) and binocular positional disparity ("stereoscopic" cues), have been used in psychophysical studies to manipulate perceptual interpretation of the spatial relationships between the objects in the scene. This interpretation has, in turn, a profound influence upon the motion that is perceived. Electrophysiological experiments have been conducted using stimuli containing similar contextual cues for scene segmentation. Neuronal activity in area MT is altered by context, such that the direction of motion represented neuronally matches the direction of object motion perceived (Stoner and Albright 1992). These results suggest that the transformation from a representation of retinal image motion to one of scene motion occurs in, or prior to, area MT and is modulated by signals encoding the spatial relationships between moving objects.

The final utility of visual motion processing is, of course, MOTOR CONTROL—for example, reaching a hand to catch a ball, adjusting posture to maintain balance during figure skating, or using smooth eye movements to follow a moving target. The OCULOMOTOR CONTROL system is particularly well understood and has served as a model for investigation of the link between vision and action. The motion-processing areas of the parietal cortical stream (e.g., areas MT and MST) have anatomical projections to brain regions known to be involved in control of smooth pursuit EYE MOVEMENTS (e.g., dorsolateral pons). Electrophysiological data linking the activity of MT and MST neurons to smooth pursuit are plentiful. For one, the temporal characteristics of neuronal responses in area MT are correlated with the dynamics of pursuit initiation, suggesting a causal role. MST neurons respond well during visual pur-

suit; many even do so through the momentary absence of a pursuit target. The latter finding suggests that such neurons receive a "copy" of the efferent motor command, which may be used to interpret retinal motion signals during eye movements, as well as to perpetuate pursuit when the target briefly passes behind an occluding surface. Finally, neuropsychological studies have shown that smooth pursuit is severely impaired following damage to areas MT and MST. In concert, these studies demonstrate that cortical motion-processing areas—particularly MT and MST—forward precise measurements of object direction and speed to the oculomotor system to be used for pursuit generation. Similar visual-motor links are likely to be responsible for head, limb, and body movements.

As evident from the foregoing discussion, basic knowledge of the neural substrates of motion perception has come largely from investigation of nonhuman primates and other mammalian species. The general mechanistic and organizational principles gleaned from this work are believed to hold for the human visual system as well. Neuropsychological studies, in conjunction with recent advances in functional brain imaging tools such as MAGNETIC RESONANCE IMAGING (MRI) and POSITRON EMISSION TOMOGRAPHY (PET), have yielded initial support to this hypothesis. In particular, clinical cases of selective impairment of visual motion perception following discrete cortical lesions have been hailed as evidence for a human homologue of areas MT and MST (Zihl, von Cramon, and Mai 1983). Neuronal activity-related signals (PET and functional MRI) recorded from human subjects viewing moving stimuli have identified a motion-sensitive cortical zone in approximately the same location as that implicated from the effects of lesions (Tootell et al. 1995).

These observations from the human visual system, in combination with fine-scale electrophysiological, anatomical, and behavioral studies in nonhuman species, paint an increasingly rich portrait of cortical motion-processing substrates. Indeed, motion processing is now arguably the most well-understood sensory subsystem in the primate brain. As briefly revealed herein, one can readily identify the computational goals of the system, link them to specific loci in a distributed and hierarchically organized neural system, and document their functional significance in a real-world sensory-behavioral context. The technical and conceptual roots of this success provide a valuable model for the investigation of other sensory, perceptual, and cognitive systems.

Motivation

Motivation is a modulating and coordinating influence on the direction, vigor, and composition of behavior. This influence arises from a wide variety of internal, environmental, and social sources and is manifested at many levels of behavioral and neural organization.

As an illustration of motivational influence, consider the cyclical changes in sexual interest and receptivity shown by a female rat (McClintock 1984). Two days following the onset of her last period of sexual receptivity, she encounters one of the male rats with which she shares a communal burrow. The rats sniff each other indifferently and continue on their separate ways. Two days later, their paths cross again. Levels of gonadal hormones in the female's blood (see NEUROENDO-CRINOLOGY) have increased markedly since her last encounter with the male, and she now responds in a strikingly different fashion, approaching, nuzzling, and crawling over him. Turning away, she runs a short distance and stops. The male follows hesitantly, but then spies a puddle and stops to drink, appearing to lose interest in the female. Undeterred, the female returns and repeats the pattern of approach and contact followed by turning, running away, and stopping. She soon succeeds in attracting and holding the attention of the male, and he follows her on a tortuous high-speed chase. The female then halts abruptly, and coitus ensues.

During the first encounter, the female treats the male as a neutral stimulus, whereas during the second, she treats him as a valuable goal object. Had he grasped her flanks with his forepaws during the first encounter, the female would have kicked him away, but when he delivers similar sensory stimulation during the second encounter, she responds by adopting a posture that allows him to mount her and mate. During the first encounter, the female's gait is similar to that of the male, whereas during the second encounter, her gait includes a distinctive combination of darts and hops followed by pauses that may be accompanied by vigorous ear wiggling. Finally, her prodding of the male, distinctive motor patterns, and postural response vary in intensity as a function of her hormonal status and recent experience. Such coordinated changes in the evaluation of goal objects (Shizgal forthcoming), the impact of external stimuli, the prepotency of sensorimotor units of action (Gallistel 1980), and the vigor of performance can be said to reflect a common motivational influence; the set of internal conditions responsible for this common influence can be said to constitute a motivational state.

The response of the male to the solicitation of the female illustrates the contribution of external as well as internal inputs to the genesis and maintenance of a motivational state (Bindra 1969). Such external inputs, called "incentive stimuli," are important both to behavioral continuity and change. Positive feedback between incentive stimuli and motivational states tends to lock in commitment to a particular course of action. The more the male interacts with the female, the more he exposes himself to olfactory, tactile, and visual stimuli that increase the likelihood of further interaction. Thus his initial hesitancy gives way to vigorous pursuit. Moreover, sufficiently powerful incentive stimuli incompatible with a current objective can trigger an abrupt, self-reinforcing switch in the direction of the solicited behavior, as when the male rat is sidetracked from slaking his thirst by the intervention of the female.

Motivational states not only modulate the stimulus control of behavior, they also act as intermediaries in its temporal control by transducing internal and external signals indicating the season and time of day into changes in the likelihood of initiating different goal-directed activities. Timing signals make it possible for behavior to anticipate physiological need states, thus lessening the risk that supplies will be depleted and that the physiological imbalance will compromise the capacity of the animal to procure additional resources. For example, migrating birds eat voraciously and greatly increase their body weight prior to their departure. Nonetheless, anticipatory intake may prove insufficient to meet later needs or may exceed subsequent expenditures. Thus the contribution of motivation to the regulation of the internal environment depends both on signals that predict future physiological states and on signals that reflect current ones (Fitzsimons 1979).

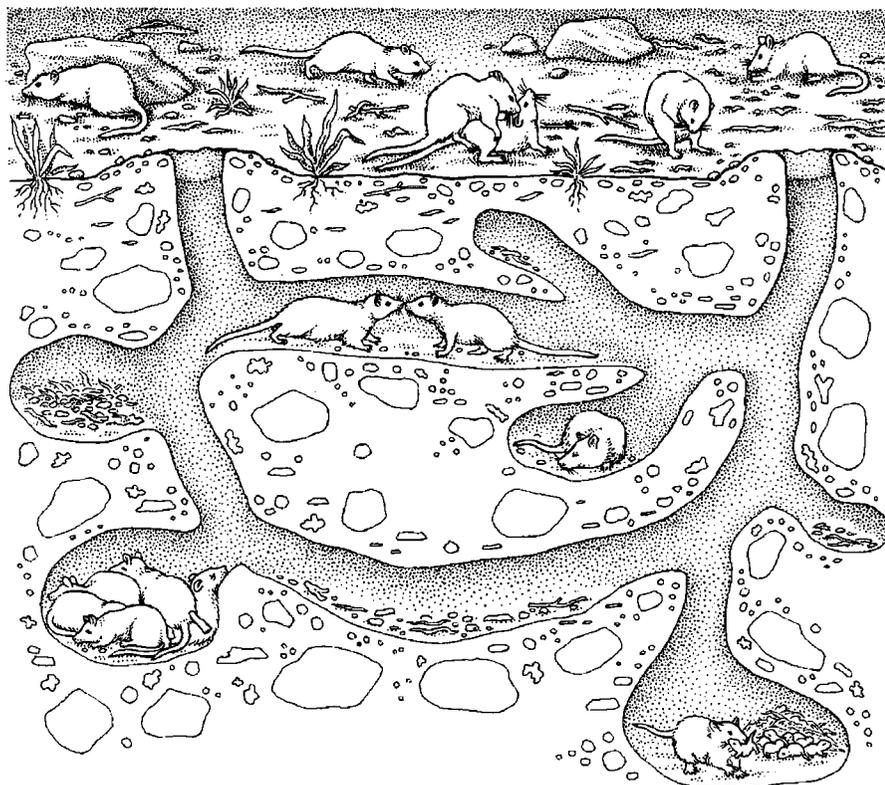
To illustrate the regulatory challenges addressed by the motivational modulation of behavior, let us revisit the female rat as she begins to wean her litter, about six weeks after she has mated successfully. The total weight of her pups now exceeds her own. First via her bloodstream and then via her milk, she has succeeded in providing the necessary resources without seriously compromising her own viability. Accomplishing this feat has required dramatic


Figure 1. The reproductive behavior of rats illustrates multiple facets of motivational influence (from McClintock 1987). Changes in hormonal status and experience alter the evaluation and selection of goal objects, the impact of external stimuli, the vigor of goal-directed behavior, and the prepotency of sensorimotor units of action.

alteration in her intake patterns. For example, her caloric intake and calcium consumption during lactation will have reached 2–3 times postweaning levels, reflecting both hormonally driven anticipatory changes and feedback from the physiological consequences of increased expenditures (Millelire and Woodside 1989).

The motivational modulation of preferences can extend beyond the point of neutrality, rendering previously repulsive stimuli attractive and vice versa (Cabanac 1971). Prior to her first pregnancy, a female rat will treat a rat pup as an aversive stimulus, positioning herself as far away from it as possible when placed together with the pup in an enclosure. In contrast, when she is in the maternal state, the female will actively retrieve pups, even if they are not her own (Fleming 1986).

Changes in motivational state are expressed at many levels of behavioral and neural organization. For example, the posture adopted by a receptive female rat during copulation reflects the highly stereotyped operation of a spinal reflex (Pfaff 1982). Provided the female is sexually receptive, the reflex can be triggered in response to pressure on the flanks regardless of whether the stimulus is applied by the forepaws of the male rat or the hand of a human. Although facilitation from brain stem neurons is necessary for execution of the reflex (Pfaff 1982), the integrity of the cerebral cortex is not (Beach 1944). In contrast, the organization of the individual components of solicitation into the pattern of approach, contact, withdrawal, and pausing is context-sensitive, flexible (McClintock 1984), and dependent on cortical integrity (Beach 1944). The solicitation behavior of the intact female is directed preferentially at an appropriate

sexual partner, and each of the constituent acts may be varied in intensity and duration or omitted entirely, depending on the response of the male. Following removal of the CEREBRAL CORTEX, components of the behavior survive, but their patterning is disrupted and is no longer well coordinated with the behavior of the male.

At higher levels of behavioral and neural organization, motivational states interact with cognitive processes in influencing behavior. For example, the information directing ongoing behavior may be drawn from COGNITIVE MAPS of the environment rather than from current sensory input (Gallistel 1990; Marlow and Tollestrup 1982; see ANIMAL NAVIGATION). Another point of contact between motivation and cognition is the control of ATTENTION (Simon 1993). Changes in motivational state alter the likelihood that a stimulus will attract attentional resources, and directing these resources at a stimulus can boost its incentive effects (Shizgal 1996). By gating input to WORKING MEMORY, attention can restrict the set from which goals are selected and control the access of goal-related information to the processes involved in PLANNING.

In the examples provided above, the objects of evaluation and goal selection are physical resources and activities. In humans, and perhaps in other animals as well, abstractions can serve as goals and as the objects of evaluation (see MOTIVATION AND CULTURE). For example, our evaluations of ourselves have profound motivational consequences (Higgins, Strauman, and Klein 1986), and our objectives may be defined with respect to current and projected self-concepts (Cantor and Fleeson 1993). Nonetheless, the psychological and neural foundations for such

abstract expressions of motivational influence may have much in common with mechanisms, perhaps highly conserved across animal species, that modulate pursuit of concrete biological goals.

Motivational influences are incorporated in some artificial intelligence models. For example, such signals provide contextual information in an important model of REINFORCEMENT LEARNING (Barto 1995), although the manner in which motivational signals are processed to modulate the impact of rewards and to guide action tends to be left unspecified in such models. A hierarchical account of motor control (Gallistel 1980) and recent modeling (Shizgal 1997, forthcoming) of the neural and computational processes underlying goal evaluation and selection (see DECISION MAKING and UTILITY THEORY) represent early steps toward formal description of the motivational influence on behavior.

Motivation and Culture

Studies of motivation try to explain the initiation, persistence, and intensity of behavior (Geen 1995; see also MOTIVATION). Culture, learned schemas shared by some people due to common, humanly mediated experiences, as well as the practices and objects creating and created by these schemas, plays a large role in nearly all human behavior. Even such biologically adaptive motivations as hunger and sex instigate somewhat different behaviors in different societies, depending on learned schemas for desirable objects, appropriate and effective ways to obtain these, and skills for doing so (Mook 1987).

The motivational effects of culturally variable beliefs can be illustrated by considering causal attribution processes. Weiner (1991) argues that we are unlikely to persist at a voluntary behavior if we have failed in the past and we attribute that failure to an unchanging and uncontrollable aspect of ourselves or the situation. Some studies show that people in Japan tend to attribute poor academic performance to insuf-

ficient effort, while people in the United States give greater weight than do their Japanese counterparts to lack of ability (Markus and Kitayama 1991; Weiner 1991). Given these assumptions, U.S. schoolchildren who receive poor grades should thereafter put less effort into their schoolwork, while Japanese schoolchildren who receive poor grades should increase their effort.

Is there a fixed, limited number of universal basic motives, which vary cross-culturally only in their strength? Or is cross-cultural variation qualitative as well as quantitative, making it impossible to delimit universally applicable basic motives? McClelland (1985; Weinberger and McClelland 1990) has argued for the first position. He has found cross-societal as well as intrasocietal differences in the average levels of such basic motives as achievement and affiliation, and he posits that human as well as other animal behavior is motivated by a limited set of stable, "implicit motives" such as these, which draw on the "natural incentive" of neurohormone release. Cantor and her colleagues (1986), by contrast, focus on idiosyncratically variable self-concepts. These are conscious, change over time, and include a variety of understandings and images, positive and negative roles and behaviors in the past and present as well as various future "possible selves," namely, "those selves that individuals *could* become, would *like* to become, or are *afraid* of becoming" (p. 99). They illustrate the possible variability among such self-conceptions with the example of students preparing for a final examination. One, fearing exposure as a fraud, parties the night before the exam so that no one will attribute her failure to lack of ability. Another, having a feared "careless failure" possible self, studies very hard. The enormous variability among such self-conceptions, even within a single society, suggests the potential for limitless cross-cultural variation. Markus and Kitayama (1991), on the other hand, while continuing to link motivation to self-conceptions, posit a general distinction between societies with conceptions of self as independent of others and societies with conceptions of self as interdependent with others (see also Miller 1997). D'Andrade (1992) likewise advocates the infinite variability position. Discussing the potential for a wide variety of schemas (not just self or conscious schemas) to function as goals, he offers as a classic example from the ethnographic literature the intensity of most Nuers's interest in cattle (Evans-Pritchard 1947).

McClelland proposes (Weinberger and McClelland 1990) that the differences between his approach and that of Cantor et al. (1986) can be resolved by treating them as describing two sorts of motivation. He provides evidence that the implicit motives he discusses are derived largely from pre-verbal "affective experiences" (such as early parent-child interaction in feeding, elimination control, and so on) and explain behavior over the long term and in less structured situations. In contrast, the explicit self-conceptions discussed by Cantor et al. are acquired with the mediation of language and explain choices in structured tasks, especially ones that make self-conceptions salient.

This categorization of kinds of motivation could be expanded. Neither McClelland's nor Cantor et al.'s model accounts for the sort of behavior that is enacted because it is typical in one's social group, making other behaviors less available for consideration, likely to provoke disapproval, or inconvenient. Examples are body language, table manners and food choices, house design, mode of dress, occupations, and forms of worship. When action follows the patterns learned from repeated observation of the typical behavior of other people like oneself, as well as social facilitation of certain ways of acting over others, it could be said to draw on routine motivation (Strauss and Quinn 1997). In many cases, routine motivation is acquired nonverbally, is internalized as implicit schemas, and is not strongly affectively charged or linked to self-conceptions. Particularly important routine motivations (e.g., schemas for being a good parent or reliable breadwinner), however, may be internalized with an explicit verbal component and linked to emotions (e.g., fear or pride) and self-conceptions, depending on how they were learned.

The different forms of motivation, and various ways in which these are learned, highlight the fact that a culture is not a single thing. In particular, cultures cannot be thought of as master programmers loading up instructions that determine people's behavior. In every society various, not always consistent, values are proclaimed explicitly. Some of these values are the basis for motivations that socializers try to teach children, others are ignored, remaining "cultural clichés" (Spiro 1987; see also Strauss 1992; and Strauss and Quinn 1997). Finally, in addition to motivations that are deliberately instilled, there are needs and expectations derived from preverbal parent-child interactions (McClelland 1985, Weinberger and McClelland 1990, see also Paul 1990), as well as ongoing observations of the normal way of acting in one's social group.

Motor Control

To specify a plan of action, the central nervous system (CNS) must first transfer sensory inputs into motor goals such as the direction, amplitude, and velocity of the intended movement. Then, to execute movements, the CNS must convert these desired goals into signals controlling the muscles that are active during the execution of even the simplest kind of limb trajectory. Thus, the CNS must transform information about a small number of variables (direction, amplitude, and velocity) into a large number of signals to many muscles. Any transformation of this type is "ill-posed" in the sense that an exact solution may be either not available or not unique. How the nervous system computes these transformations has been the focus of recent studies.

Specifically, to plan an arm trajectory toward an object, the CNS first must locate the position of the object with respect to the body and represent the initial position of the arm. Recordings from single neurons in the parietal cortex and superior colliculus in awake monkeys have significantly contributed to our understanding of how space is represented. There is some evidence that in the parietal cortical areas there are retinotopic neurons whose activity is tuned by signals derived from somatosensory sources. Their visual receptive field is modified by signals representing both eye and head position. This result suggests that parietal area 7a contains a representation of space in body-centered space. Neurons representing object location in body-independent (allocentric) coordinates have also been found in the parietal cortex and in the HIPPOCAMPUS (Andersen et al. 1993).

To specify the limb's trajectory toward a target, the CNS must locate not only the position of an object with respect to the body but also the initial position of the arm. The conven-

tional wisdom is that proprioception provides information about arm configuration to be used in the programming of the arm's trajectory. However there is experimental evidence indicating that information about the initial position of the limb derives from a number of sources, including the visual afferences (Ghez, Gordon, and Ghilardi 1993).

The current view on the formation of arm trajectories is that the CNS formulates the appropriate command for the desired trajectory on the basis of knowledge about the initial arm position and the target's location. Recent psychophysical evidence supports the hypothesis that the planning of limbs' movements constitutes an early and separate stage of information processing. According to this view, during planning the brain is mainly concerned with establishing movement kinematics, a sequence of positions that the hand is expected to occupy at different times within the extrapersonal space. Later, during execution, the dynamics of the musculoskeletal system are controlled in such a way as to enforce the plan of movement within different environmental conditions.

There is evidence indicating that the planning of arm trajectories is specified by the CNS in extrinsic coordinates. The analysis of arm movements has revealed kinematic invariances (Abend, Bizzi, and Morasso, 1982; Morasso 1981). Remarkably, these simple and invariant features were detected only when the hand motion was described with respect to a fixed Cartesian reference frame, a fact suggesting that CNS planning takes place in terms of the hand's motion in space (Flash and Hogan 1985). Even complex curved movements performed by human subjects in an obstacle-avoidance task displayed invariances in the hand's motion and not in joint motion (Abend et al. 1982). The data derived from straight and curved movements indicate that the kinematic invariances could be derived from a single organizing principle based on optimizing endpoint smoothness (Flash and Hogan 1985). It follows that if actions are planned in spatial or extrinsic coordinates, then for the execution of movement, the CNS must convert the desired direction and velocity of the limb into signals that control muscles.

Investigators of motor control have been well aware of the computational complexities involved in the production of muscle forces. A variety of proposals have been made to explain these complexities. In theory, in a multijoint limb, the problem of generation forces may be addressed only after the trajectory of the joint angles has been derived from the trajectory of the endpoint—that is, after an inverse kinematics problem has been solved. Investigations in robot control in the late 1970s and early 1980s have shown that both the inverse kinematic and inverse dynamic problems may be efficiently implemented in a digital computer for many robot geometries. On the basis of these studies, investigators have argued that the brain may be carrying out inverse kinematic and dynamic computations when moving the arm in a purposeful way.

One way to compute inverse dynamics is based on carrying out explicitly the algebraic operations after representing variables such as positions, velocity acceleration, torque, and inertia. This hypothesis, however, is unsatisfactory because there is no allowance for the inevitable mechanical

vagaries associated with any interaction with the environment.

Alternative proposals have been made that do not depend on the solution of the complicated inverse-dynamic problem. Specifically, it has been proposed that the CNS may transform the desired hand motion into a series of equilibrium positions (Bizzi et al. 1984). The forces needed to track the equilibrium trajectory result from the intrinsic elastic properties of the muscles (Feldman 1974).

According to the equilibrium-point hypothesis, as first proposed by Feldman, limb movements result from a shift in the neurally specified equilibrium point. Studies of single and multijoint movements have provided experimental evidence that supports the equilibrium-point hypothesis (Bizzi et al. 1984). The equilibrium-point hypothesis has implications both for the control and for the computation of movements. With respect to control, the elastic properties of the muscles provide instantaneous correcting forces when a limb is moved away from the intended trajectory by some external perturbation. With respect to computation, the same elastic properties offer the brain an opportunity to deal with the inverse-dynamics problem. Once the brain has achieved the ability to represent and control equilibrium postures, it can master movements as temporal sequences of such postures. In this context, a representation in the CNS of the inertial, viscous, and gravitational parameters contained in the equations of motion is no longer necessary.

Recently, a set of experiments performed in frogs with spinal cords that were surgically disconnected from the brain stem has provided neurophysiological support for the equilibrium-point hypothesis. Microstimulation of the spinal cord demonstrated that this region is organized to produce the neural synergies necessary for the expression of equilibrium points. These experiments have indicated that the spinal cord contains circuitry that, when activated, produces precisely balanced contractions in groups of muscles. These synergistic contractions generate forces that direct the limb toward an equilibrium point in space (Bizzi, Mussa-Ivaldi, and Giszter 1991).

Experimental evidence also indicates that microstimulation of the lumbar gray results in a limited number of force patterns. More importantly, the simultaneous stimulation of two sites, each generating a force field, results in a force field proportional to the vector sum of the two fields (Mussa-Ivaldi, Giszter, and Bizzi 1994). Vector summation of force fields implies that the complex nonlinearities that characterize the interactions both among neurons and between neurons and muscles are in some way eliminated. This result has led to a novel hypothesis for explaining movement and posture based on combinations of a few basic elements. The limited-force pattern may be viewed as representing an elementary alphabet from which, through superimposition, a vast number of movements could be fashioned by impulses conveyed by supraspinal pathways. With mathematical modeling, experimenters have verified that this novel view of the generation of movement and posture has the competence required for controlling a wide repertoire of motor behaviors.

The hypothesis that the premotor zones in the spinal gray may be the structures underlying the transformation from extrinsic to intrinsic coordinates is consistent with the results obtained by other groups of investigators, who have demonstrated the existence of a few separate circuits for controlling horizontal and vertical head movements in the owl. These structures, which are located in the brain stem, receive inputs from the tectum and transform the tectal movement vectors into the neck motor-neural activation.

Motor Learning

Humans are capable of an impressive repertoire of motor skills that range from simple movements, such as looking at an object of interest by turning the head and eyes, to complex and intricate series of movements, such as playing a violin or executing a triple somersault from a balance beam. Most movements are not performed perfectly the first time around, but instead require extensive periods of practice. During practice, we detect errors in motor performance and then modify subsequent movements to reduce or eliminate those errors. The iterative process of improving motor performance by executing movements, identifying errors, and correcting those errors in subsequent movements is called motor learning.

Motor learning occurs in behaviors that range in complexity from simple reflexive movements to highly developed skills. The simplest form of motor learning is adaptation, in

which muscular force generation changes to compensate for altered mechanical loads or sensory inputs. Adaptation can involve movements across either a single joint or multiple joints, and can occur in both reflexive and voluntary movements. The best understood example of this type of motor learning is in the vestibulo-ocular reflex, in which EYE MOVEMENTS normally compensate for motion of the head such that images remain stable on the RETINA during head movements. If subjects experience persistent image motion during head movements (e.g., after vestibular trauma or when wearing new corrective lenses), motor learning produces adaptive increases or decreases in compensatory eye movements that restore image stability during head movements.

Motor learning is not a unitary phenomenon, but can affect many different components of sensory and motor processing. MOTOR CONTROL involves both simple movement trajectories and complex series of movements in which multiple muscles and joints must be controlled in precise temporal sequence. Motor learning refines simple movements by altering the magnitude and timing of muscular force generation. For complex movements, motor learning is required to select and coordinate the appropriate muscular contractions, to link together motor subroutines, and to create new motor synergies by combining forces generated across multiple joints in novel spatial and temporal patterns.

Sensory processing is intimately linked with motor learning. Sensory information about the outcome of a movement is used to detect and evaluate errors in motor performance. The nature of the sensory information used can vary and depends on the movement being learned. For example, when one is learning to hit a tennis ball, vision provides the most salient information about the accuracy of the shot, but somatosensory information about the angles of the elbow and wrist and the feel of the ball against the racket also provide important cues. A violin player evaluates his or her performance with the auditory system, by listening for mistakes, and also by monitoring the pressure of strings against fingers. As subjects attempt new movements and refine existing skills, they develop expectations of the sensory consequences of their movements. During motor learning, the expected sensory outcomes of a movement are compared with the actual outcomes, and the difference between what was expected and what actually occurred is used to drive changes in subsequent movements.

The sensory inputs used to detect and correct errors in motor performance can change with practice. At the initial stages of motor learning, a subject may attend to a variety of sensory stimuli, but as learning proceeds, attention becomes restricted to salient sensory stimuli until eventually, as the movement becomes perfected, the reliance on sensory cues can disappear altogether.

The memories formed during motor learning are not accessible to conscious recall, but instead are expressed in the context of motor performance. This type of subconscious recollection of gradually learned skills is called "procedural" (or "implicit") memory and is also a feature of the expression and formation of mental habits. In contrast, the memory of facts and events, which can be learned in a single trial and are subject to conscious recall, is termed "declarative" (or "explicit") memory (see IMPLICIT VS. EXPLICIT MEMORY and MEMORY). The distinction between procedural and declarative memory was prompted by studies of patients with amnesia caused by dysfunction of the part of the cerebral cortex called the medial temporal lobe. Despite a profound inability to remember the training sessions and other events and facts, amnesiac patients could be trained to learn new motor skills or to improve existing skills with practice. This finding indicates that procedural and declarative memory involve distinct brain areas and mechanisms.

Our knowledge of the brain regions involved in motor learning and memory derives from clinical studies of patients who have neurological diseases, stroke, or other localized brain dysfunction, from brain imaging studies in humans, and from neurophysiological recordings in animal models. A number of distinct brain regions are involved in motor learning. The CEREBELLUM is required for adaptation, for conditioning, and for the learning and coordination of movements that involve multiple joints and muscles. The BASAL GANGLIA are involved in learning sequences of movements, and are also critical for habit formation. Although the studies of amnesiac patients indicate that the medial temporal lobes are not required for motor learning, other cortical regions are clearly involved in the learning of motor skills and the associations of sensory cues with appropriate motor programs. These include primary motor cortex, somatosensory cortex, prefrontal cortex, and the supplementary motor areas. As learning proceeds and motor memories become consolidated, the relative contributions of neuronal activity in the various brain regions involved in motor learning can vary. The precise roles of distinct brain areas in motor learning and the neural mechanisms that underlie the acquisition and retention of motor skills are areas of active investigation in neuroscience.

Multiagent Systems

Multiagent systems are distributed computer systems in which the designers ascribe to component modules autonomy, mental state, and other characteristics of agency. Software developers have applied multiagent systems to solve problems in power management, transportation scheduling, and a variety of other tasks. With the growth of the Internet and networked information systems generally, separately designed and constructed programs increasingly need to interact substantively; such complexes also constitute multiagent systems.

In the study of multiagent systems, including the field of "distributed AI" (Bond and Gasser 1988) and much of the current activity in "software agents" (Huhns and Singh 1997), researchers aim to relate aggregate behavior of the composite system with individual behaviors of the component agents and properties of the interaction protocol and environment. Frameworks for constructing and analyzing multiagent systems often draw on metaphors—as well as models and theories—from the social and ecological sciences (Huberman 1988). Such social conceptions are sometimes applied within an agent to describe its behaviors in terms of interacting subagents, as in Minsky's *society of mind* theory (Minsky 1986).

Design of a distributed system typically focuses on the *interaction mechanism*—specification of agent communication languages and interaction protocols. The interaction mechanism generally includes means to implement decisions or agreements reached as a function of the agents' interactions. Depending on the context, developers of a distributed system may also control the configuration of participating agents, the INTELLIGENT AGENT ARCHITECTURE, or even the implementation of agents themselves. In any case, principled design of the interaction mechanism requires some model of how agents behave within the mechanism, and design of agents requires a model of the mechanism rules, and (sometimes) models of the other agents.

One fundamental characteristic that bears on design of interaction mechanisms is whether the agents are presumed to be *cooperative,* which in the technical sense used here means that they have the same objectives (they may have heterogeneous capabilities, and may also differ on beliefs and other agent attitudes). In a cooperative setting, the role of the mechanism is to coordinate local decisions and disseminate local information in order to promote these global objectives. At one extreme, the mechanism could attempt to *centralize* the system by directing each agent to transmit its local state to a central source, which then treats its problem as a single-agent decision. This approach may be infeasible or expensive, due to the difficulty of aggregating belief states, increased complexity of scale, and the costs and delays of communication. Solving the problem in a *decentralized* manner, in contrast, forces the designer to deal directly with issues of reconciling inconsistent beliefs and accommodating local decisions made on the basis of partial, conflicting information (Durfee, Lesser, and Corkill 1992).

Even among cooperative agents, *negotiation* is often necessary to reach joint decisions. Through a negotiation process, for example, agents can convey the relevant information about their local knowledge and capabilities necessary to determine a principled allocation of resources or tasks among them. In the *contract net protocol* and its variants, agents submit "bids" describing their abilities to perform particular tasks, and a designated contract manager assigns tasks to agents based on these bids. When tasks are not easily decomposable, protocols for managing shared information in global memory are required. Systems based on a *blackboard architecture* use this global memory both to direct coordinated actions of the agents and to share intermediate results relevant to multiple tasks.

In a noncooperative setting, objectives as well as beliefs and capabilities vary across agents. Noncooperative systems are the norm when agents represent the interests of disparate humans or human organizations. Note that having distinct objectives does not necessarily mean that the agents are adversarial or even averse to cooperation. It merely means that agents cooperate exactly when they determine that it is in their individual interests to do so.

The standard assumption for noncooperative multiagent systems is that agents behave according to principles of RATIONAL DECISION MAKING. That is, each agent acts to further its individual objectives (typically characterized in terms of UTILITY THEORY), subject to its beliefs and capabilities. In this case, the problem of designing an interaction mechanism corresponds to the standard economic concept of *mechanism design,* and the mathematical tools of GAME THEORY apply. Much current work in multiagent systems is devoted to game-theoretic analyses of interaction mechanisms, and especially negotiation protocols applied within such mechanisms (Rosenschein and Zlotkin 1994). Economic concepts expressly drive the design of multiagent interaction mechanisms based on market price systems (Clearwater 1996).

Both cooperative and noncooperative agents may derive some benefit by reasoning expressly about the other agents. Cooperative agents may be able to propose more effective joint plans if they know the capabilities and intentions of the other agents. Noncooperative agents can improve their bargaining positions through awareness of the options and preferences of others (agents that exploit such bargaining power are called "strategic"; those that neglect to do so are "competitive"). Because direct knowledge of other agents may be difficult to come by, agents typically induce their models of others from observations (e.g., "plan recognition"), within an interaction or across repeated interactions.

Multisensory Integration

Because of its importance in forming an appropriate picture of the external world, the representation of sensory information has been a powerful driving force in EVOLUTION. Extant organisms possess an impressive array of specialized sensory systems that allow them to monitor simultaneously a host of environmental cues. This "parallel" processing of multiple cues not only increases the probability of detecting a given stimulus but, because the information carried along each sensory channel reflects a different feature of that stimulus, it also increases the likelihood of its accurate identification. For example, stimuli that are similar along one physical dimension (how they sound) might be identified on the basis of a second dimension (how they look). But if a coherent representation of the external world is to be constructed, and if the appropriate responses are to be generated, the brain must synthesize the information originating from these different sensory channels. One way in which such a multimodal representation is generated is by having information from different sensory systems converge on a common group of neurons.

During the evolution of sensory systems, mechanisms were preserved or elaborated so that the combined action of sensory systems would provide information not available within any single sensory channel. Indeed, in many circumstances, events are more readily perceived, have less ambiguity, and elicit a response far more rapidly when signaled by the coordinated action of multiple sensory modalities. Sensory systems have evolved to work in concert, and normally, different sensory cues that originate from the same event are concordant in both space and time. The products of this spatial and temporal coherence are synergistic intersensory interactions within the central nervous system (CNS), interactions that are presumed to enhance the salience of the initiating event. For example, seeing a speaker's face makes the spoken message far easier to understand, especially in a noisy room (Sumby and Pollack 1954).

Similarly, discordant cues from different modalities can have powerful effects on perception, as illustrated by a host of interesting cross-modal illusions. One of the most compelling of these is the so-called McGurk effect, wherein a speaker lip-synchs the syllable "ga" in time with the sound "ba" (McGurk and MacDonald 1976). The perception is of neither "ga" nor "ba," but a synthesis of the two, "da." Similarly, in the "ventriloquism effect," the sight of movement (i.e., the dummy's head and lips) compels one to believe it is also the source of the sound.

Multisensory neurons, which receive input from more than a single sensory modality, are found in many areas of the CNS (see Stein and Meredith 1993 for a review). These neurons are involved in a number of circuits, and presumably in a variety of cognitive and behavioral functions. Thus, for example, multisensory neurons in neocortex are likely participants in the perceptual, mnemonic, and associative processes that serve to bind together the modality-specific components of a multisensory experience. Still other multisensory neurons, positioned at the sensorimotor interface, are known to mediate goal-directed orientation behavior. Such neurons, a high incidence of which are found in the superior colliculus (SC), have been the most extensively studied, and serve as the model for deciphering how multiple sensory cues are integrated at the level of the single neuron (see Stein and Meredith 1993 for review). Visual, auditory, and somatosensory inputs converge on individual neurons in the SC, where each of these modalities is represented in a common coordinate frame. As a result, the modality-specific receptive fields of an individual multisensory neuron represent similar regions of space.

An example of an SC neuron's ability to integrate two different sensory inputs is illustrated in figure 1. When presented simultaneously and paired within their receptive fields, a visual and auditory stimulus result in a substantial response enhancement, well above the sum of the two individual responses (see A_1V). Conversely, when the auditory stimulus is presented outside its receptive field, the neuron's ability to generate a vigorous response to the visual stimulus is suppressed (see A_2V). The timing of these stimuli is critical, and the magnitude of their interaction changes when the interval between the two stimuli is manipulated (Meredith and Stein 1986). However, this interval or "temporal window" generally is quite broad (e.g., several hundred milliseconds).

The multisensory interactions that are observable at the level of the single neuron are reflected in the animal's behavior (Stein et al. 1989). Thus, its ability to detect and orient toward a visual stimulus is markedly enhanced when it is paired with a neutral auditory cue at the same position in space. However, if the auditory cue is spatially disparate from the visual, the response is strongly degraded.

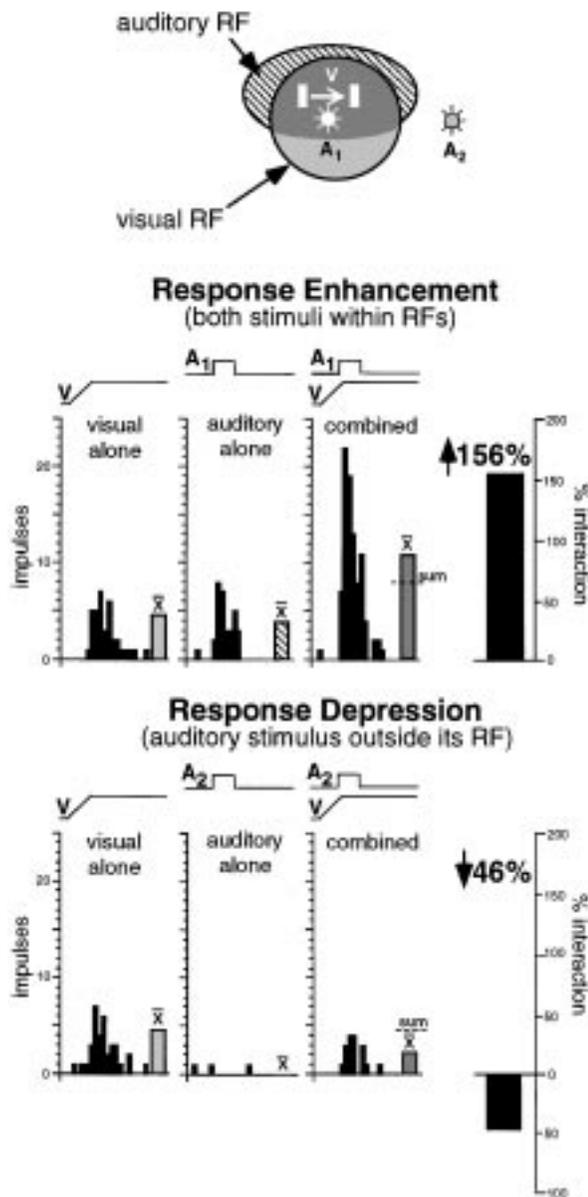
Although SC neurons can respond to different sensory stimuli via inputs from a variety of structures, their ability to integrate multisensory information depends on projections from a specific region of neocortex (Wallace and Stein 1994). If these inputs from cortex are removed, SC neurons continue to respond to stimuli from different sensory modalities but fail to exhibit the synergistic interactions that characterize multisensory integration. At the behavioral level, animals can still orient normally to unimodal cues, but the benefit derived from combined cues is markedly diminished (Wilkinson, Meredith, and Stein 1996). This intimate relationship between cortex and SC suggests that the higher-level cognitive functions of the neocortex play a substantial role in controlling the information-processing capability of multisensory neurons in the SC, as well as the overt behaviors they mediate.


Figure 1. Multisensory integration in a visual-auditory SC neuron. The two receptive fields (RFs) of this neuron (dark gray shading shows the region of their overlap) are shown at the top. Icons depict stimuli: visual (V) is a moving bar of light, auditory is a broad-band noise burst from a speaker either within (A1), or outside (A2) the RF. Below, peristimulus time histograms and bar graphs (means) show responses to the visual stimulus alone (movement is represented by a ramp), the within-field auditory stimulus alone (square wave), and the stimulus combination. The summary bar graph shows that the large response enhancement is greater than the sum of A+V. The bottom panel illustrates the inhibition of the visual response when the auditory stimulus is outside its RF.

At present, comparatively little is known about the multisensory integrative properties of the cortical multisensory neurons presumed to be involved in various aspects of perception. However, they have been shown to share some of the features of SC neurons (Wallace, Meredith, and Stein 1992). Future studies detailing their response properties and associated circuitry should greatly aid in our understanding of how multisensory information is used in higher cognitive functions and, in doing so, reveal the neural basis of a fully integrated multisensory experience.

Naive Biology

See FOLK BIOLOGY

Naive Mathematics

Whether or not schooling is offered, children and adults all over the world develop an intuitive, naive mathematics. As long as number-relevant examples are part of their culture,

people will learn to reason about and solve addition and subtraction problems with positive natural numbers. They also will rank order and compare continuous amounts, if they do not have to measure with equal units. The notion of equal units is hard, save for the cases of money and time. Universally, and without formal instruction, everyone can use money. Examples abound of child candy sellers, taxicab drivers, fishermen, carpenters, and so on developing fluent quantitative scripts, including one for proportional reasoning. Of note is that almost always these strategies use the natural numbers and nonformal notions of mathematical operations. For example, the favored proportions strategy for Brazilian fishermen can be dubbed the "integer proportional reasoning": the rule for reasoning is that one whole number goes into another *X* number of times and there is no remainder.

Intuitive mathematics serves a wide range of everyday math tasks. For example, Liberian tailors who have no schooling can solve arithmetic problems by laying out and counting familiar objects, such as buttons. Taxicab drivers and child fruit vendors in Brazil invent solutions that serve them well (Nunes, Schliemann, and Carraher 1993).

Two kinds of theories vie for an account of the origins and acquisition of intuitive arithmetic. One idea is that knowledge of the counting numbers and their use in arithmetic tasks builds from a set of reinforced bits of learning about situated counting number routines. Given enough learning opportunities, principles of counting and arithmetic are induced (Fuson 1988). Despite the clear evidence that there are pockets of early mathematical competence, young children are far from perfect on tasks they can negotiate. Additionally, the range of set sizes and tasks they can deal with is limited. These facts constitute the empirical foundation for the "bit-bit" theory and would seem to constitute a problem for the "principle-first" account of intuitive mathematics, which proposes an innate, domain-specific, learning-enabling structure. Although skeleton-like to start, such a structure serves to draw the beginning learner's attention to seek out, attend to, and assimilate number-relevant data—be these in the physical, social, cultural and mental environments—that are available for the epigenesis of number-specific knowledge.

True, there are many arithmetic reasoning tasks that young children cannot do, and early performances are shaky. But this would be expected for any learning account. Those who favor the principle-first account (Geary 1996; Gelman and Williams 1997) point to an ever-increasing number of converging lines of evidence: animals and infants respond to the numerical value of displays (Gallistel and Gelman 1992; Wynn 1995); retarded children have considerable difficulty with simple arithmetic facts, money, time, and novel counting or arithmetic tasks—despite extensive in-school practice (e.g., Gelman and Cohen 1988); preschool children distinguish between novel count sequences that are wrong and those which are unusual but correct; they also invent counting solutions to solve arithmetic problems (Siegler and Shrager 1984; Starkey and Gelman 1982); and elementary school children invent counting solutions to solve school arithmetic tasks in ways that differ from those they are taught in school (Resnick 1989). Moreover, there is

cross-language variability in the transparency of the base rules for number word generation. For example, in Chinese, the words for 10, 11, 12, 13 . . . 20, 21 . . . 30, 31 . . . and so forth, translate as 10, 10–1, 10–2, 10–3, . . . 2–10s-1 . . . 3–10s-1 . . . 3–10s, and so forth. English has no comparable pattern for the teens. This difference influences the rate at which children in different countries master the code for generating large numbers although it does not affect rate of learning of the count words for 1–9. American and Chinese children learn these at comparable rates and use them equally well to solve simple arithmetic problems (Miller et al. 1995).

Almost all of the mathematics or arithmetic revealed in the above examples from divergent settings, ages, and cultural conditions map onto a common structure. Different count lists all honor the same counting principles, and different numbers are made by adding, subtracting, composing, and decomposing natural numbers that are thought of in terms of counted sets. The favored mathematical entities are the natural numbers; the favored operations addition and subtraction, even if the task is stated as multiplication or division. The general rule seems to be, find a way to use whole numbers, either by counting, decomposing *N*, subtracting, or doing repeated counting and subtraction with whole numbers. Notions about continuous quantity usually are not integrated with those about discrete quantities, where people prefer to use repeated addition or subtraction if they can. This commonality of the underlying arithmetic structure and reliance on natural numbers is an important line of evidence for the idea that counting principles and simple arithmetic are universal. The reliance on whole number strategies, even when proportional reasoning is used, is consistent with this conclusion.

Understanding the mathematician's zero, negative numbers, rational and irrational numbers, and all other higher mathematics does not contribute to the knowledge base of intuitive mathematics. The formal side of mathematical understanding is outside the realm of intuitive mathematics (Hartnett and Gelman 1998). Even the mathematical concept of a fraction develops with considerable difficulty, a fact that is surely related to the problems people have learning to measure and understand the concept of equal units. Reliance on intuitive mathematics is ubiquitous, sometimes even to the point where it becomes a barrier to learning new mathematical concepts that are related to different structures (Gelman and Williams 1997). A salient case in point is the concept of rational numbers and the related symbol systems for representing them. Rational numbers are not generated by the counting principles. They are the result of dividing one cardinal number by another. Nevertheless, there is a potent tendency for elementary school children to interpret lessons about rational numbers as if these were opportunities to generalize their knowledge of natural numbers. For example, they rank order fractions on the basis of the denominator and therefore say 1/75 is larger than 1/56, and so on. There is a growing body of evidence that the mastery of mathematical concepts outside the range of those encompassed by intuitive mathematics constitutes a difficult conceptual challenge.

Naive Physics

Naive physics refers to the commonsense beliefs that people hold about the way the world works, particularly with respect to classical mechanics. Being the oldest branch of physics, classical mechanics has priority because mechanical systems can be seen, whereas the motions relevant to other branches of physics are invisible. Because the motions of mechanical systems are both lawful and obvious, it is always intriguing to find instances in which people hold beliefs about mechanics that are not just underdeveloped but systematically wrong.

Jean PIAGET (1952, 1954) studied how young children acquire an understanding of the basic physical dimensions of the world and demonstrated that at young ages, children are systematically disposed to construe the world in biased ways. Interestingly, it was also found that adults often do not exhibit simple physical concepts that Piaget assumed they must have. A notable example of this is the water level problem introduced by Piaget and Inhelder (1956). When asked to indicate the surface orientation of water in a tilted container, about 40 percent of the adult population produce estimates that systematically deviate from the horizontal by more than 5 degrees (cf. McAfee and Proffitt 1991).

A large number of studies have found that adults express systematic errors in their reasoning about how objects naturally move in the world (Champagne, Klopher, and Anderson 1980; Clement 1982; Kaiser, Jonides, and Alexander 1986; McCloskey 1983; McCloskey, Caramazza, and Green 1980; McCloskey and Kohl 1983; Shanon 1976). An excellent introduction to this research can be found in McCloskey (1983), who dubbed this field of study "Intuitive Physics." The best-known example of these problems is the C-shaped tube problem, in which a participant is asked to predict the trajectory taken by a ball after it exits a C-shaped tube lying flat on a table (McCloskey, Caramazza, and Green 1980). The correct answer is that the ball

will follow a straight trajectory tangent to the tube's curvature at the point of exit. About 40 percent of college students get this problem wrong and predict instead that the ball will continue to curve after exiting the tube.

There are two classes of explanations for these findings. The first supposes that people possess a general mental model that dictates the form of their errors (*see* MENTAL MODELS). One such proposal is that naive physics reflects an Aristotelian model of mechanics. Shanon (1976) found that many people reasoned, like Aristotle, that objects will fall at a constant velocity proportional to their mass. In his early writings, diSessa (1982) also argued that people display Aristotelian tendencies. McCloskey (1983) suggested that people's intuitive model resembled medieval impetus theory. By this account, an object is made to move by an impetus that dissipates over time. However, there are at least two problems with these mental model approaches to naive physics. The first is that people are not internally consistent (Cooke and Breedin 1994; diSessa 1983; Kaiser et al. 1992; Ranney and Thagard 1988; Shanon 1976). The same person will respond to different problems in a manner that suggests the application of different models. The second problem is that people are strongly influenced by the surface structure of the problem. Kaiser, Jonides, and Alexander (1986) found that people do not err on the C-shaped tube problem when the situation is put in a more familiar context. For example, no one predicts that water exiting a curved hose will continue to curve upon exit. Although people's dynamical judgments seem not to adhere to either implicit Aristotelian or impetus theories, this does not imply that they have no mental models applicable to natural dynamics. People may possess general models having some as yet undetermined structure, or their models may be domain specific.

The second type of EXPLANATION for people's systematic errors appeals to issues of problem complexity. Proffitt and Gilden (1989) proposed an account of dynamical event complexity that parsed mechanical systems into two classes. Particle motions are those that can be described mathematically by treating the moving object as if it were a point located at its center of mass. Extended-body motions are those contexts in which the object's mass distribution, size, and orientation influence its motion. As an example, consider a wheel. If the wheel is dropped in a vacuum, then its velocity is simply a function of the distance that its center of mass has fallen. Ignoring air resistance, freefall is a particle motion. On the other hand, if the wheel is placed on an inclined plane and released, then the wheel's shape—its moment of inertia—is dynamically relevant. This is an extended-body motion context. People reason fairly well about particle motion problems but not extended-body motion ones. In addition, people also err when they misrepresent a particle motion as being an extended-body motion as, for example, in the C-shaped tube problem. In doing so, they attribute more dimensionality to the problem than is actually there.

Given that people often predict that events will follow unnatural courses—for example, that a ball exiting a C-shaped tube will persist to follow a curved path—it is interesting to ask what would happen if they actually saw such an event occur. Would it look odd or natural? Kaiser and Proffitt (Kaiser, Proffitt, and Anderson 1985; Kaiser et al.

1992; Proffitt, Kaiser, and Whelan 1990) found that when presented with animations of particle motion problems, people judged their own predictions to be unnatural and selected natural motions as appearing correct. For example, when contrived animations were presented to people who drew curved paths on the paper-and-pencil version of the problem, these people reported that balls rolling through a C-shaped tube and continuing to curve upon exit looked very odd, whereas straight paths appeared natural. Animations, however, did not evoke more accurate judgments for extended-body motions (Proffitt, Kaiser, and Whelan 1990). For example, Howard (1978) and McAfee and Proffitt (1991) found that viewing animations of liquids moving to nonhorizontal orientations in tilting containers did not evoke more accurate judgments from people prone to err on this problem.

Adults' naive conceptions about how the world works appear to be simplistic, inconsistent, and situation-specific. However, recent research with infants suggests that a few core beliefs may underlie all dynamical reasoning (*see* INFANT COGNITION). Baillargeon (1993) and Spelke et al. (1992) have shown that, by around 2 1/2 months of age, infants can reason about the continuity and solidity of objects involved in simple events. Other physical concepts, such as gravity and inertia, do not seem to enter infants' reasoning until much later, around 6 months of age (Spelke et al. 1992). Spelke et al. proposed the intriguing notion that continuity and solidity are core principles that persist throughout the development of people's naive physics.

Naive Psychology

See FOLK PSYCHOLOGY

Naive Sociology

Humans everywhere possess elaborate and often articulate knowledge of the social world. Central to this knowledge is the recognition of and reasoning about those groupings of individuals that constitute the social world. Naive sociology is the study of the cognitive processes underlying these everyday beliefs about human groups and human group affiliation.

That humans develop complex representations of society is not surprising. Humans almost certainly know more about other humans than they do about any other aspect of the world, and group living is a hallmark of human existence. Group living likely includes adaptation to the fact that humans may be the only species in which conspecifics are the principal predator (Alexander 1989). Since much of this predation is regulated by and implemented through social groups, cognitive skills, like the capacity to rapidly and accurately interpret the behavior and motivations of others, are critical for survival.

Human social groupings are more complex and more fluid than those of other social species. Consequently, the rapid and accurate appraisal of the social environment is both difficult to achieve and demanding of cognitive resources. Major tasks include the capacity to represent and to compute information about (1) large numbers of groups, (2) varied group affiliations, and (3) shifting coalitions between groups. A number of mechanisms underlie these capacities, and their precise nature remains a matter of some controversy.

Considerable research in social psychology, particularly group dynamics, has revealed and interpreted many processes pertinent to these capacities. Like the bulk of psychology, work in SOCIAL COGNITION tends to approach sociality from a domain-general perspective. Thus, representations of group-level phenomena, like social identity, are typically interpreted as instances of general cognitive strategies for processing categories. Patterns of inferencing associated with social categories (e.g., STEREOTYPING and prejudice), on this view, involve general category effects that simply happen to target person categories (Fiske and Taylor 1991; Hamilton 1981).

Other research in social psychology has identified mechanisms that specifically act on mental representations of human groupings. Research on stereotyping has contributed important insights into cognitions of group-level phenomena,

particularly insights into the relationship between ascribed group affiliation and explanations for the beliefs and behaviors of members of other groups (Hogg and Abrams 1988; Pettigrew 1979; Taylor and Fiske 1991; Miller and Prentice forthcoming).

Influential studies by Tajfel (1981) demonstrate that biases of this sort may be extremely general in the sense that they are not tethered to any actual group affiliation. Tajfel and his colleagues have shown that individuals, in virtually any situation, privilege members of their own group (ingroup) vis-à-vis members of other groups (outgroups). Thus, even when subjects know that the ingroup has no real-world group status (e.g., when the ingroup is composed of all persons whose social security numbers end in the same digit), they distribute pretend money more readily to members of their own group than to members of an outgroup. Biases of this sort are extremely resistant to change and attempts to inhibit spontaneous group-related favoritism have been largely ineffective (Miller and Brewer 1984; Gaertner et al. 1993).

These studies typically approach group-relevant cognitions from the perspective of the individual, both with respect to the individual who perceives group affiliation from the vantage point of him or herself and with respect to the individual as target of bias.

Evolutionary and comparative studies have been especially important in making clear that mental representations of group-level phenomena also include beliefs about groups themselves. EVOLUTIONARY PSYCHOLOGY, COGNITIVE ANTHROPOLOGY, AND ETHNOPSYCHOLOGY all speak directly or indirectly to the role representations of groups play in sociality (Alexander 1989; Dunbar 1988; Brereton 1996; Warnecke, Masters, and Kempter 1992; Fishbein 1996; Shaw and Wong 1989; Reynolds, Falger, and Vine 1987; Cosmides 1989; LeVine and Campbell 1972), as does comparative research on DOMINANCE IN ANIMAL SOCIAL GROUPS and SOCIAL COGNITION IN ANIMALS.

Much of this work reveals the importance of domain-specific and modular mechanisms to naive sociology. Evolution prepares all living things to resolve (or attempt to resolve) recurrent problems facing the organism. It is extremely likely that evolved adaptations emerged in response to recurring social problems that our ancestral populations faced (Baron-Cohen 1995). Relevant evolved adaptations include specialized mechanisms in both humans and nonhuman animals (particularly primates) such as a THEORY OF MIND; domain-specific devices for the recognition of faces, voices, and affective states; cheater detectors; and capacities for representing social dominance.

Other capacities that evolved to coordinate information relevant to nonsocial phenomena may have also been recruited to treat social group-level phenomena. Scholars in the domain-specific tradition, using beliefs about NATURAL KINDS as a point of departure, have proposed that concepts of human groupings are organized around principles that initially emerge in naive understanding of nonhuman groupings (particularly the folk notion of species). Strategies for classifying and reasoning about human groups are strikingly similar to strategies for classifying and reasoning about nonhuman species. It has been argued that notions that capture human diversity (e.g., race, ethnicity, nationality, and gender) may derive via analogy from the notion of species in FOLK BIOLOGY (Atran 1990; Boyer 1990; Rothbart and Taylor 1990). In much the same vein, other aspects of social reasoning (e.g., the willingness to interpret behavior in terms of traits and dispositions) have been attributed to theory of mind (Wellman 1990).

Hirschfeld (1995) and Jackendoff (1992) argue that mental representations of human groups are also governed by a distinct cognitive faculty of social cognition or naive sociology. Noam Chomsky (1988), in a discussion of bilingualism, implies something of the same when he observes that young children have theories of both language and society that they must coordinate in determining, among other things, the particular language to speak in a given context. The basic task of a faculty of social cognition is to develop an integrated picture of the self in society. Whereas the fundamental units of spatial cognition are physical objects in space, those of social cognition are persons in social interaction (Jackendoff 1992: 72). On this view, the notion of *persons in social interaction* involves at least two elements that set the domain of social cognition apart from other domains. First, the causal principles of social relations (e.g., consanguinity, group membership, and dominance) appear to be unrelated to those underlying other domains of knowledge. Second, the fundamental unit of social cognition, the person, is a singular conceptual entity. As already noted, humans have a number of highly specialized input devices that allow the identification of specific persons and the interpretation of their actions.

The concept of the person itself may be contingent on group-relevant cognitions. The image of a social person, for instance, may be a conceptual prerequisite for other individually oriented domain-specific competencies. Recent work with young children, for example, suggests that the notion *group* may developmentally preceed the notion of self (Hirschfeld 1996). Similarly, in theory of mind the person is the entity to which beliefs and desires are attributable (except in rare and pathological circumstances, like multiple personality disorder; see Hacking 1995). Yet belief/desire psychology, taken by some to be the backbone of social reasoning (e.g., Baron-Cohen 1995), may well be insufficient to account for social reasoning in that it is insufficient to account for representations of groups. For instance, it is a commonplace in anthropological analysis to proceed without reference to individuals at all on the belief that social groups and social affiliation are distinct from (and perhaps antecedent to) knowledge of individuals (Mauss 1985). Indeed, social analysis would be impoverished without invoking the notion of corporate groups (groups that are conceptualized as corporate individuals rather than collections of individuals; Brown 1976).

A major cognitive issue in this regard is the nature and scope of cognitive resources that human sociality demands. The social units with which any individual can affiliate are many and varied. A critical task for both children and adults is to develop skills at high-speed scanning of social contexts and high-speed identification of the appropriate (or strategic) affiliations and allegiances invoked in a given context. For example, choosing something as "simple" as the correct

register of speech for a particular situation depends on adequately parsing the social affiliations of the individuals in that context (Hirschfeld and Gelman 1997).

The complexity of the social environment led Hirschfeld (1996) to propose the existence of specialized knowledge structures dedicated to social group understanding. He argues that identifying and reasoning about "natural" groupings (i.e., groups such as race and gender that are considered immutable and derived from a unique group essence) rest on mechanisms unique to social reasoning. Thus, despite the predominant view that preschoolers are conceptually unable to reason beyond external properties (Aboud 1988), Hirschfeld found that even quite young children represent the social environment in terms of abstract principles and nonvisible qualities. For instance, even 3-year-olds distinguish "natural" human kinds from other ways of sorting people and attribute group membership to underlying and unique essences that are transmitted from parent to child.

In sum, cognitive science has provided important insights into the nature and scope of group living. Many questions remain open. What is the relationship between knowledge of group-level and individual-level phenomena? Given the marked variation in sociality, what role does the cultural environment play in shaping social understanding? To what extent does this marked variation preclude evolutionary accounts? If it does not, what kinds of adaptations evolved to treat social phenomena? What was the evolutionary environment like in which these adaptations emerged?

Narrow Content

According to some causal theories, the referent of a term like "water" is whatever substance bears the appropriate causal relation to the use of that term (Putnam 1975; Kripke

1980; see also Fodor 1987; Dretske 1981; Stampe 1977). This view is supported by Putnam's TWIN EARTH example, according to which the referents of our terms, and hence the truth conditions and meanings of utterances and the contents of our thoughts, depend on conditions in our environment and so are not determined by (do not supervene on) our individual, internal psychology alone. Content that does not supervene on an individual subject's internal psychology is called broad content.

Several considerations, however, suggest the need for a concept of content that *would* supervene on internal psychology, that is, a concept of narrow content. We normally assume that our behavior is causally explained by our intentional states such as beliefs and desires (see INTENTIONALITY). We also assume that our behavior has its causal explanation in our individual, internal psychological makeup (see INDIVIDUALISM). But if the explanation of behavior supervenes on individual, internal psychology, and the broad contents of our intentional states do not, then it seems that either those states will not figure in the causal explanations of a genuine psychological science or that a notion of narrow content is required. Some theorists have challenged this argument, however, by denying the first assumption (Stich 1978; 1983), some have denied the second (Wilson 1995), and some have denied that the conclusion follows (Fodor 1994). Even the legitimacy of a distinction between broad and narrow content along these lines has been challenged (Bilgrami 1992; Chomsky 1995). Thus the implication that the scientific explanation of behavior requires narrow content remains controversial.

For this reason, other arguments for narrow content have been advanced that involve not just the causal explanation of behavior but explanations that capture the subject's own perspective on the world and thus rationalize and justify that behavior. For example, if all content is the broad content postulated by causal theories, a brain in a vat being fed artificial sensory inputs by a computer will either have no beliefs or its beliefs will be about the computer's internal states, regardless of the nature of the stimulus inputs. Thus although the question how the world presents itself seems just as legitimate for the brain in the vat as for a normal subject, a theory of belief that restricts itself to broad content apparently cannot provide an adequate account.

A third consideration favoring narrow content derives from a problem raised by Gottlob FREGE (1952). Though the expressions "Hesperus" and "Phosphorus" both refer to the same object—Venus—a person who was sufficiently uninformed could be perfectly rational in believing and assenting to what he would express by saying both "Hesperus is inhabited" and "Phosphorus is not inhabited." The problem is that according to the causal theory these two beliefs are about the same object and say contradictory things about it. And we cannot counter the implication of the causal theory that the subject is irrational by appeal to the different descriptions that the subject associates with the two terms; to do so would undermine the claim of the causal theory that reference is independent of the descriptions available to the subject. Nor can we appeal to the differences in the causal chains connecting Venus with "Hesperus" and "Phospho-rus," because these are unavailable to the subject and so cannot explain how it could be rational to hold these beliefs simultaneously. This last point reveals a problem for conceptual or FUNCTIONAL ROLE SEMANTICS and for procedural semantics as accounts of narrow content (Block 1986; Loar 1982; Field 1977; Schiffer 1981; Miller and Johnson-Laird 1976; Johnson-Laird 1977; see also Harman 1982). Functional role semantics answers the question what the subjects and their Twin Earth doppelgängers have in common by reference to the equivalence of the functional states underlying their beliefs (see FUNCTIONALISM). But, because these functional properties, like the causal chains, are not available to the subject in question, this approach cannot characterize the world as it presents itself to the brain in the vat or rationalize and justify the behavior of the uninformed subject.

Another approach to narrow content exploits an analogy between broad contents and the contents of token-reflexive utterances involving INDEXICALS AND DEMONSTRATIVES (White 1982; Fodor 1987). Suppose Jones and Jones' doppelgänger on Twin Earth both say "It's warm here." Because they have different locations, they say different things and express different belief contents. What is common to the two expressions, however, is a function from their *contexts of utterance* to the contents expressed. If Jones had uttered what he did at his doppelgänger's location, he would have expressed what his doppelgänger did and vice versa. Suppose now that Jones and his duplicate both say "Water is wet." What Jones says is true just in case H_2O is wet, and the same goes for his duplicate and the twin Earth analogue of water, XYZ. Again they express different propositions, and their utterances have different broad contents. But suppose Jones had acquired his word "water" not on Earth but on Twin Earth. Then the broad content of his utterance would have been the same as that of his duplicate. In this case too, what the broad contents of their utterances have in common can be expressed as a function—this time from *contexts of acquisition* to broad contents.

We can also appeal to such functions to show what the brain in the vat has in common with normal subjects. Had the brain acquired its beliefs in the same context as normal subjects, it would have had the same broad-content beliefs that they have, and vice versa. Thus in this example as well, the narrow contents that the beliefs have in common can be expressed as functions from contexts of acquisition to broad contents. Furthermore, we can appeal to the same functions to distinguish the content the uninformed subject would express in saying "Hesperus is inhabited" from what that subject would express in saying "Phosphorus is inhabited." Though there is no possible world at which Hesperus is not identical with Phosphorus, there are worlds epistemically identical with the actual one such that had the subject acquired the terms at those worlds they would have referred to different planets. Thus the terms "Hesperus" and "Phosphorus," though they have the same referent, are associated with different functions from contexts of acquisition to referents. Hence the two beliefs whose broad contents are contradictory have narrow contents that do not support the charge of irrationality.

The appeal to narrow content in this sense answers the three objections to broad content that we have been con-

sidering. This approach, however, is not fully satisfactory. First, it underestimates the theoretical significance of narrow content by making its ascription parasitic on the ascription of broad content. Second, it provides only an indirect answer to the question *what* the subject believes, where the question concerns narrow belief. Third, narrow contents, so defined, do not lend themselves easily to a characterization of the logical or epistemic relations among a subject's beliefs, nor to an analysis of the relations in virtue of which they figure in practical reasoning or decision-making.

An alternative approach to narrow content takes its cue from the fact that the truth conditions of a belief or utterance are often represented as the set of possible worlds at which that belief or utterance is true. As we have seen, the causal theorist's notion of truth and truth conditions leads directly to broad content. However, we can represent the narrow contents of the subject's beliefs as the set of worlds where those beliefs are accurate or veridical and then define these in a way that is independent of truth. One suggestion is that there is a conceptual connection between possible worlds at which one's beliefs are accurate and worlds at which one's actions are optimal (and nonaccidentally so), given one's desires and one's available alternatives. The intuition is that if one performs an action that from one's own point of view is the best action under the circumstances (it is not weak willed, etc.), then it could only fail to be optimal if some of one's beliefs were inaccurate (White 1991).

Nativism

Nativism is often understood as the view that a significant body of knowledge is "built in" to an organism, or at least innately predetermined. This characterization, however, fails to capture contemporary nativism as well as being inadequate for many older views (see NATIVISM, HISTORY OF). Few nativists argue today for the full predetermination of specific concepts, ideas, or cognitive structures such as a language's grammar; and few empiricists fail to argue for certain kinds of information processing, such as back propagation (see SUPERVISED LEARNING), as being built in. Every party to current debates about nativism in fact shares the view that there is something special and intrinsic, that is

innate, to particular types of organisms that enables them to more easily come to engage in some behaviors as opposed to others. It is the nature of those intrinsic structures and processes that is the true focus of debates about whether some aspect of cognition or perception is compatible with a nativist perspective. In particular, nativist views endorse the presence of multiple learning systems each of which is especially effective at acquiring a particular kind of information and where that effectiveness arises from specializations for information that occurs at all levels in that learning system, not just in the initial stages of processing. The rise of connectionism (see CONNECTIONISM, PHILOSOPHICAL ISSUES and COGNITIVE MODELING, CONNECTIONIST) has been said to pose a fatal challenge to nativism; but as seen later in this article, it in itself in no way renders nativism obsolete.

Confusions about nativism often arise in cases where one organism can acquire a body of knowledge or an ability that another cannot. Thus, attempts to teach human language to primates are often seen as bearing directly on nativist views of an innate language even as the researchers on such topics are usually much more cautious (e.g., Savage-Rumbaugh et. al. 1993). But differential success at learning is in itself not relevant. This irrelevance is clear when more extreme comparisons are made. When a child acquires language and a pet gerbil in the same environment does not, no one argues that language is therefore innate in humans. Failure to learn can arise for many reasons, only some of which support a nativist perspective. There may be general cognitive capacity requirements necessary for learning complex knowledge that exceed the capacities of some organisms. When a gerbil fails to learn language, we might well assume that it simply could not acquire any knowledge system with the structural complexity and memory loads imposed by language. When a primate fails to learn a language, it too may fail to pass some general capacity threshold. Alternatively, a primate that is highly adept in some sorts of complex cognitions might fail at language acquisition because it does not have capacities that are specifically tailored for the pickup and learning of linguistic structure. It may fail because it does not "know" enough in advance about some specific properties in the domain of natural language, a pattern of failure that is compatible with a nativist view of knowledge and its origins. But that prior "knowledge" does not have to be in the form of an innately represented set of grammatical rules; it can be a set of powerful biases for interpreting linguistic information in highly constrained ways. Specifying those biases and constraints is where the real distinctions between contemporary nativists and empiricists reside (Keil 1981, 1998). Indeed, it has recently been argued that, even in traditional biology, constraints thought of as "canalization" are the best way of understanding innateness (Ariew 1996).

Although it is more common in philosophy to distinguish RATIONALISM VS. EMPIRICISM, in cognitive science today it is nativism that is usually pitted against empiricism, where, for a nativist, knowledge of such things as grammar or folk psychology does not arise from simply having rational thought and its logical consequences, but rather from having information-specific learning biases that go beyond the more content-neutral mechanisms of learning favored by empiricists, such as unconstrained associationism. Nativists

and empiricists disagree on whether one organism achieves greater learning success than another because it is more cognitively capable in general or because it has specialized structures tuned to learn a particular kind of knowledge. This is the question of DOMAIN SPECIFICITY that has become such a pivotal issue in cognitive science today, especially in EVOLUTIONARY PSYCHOLOGY (Fodor 1983; Hirschfeld and Gelman 1994; Keil 1981; Cosmides and Tooby 1994).

Domain specificity alone, however, is not enough to characterize nativism. The specialization for information must involve a certain kind and "level" of processing. The eye is tailored for different kinds of information than the ear (VISUAL ANATOMY AND PHYSIOLOGY, AUDITORY PHYSIOLOGY), a fact well known to both nativists and empiricists for centuries. But empiricists see those specializations as soon disappearing when that information flows beyond the sensory transducers. If all of thought and all patterns of learning can be explained by general laws, such as those of association, once one goes beyond the specializations of the sense organs, then nativism founders. If, however, there are specialized systems for building up representations and processes in specific domains, whether they be language, biology, or number (LANGUAGE ACQUISITION, FOLK BIOLOGY, NAIVE MATHEMATICS), and general learning principles seem inadequate, nativism is supported.

Consider the difference between having a system that is tuned to expect certain patterns in a specific modality, such as the eye's "expectations" concerning reflected light patterns, and a system that has expectations that transcend modalities, such as that two physical bodies cannot interpenetrate (Spelke 1994). The second expectation can be borne out tactilely, visually, and possibly even auditorily. This expectation is still domain specific in that it applies only to bounded physical objects and not fluids, gases, or aggregates. Systems that are tuned to patterns that transcend modalities would therefore be more likely to fit with a nativist stance.

Connectionist architectures can favor either empiricist or nativist orientations depending on their implementation. A system with preset weights and compression algorithms that seem to be optimized for learning only certain kinds of information, such as that of spatial layout, might well support a nativist account. If such weights, however, only bias the learner toward low-level perceptual features, an empiricist approach is supported (Seidenberg 1992). In some models, a low-level bias, such as selective attention in human infants for moving triangular dot patterns, has been argued to result in a "face processing area of the brain," even though there were no initial biases in that region for faces initially (Johnson and Morton 1991). Thus, an end state of domain-specific processing of a particular kind of information that is localized in a specific region of the brain is not by itself nativist. The way in which that specialized processing was set up is critical. Similarly, a recent interest in "emergentism" in connectionist systems, namely ways in which general learning systems can yield unpredictable emergent higher-order properties (MacWhinney forthcoming), does not displace nativism as much as it makes apparent the subtlety needed for arguments about the origins of various types of knowledge.

In short, nativists and empiricists primarily disagree on the extent to which pre-existing biases for specific domains of information go beyond those in effect at the levels of sensory transducers. The sense of domain also shifts, with domains at the sensory levels being patterns of information such as "light" or "sound waves" and domains at higher levels being patterns corresponding to such things as bounded physical objects, intentional agents, number, or spatial layout. All of these domains of the second sort clearly are amodal and more cognitive than perceptual.

Biases on high-level cognition that work in domain-general ways do not need to support nativism. For example, the base rate fallacy (Kahneman, Slovic, and Tversky 1982) would seem to apply to any kind of experienced information, regardless of its domain. As such, it would seem to be a further modification of general laws of learning, such as those on association, all of which fits with empiricism. If, however, this bias were to be much more prominent in cases of social attribution, and seemed to help learning about social situations, it would be considered domain specific.

Some have argued that the nativism/empiricism controversy is seriously misguided because of the intrinsically interactional nature of development (Lehrman 1953). This notion has been raised again more recently (Elman et al. 1996) in attempts to argue that it makes no sense to ask what is innate in dynamic learning systems. These objections, however, attack a caricature of "innate structures" and not the current debate between nativists and empiricists. Part of the confusion is between specifying particular behaviors or pieces of knowledge as innate, as opposed to being products of the learning function itself and the cognitive biases it engenders. When learning is considered as a function from sets of environments to sets of mental representations (Chomsky 1980), the intrinsically interactional nature of learning is part of the formulation.

Nativism, History of

Our understanding of ourselves and of our world rests on two factors: the innate nature of our minds and the specific character of our experience. For 2,500 years there has been an on-again off-again debate over which of these factors is paramount. NATIVISM champions our innate endowment; *empiricism,* the role of experience (cf. RATIONALISM VS. EMPIRICISM). There have been three significant moments in the historical development of nativism: Plato's doctrine of anamnesis, the rationalist defense of innateness in the seventeenth and eighteenth centuries, and the contemporary revival of nativism in the cognitive sciences.

Platonic Nativism

Plato presents the first explicit defense of nativism in the *Meno,* where Socrates draws out a geometrical theorem from an uneducated slave, and argues that this is possible only because the slave implicitly had the theorem in him all along. He had merely forgotten it, and questioning helped him to recollect. For Plato, all genuine learning is a matter of recollecting (*anamnesis*) what is innate but forgotten. Socrates goes on to argue that because the slave had not been taught geometry, he must have acquired the knowledge in an earlier existence. In the *Phaedo,* Plato connects innateness to the theory of forms and argues that our grasp of the form of equality could not come from perceived equals, and must therefore also be innate. For Plato, nativism is more than a solution to the epistemological problem of knowledge acquisition; it also provides evidence for the preexistence and immortality of the soul.

Plato's claims have served as the touchstone for defenders of nativism (so much so that the doctrine is sometimes referred to as "Platonism"), but it is difficult to pin down a specific Platonic innateness "doctrine." The problem is that Plato's nativism is embedded in an epistemological framework that takes transcendent forms to be the only objects of genuine knowledge, and there are unresolved questions about the exact nature of that framework. Plato never definitively says what forms there are, or what role our grasp of the forms plays in ordinary cognition. It is therefore difficult to say confidently what Plato took to be innate, or how he conceived the influence of the innate in thinking. Apart from these uncertainties, his argument seems threatened by a potentially devastating regress: if knowledge acquisition is recollection, how is it that we acquire knowledge in an earlier existence?

Nativism and Continental Rationalism

In the *Meditations,* René DESCARTES argues that concepts such as God and infinity can not be derived from experience and must therefore be innate. At some points he even suggests that no ideas can come to us via experience; all must be innate. Gottfried Wilhelm Leibniz, the main rationalist spokesman for nativism, argues that our certain knowledge of necessary truths (of mathematics, logic, metaphysics, and so on) is wholly inexplicable on the empiricist position. Our experience is always particular and contingent; how could our knowledge be universal and necessary? Such knowledge must instead rest on innate principles. Leibniz also argues that even our ordinary empirical concepts contain an innate element. Our concept of a man, for instance, draws upon our innate general concept of substance as well as on the specific features of men that we discover in experience. A priori knowledge about substance is possible because we can mine this innate source, and such knowledge is therefore immune from the contingencies of the specific substances we experience.

Leibniz's position illustrates the fit between seventeenth-century rationalism and nativism. Rationalism holds that the mind can go beyond appearances and provide us with insight into the intelligible nature of things; this insight yields a priori knowledge. But how do we get such insight? Here nativism is invoked: our innate ideas and principles are the source of our a priori understanding. The problem with this package is that even if something is innate, that does not in itself establish its truth; it certainly cannot establish its necessity. René Descartes implicitly recognizes this when he introduces a benevolent God into his epistemology as the ultimate guarantor of our knowledge. The idea is that if something is innate, a benevolent God must have put it there for our edification, and a benevolent God would not mislead us.

The historical result was that nativism became entangled with an excess of philosophical baggage. Plato, as we saw, joined it to a transcendent world of forms and a mystical doctrine of the preexistence of the soul. From rationalism it inherited an exalted conception of the power of pure reason and an epistemology that seemed to ultimately require a theological basis. Whatever the original merits of the basic nativist claim about the initial state of the mind, the position began to seem out of step with the more naturalistic world view of the Newtonian revolution.

Empiricism

John Locke's *Essay,* the first systematic defense of empiricism, is a philosophical expression of this more naturalistic perspective. Locke begins with an extended polemic against nativism, in which he charges that it is either blatantly false, because there are no principles that can claim the "universal consent" that an innate principle would produce, or that it reduces to the trivial claim that we have an inborn capacity to come to know everything we know. Leibniz responds to these preemptive strikes in his *New Essays,* where a number of innovative ideas are introduced—for example, the notion of unconscious knowledge, the procedural-declarative distinction, the suggestion of innate biases that may or may not be expressed. But although this part of the debate has had greater visibility, the more important empiricist attack—and this is the main point of Locke's *Essay* and of subsequent empiricist theorizing—is that nativism is an unnecessary extravagance, because our knowledge can be explained with

the simpler empiricist hypothesis. The empiricist project exerted a dominant influence in both philosophy and psychology well into the twentieth century. It was widely assumed that the program had to eventually succeed, because nativism was stigmatized as a backward superstition and not a serious "scientific" alternative. Empiricist-oriented psychologists carried over the early associationist thinking of David HUME, John Stuart Mill, and others into the behaviorist analyses of learning, while their counterparts in philosophy pursued technical analyses of INDUCTION and CONCEPT formation.

Chomsky and the INNATENESS OF LANGUAGE

The reign of this presumptive empiricism ended at mid-century with Noam Chomsky's groundbreaking work in linguistics. Chomsky has revived nativism by arguing that a child's mastery of language cannot be accounted for in terms of empiricist learning mechanisms. His case rests on the POVERTY OF THE STIMULUS ARGUMENTS. Speakers adhere to a complex system of grammatical rules that must somehow be reflected in the speaker's psychological processors; otherwise we cannot explain the adherence. But these rules involve categories and classifications that are abstract and far removed from the linguistic evidence available to the learner, and their specific content is underdetermined by the evidence available. The empiricist's inductive manipulation of the data available to the child cannot produce the rule-information that the child must have. But despite this shortfall, normal children acquire the right set of rules with little or no rule-instruction, and at an age at which they cannot master much else. Chomsky's hypothesis is that language learners have innately specified information that is specifically about the nature of human language ("universal grammar"). The child is not simply dropped into the wholly alien terrain of language; instead she comes to the language-learning task with a "head start"—a rough map giving her some idea of what to look for. Chomsky's claims have attracted criticism both from within and outside linguistics, but the preponderant view is that as far as language goes, empiricism is wrong and nativism is right.

This nativist revival in linguistics led to the reassessment of established empiricist approaches to development in other areas like mathematics, physical causality, visual perception, and so on. In many of these areas, nativists have developed new evidence to support their positions, and in some cases have argued that older findings were misinterpreted. A case in point is Jerry Fodor's contention that the whole empiricist "concept-learning" paradigm—the sort of "learning by example" that has been championed from Locke to the present—has at its core a surprising and unavoidable nativist commitment. Empiricists have of course not given up; new connectionist models of learning have been touted as using only empiricist-sanctioned principles, but as nevertheless being able to learn what nativists have claimed was unlearnable without domain-specific innate structure.

Regardless of how the empirical issues are resolved in any particular domain, nativism has been at least reestab-

lished in contemporary cognitive science as a viable alternative to empiricism. The core question-schema it addresses remains cogent: are our ideas, beliefs, knowledge, and so forth in any particular domain derived solely from experience, or are they to some extent traceable to domain-specific features of the mind's initial endowment? There is nothing obscure or unscientific about nativist answers. They are on the contrary very much in line with our understanding of the way brain adaptations equip organisms to function in their environmental niches. Cognitive ethologists (*see* COGNITIVE ETHOLOGY) have shown that rats are born with a grasp of their nutritional needs, and that ants do not need to be taught the system of dead reckoning they use in foraging expeditions. Nativists extend this pattern of findings to the higher cognitive functions found in humans. The new field of EVOLUTIONARY PSYCHOLOGY, which adopts a thoroughgoing nativist perspective, focuses especially on the sorts of cognitive and motivational structures that might have developed as adaptations in the original ancestral settings in which humans evolved.

This newly secured scientific respectability has come at a philosophical price. The "transcendental" nativism of Plato and Descartes had significant epistemological and metaphysical ramifications that the new nativism cannot secure with the same ease.

Natural Kinds

Some systems of classification are *merely conventional:* they divide a population of objects into kinds, and the principles by which objects are categorized are designed to answer to some specific purpose. There is no antecedently correct or incorrect way to categorize various objects apart from the purposes to which the system of classification will be put. Thus, for example, we divide the world into different time zones, and our purpose in so doing is to allow for coordination of activities in different locales, but there is no right or wrong way to draw the boundaries of time zones; there are merely more or less convenient ways that answer better or worse the concerns that led us to devise these categories in the first place. The view that all systems of categorization are merely conventional is called *conventionalism* about kinds.

Some systems of CATEGORIZATION, however, do not seem to be merely conventional. Rather, they attempt to draw conceptual boundaries that correspond to real distinctions in nature, boundaries which, in Plato's phrase, "cut nature at its joints." Thus, for example, the periodic table of elements seems not merely an arbitrary or convenient system of classification, a system that makes certain calculations or predictions easier; rather, it seems to describe real kinds in nature, kinds whose existence is not just a product of our classificatory activity. Kinds of this sort, which are not merely conventional, are called *natural kinds.* Those who believe that there are natural kinds, called *realists* about kinds, believe that it is part of the business of the various sciences to discover what the natural kinds are; scientific taxonomies, in this view, attempt to provide a proper account of these kinds.

The notion of a natural kind figures in to important questions in the methodology of the cognitive sciences, as well as work in COGNITIVE DEVELOPMENT, the psychology of reasoning, and COGNITIVE ANTHROPOLOGY.

According to conventionalism, many disputes about proper taxonomy in the sciences are misguided. Taxonomic systems, in this view, cannot themselves "get things right" or "get things wrong," although some will, of course, be more convenient than others. Disputes about taxonomy, in this view, do not involve genuine disagreement about substantive scientific questions. Realists, however, regard disputes about proper taxonomy in the various sciences as substantive. Consider, for example, the categorization of psychopathologies in the *Diagnostic and Statistical Manual* (1994). Those who think of psychodiagnostic categories as merely conventional will regard questions about categorization here as ones of convenience; a proper system of categorization is merely one that well serves the purposes for which it was designed. If, however, the various psychodiagnostic categories constitute a system of natural kinds, then there are substantive theoretical questions about the boundaries of those kinds. In this view, certain ways of drawing the boundaries among psychopathologies are simply mistaken, and not merely inconvenient or ill-suited to the purposes for which we have devised our classificatory scheme. More important, some systems of classification might be extremely useful for certain purposes without giving a proper account of the nature and boundaries of the items classified.

Those who believe that all classification is merely conventional thus see taxonomic disputes as shallow and the search for substantive theory to guide taxonomy as misguided; substantive scientific questions arise only *after* the choice of a taxonomic system. Realists about natural kinds, on the other hand, see taxonomic disputes as potentially important; a proper taxonomy must be guided by theoretical insight into the underlying causal structure of the phenomena under study. The dispute between conventionalists and realists is thus significant not only in issues concerning psychodiagnosis, but also in addressing taxonomic questions throughout the cognitive sciences.

The way in which questions about natural kinds influence taxonomic issues demonstrates the importance of this concept for methodological concerns in the cognitive sciences. Questions about natural kinds arise more directly, however, as well. First, natural kind CONCEPTS play a crucial role in inductive inference. Second, and relatedly, the acquisition of natural kind concepts plays an important role in cognitive development.

Natural kind concepts play an important role in successful inductive inference because members of a given natural kind tend to have many of their most fundamental properties in common. Thus, finding that one member of a kind has a certain property gives one reason for believing that others will share that property as well. This uniformity of natural kinds is part of what distinguishes them from arbitrarily specified classes of individuals, for in the case of arbitrary classes, noting that one member of the class has a certain property (other than the ones that are used to define the class) provides one with no reason at all to believe that other members of the class will share that property. Our ability to make successful inductive inferences thus depends on our ability to recognize natural kinds. Not surprisingly, many suggest an evolutionary basis for such a preestablished harmony between folk and scientific taxonomies. While no one believes that our native categories simply mirror those of the sciences, the suggestion here is that natural selection provides us with a starting point that approximately captures some of the real distinctions in nature, thereby allowing for the possibility of more elaborate and more accurate scientific taxonomies. Without some native help in identifying the real categories in nature, some have argued, we would be unable to develop accurate taxonomies at all.

It is for this reason that the acquisition of natural kind concepts is such an important intellectual achievement. Two developmental questions need to be separated here: (1) At what point are various natural kind concepts acquired? For example, when do children acquire the concept of a living thing, of an animal, of a being with mental states, and so on?

(2) At what point do children acquire the concept of a natural kind itself? A good deal of work has been done on each of these questions. Although an explicitly articulated concept of a natural kind is certainly found in no children, and indeed, in few adults, the ways in which children classify objects and the ways in which they respond to the information that two objects are members of a single taxonomic category suggest that there is a strong tendency to view the world as having a structure that presupposes the existence of natural kinds. In particular, children do not tend to classify objects merely on the basis of their most obvious observable features, features that may be unrevealing of natural kind membership; and when children are told that two individuals are members of a single category, they tend to assume that these individuals will share many fundamental properties, even when the most obvious observable features of the objects differ. Some authors have suggested that these tendencies may be innate; this would help to explain the possibility of successful inductive inference by explaining the source of the human ability to identify kinds that support inductive generalizations. A tendency to view the world in terms of the structure required by natural kinds seems, at a minimum, to be an ability already in place early in cognitive development.

Relevant here too is work in cognitive anthropology. Atran's work (1990) on folk taxonomies reveals deep similarities in the ways in which different cultures divide up the biological world. More than this, these taxonomies have much more than just a passing resemblance to the more refined taxonomic categories of the biological sciences.

Not everyone is entirely optimistic about the possibility of filling in the details of the picture presented here. Some deny that the taxonomies of the different sciences have enough in common with one another to speak of them all as displaying a single structure, the structure of natural kinds. This skepticism has been fueled by a number of factors, including the recognition that the physical world is not deterministic, as well as the fact that the kinds of the biological world crosscut one another. That scientific taxonomies are simply more messy than was once assumed has thus not only complicated the picture of natural kinds, but also made some doubt the very usefulness of the notion. Moreover, the similarity between folk taxonomies and the taxonomies of the various sciences differ substantially. The connection between our conceptual capacities and the causal structure of the world thus leaves a good deal to be discovered on all accounts.

Natural Language Generation

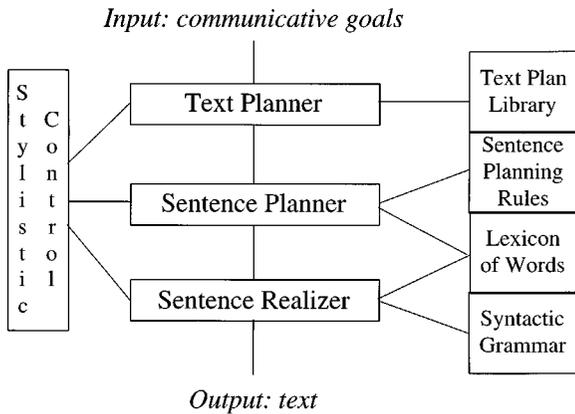
Automated natural language generation (NLG), currently about 25 years old, investigates how to build computer programs to produce high-quality text from computer-internal representations of information. Generally, NLG does not include research on the automatic production of speech, whether from text or from a more abstract input (see SPEECH SYNTHESIS). Also, with few exceptions, research has steadily moved away from modeling how people produce language to developing methods by which computers can be made to do so robustly.

The information provided to a language generator is produced by some other system (the "host" program), which may be an expert system, database access system, MACHINE TRANSLATION engine, and so on. The outputs of various host systems can differ quite significantly, a fact that makes creating a standardized input notation for generators a perennial problem.

Traditionally, workers on NLG have divided the problem into two major areas: content selection ("what shall I say?") and content expression ("how shall I say it?"). Processing in these stages is generally performed by so-called text planners and sentence realizers, respectively. More recently, two further developments have occurred: first, as generators became more expressive, the control of stylistic variation ("why should I say it this way?") has become important; second, an intermediate stage of sentence planning has been introduced to fill the "generation gap" between text planners and sentence realizers. The canonical generator architecture

Input: communicative goals

Figure 1.

Output: text


appears in figure 1. No generator created to date fully embodies all these modules. Pilot attempts at comprehensive architectures are ERMA (Clippinger 1974) and PAULINE (Hovy 1988). Most generators contain just some of these stages, in various arrangements; see Reiter (1994) and De Smedt, Horacek, and Zock (1995).

Stage 1: Text Planning

Accepting one or more communicative goals from the host system, the text planner's two tasks are to select the appropriate content material to express, and to order that material into a coherently flowing sequence. A typical input goal might be [DESCRIBE HOUSE-15] or [MOTIVATE GOING-ON-VACATION-12], where the terms with numbers denote specific packages of information. After planning, the output is generally a tree structure or an ordered list of more detailed content propositions, linked together by discourse connectives signaled by "therefore," "and," "however," and so on. Usually, each proposition represents approximately the information contained in a single-clause sentence. Thus, the initial goal [DESCRIBE HOUSE-15] may be expanded into a text plan containing (in simplified notation) [GENERATE HOUSE-IDENTIFIER] [GENERATE ADDRESS] [INTRODUCE FLOORPLAN] [ELABORATE [GENERATE GROUND-FLOOR] "and" [GENERATE TOP-FLOOR] "and" [GENERATE BASEMENT]] and so on. Generally, text planning is considered to be language-independent.

The two principal methods for performing the text planning tasks involve schemas and so-called rhetorical relations. Schemas (McKeown 1985; Paris 1993; see SCHEMATA) are the simplest and most popular, useful when the texts follow a fairly stereotypical structure, such as short encyclopedia articles or business reports. Each schema specifies the typical sequence of units of content material (or of other schemata; they may be nested); for example, the order of floors. Rhetorical relations (e.g., Elaboration, Justification, Background) organize material by specifying which units of material (or blocks of units) should be selected and linked in sequence. Several collections of relations have been proposed; Rhetorical Structure Theory (Mann and Thompson

1988) and the associated method of planning (Hovy 1993; Moore 1989) are typical.

Stage 2: Sentence Planning

Until the early 1990s, sentence-planning tasks were performed during text planning or sentence realization. Increasingly, however, sentence planning is seen as a distinct stage; this clarifies the generation process and makes focused investigation of subtasks easier.

Accepting from the text planner a text structure, some of the sentence planner's tasks include: specifying sentence boundaries; organizing (ordering, relativizing, etc.) the material internal to each sentence; planning cross-sentence reference and other anaphora; selecting appropriate words and phrases to express content; and specifying tense, mode (active or passive), as well as other syntactic parameters. The ideal output of a sentence planner is a list of clause-sized units containing a fairly complete syntactic specification for each clause; see Meteer (1990) for a thoughtful study.

In the example, the sentence planner must decide whether to generate each floor plan as a separate sentence or to conjoin them (and if so, to choose an appropriate conjunction). It must decide whether to say, for example, "the ground floor contains . . ." or "the ground floor has the following rooms . . . ," or any of numerous other formulations. It must decide whether to say "living room" or "sitting room"; "den" or "family room." The interrelatedness and wide range of variation of such individual aspects makes sentence planning a difficult task, as anyone who has ever written an essay knows. A considerable amount of research on individual sentence-planning tasks exists (see the readings below), but there is relatively little on their integration (see Appelt 1985; Nirenburg et al. 1988).

Stage 3: Sentence Realization

Accepting from the sentence planner a list of sentence specifications, the sentence realizer's tasks are to determine the grammatically correct order of words; to inflect words for tense, number, and so on, as required by the language; and to add punctuation, capitalization, and the like. These tasks are language-dependent.

Realization is the most extensively studied stage of generation. The principal knowledge required is a grammar of syntactic rules and a lexicon of words. Different theories of SYNTAX have led to very different approaches to realization. Realization algorithms include unification (Elhadad 1992), Systemic network traversal (Mann and Matthiessen 1985), phrase expansion (Meteer et al. 1987), head-driven and reversible methods (Van Noord 1990; St. Dizier 1992), simulated annealing (De Smedt 1990), connectionist architectures (Ward 1990), and statistically based management of underspecification (Knight and Hatzivassiloglou 1995). The systems Penman (Mann and Matthiessen 1985; later extended as KPML; Bateman 1994), FUF/SURGE (Elhadad 1992), and MUMBLE (Meteer et al. 1987) have been distributed and used by several external users.

In the example, the specification (in simplified form):

(1) [GENERATE (TYPE: DECLARATIVE-SENTENCE)
      (HEAD: POSSESS)
      (SUBJECT:((HEAD: FLOOR) (LEVEL-MODI-
      FIER: GROUND) (DETERMINED: YES)))
      (OBJECT:((HEAD: ROOM) (NUMBER: 4)
      (DETERMINED: NO)))
      (TENSE: PRESENT)]

as produced by the sentence planner will be interpreted by the grammar rules to form a sentence such as "the ground floor has four rooms."

Stylistic Control

Throughout the generation process, some agency has to ensure the consistency of choices, whose net effect is the style of the text. Since different styles have different communicative effects, the stylistic control module must use high-level pragmatic parameters initially specified for the system (such as degree of formality, the addressee's language level, amount of time available, communication genre) to govern its overall decision policies. These policies determine the selection of the most appropriate option from the options facing any generator module at each point during the planning and realization process.

Few studies have been performed on this aspect of generation; lexicons, grammars, and sets of planning rules are still too small to necessitate much stylistic guidance. Furthermore, the complexity of interaction of choices across the stages of generation requires deep attention: how does the choice of word "freedom fighter"/"terrorist"/"guerrilla" interact with the length of the sentences near it, or with the choice of active or passive mode? See Jameson (1987), Hovy (1988), and DiMarco and Hirst (1990) for studies.

Generation Techniques

Two core operations are performed throughout the generation process: content selection and ordering. For text planning, the items are units of meaning representation; for realization, the items are grammatical constituents and/or words. To do this, almost all generators use one of the following four basic techniques.

Canned items: Predefined sentences or paragraphs are selected and printed without modification. This approach is used for simple applications.

Templates: Predefined structures that allow some variation are selected, and their blank spaces filled with items specified by the content. The blanks usually have associated requirements that specify what kinds of information may fill them.

Cascaded patterns: An initial abstract pattern is selected, and each of its pieces are replaced by successively more detailed patterns, forming a tree structure with, at its leaves, the target elements. An example is traditional phrase-structure grammars, with words as target elements. The selection of suitable patterns for further expansion is guided by the content to be generated. Example realizer: MUMBLE (Meteer et al. 1987), using grammar rules as patterns; exam-

ple text planner: TEXT (McKeown 1985), using schemas as patterns.

Features: In the most sophisticated approach to realization, grammar rules, lexical items, and the input notation are all encoded as collections of features, using the same type of notation. A process called unification is employed to compare the input's features against all possible grammar rules and lexical items to determine which combination of rules and items matches. For example, the specification for the sentence "the ground floor has four rooms" given above will unify with the feature-based grammar rule:

(2) [SENTENCE (TYPE: DECLARATIVE-SENTENCE)
      (HEAD: X0)
      (SUBJECT: X1)
      (OBJECT: X2)
      (TENSE: X3)]

where each variable X is then associated with the appropriate portion of the input and subsequently unified against other rules. And the word "rooms" is obtained from the lexicon by successfully unifying the input's subject with the lexical item.

(3) [LEXITEM (HEAD: ROOM) (NUMBER: >1) (LEX-
      EME: "rooms")]

Example realizer: FUF/SURGE (Elhadad 1992).

Using features a different way, the influential Penman system (Mann and Matthiessen 1985) contains a network of decision points that guide the system to identify appropriate features, whose ultimate combination specifies the desired sentence structure and lexical items.

Natural Language Processing

Natural language processing is a subfield of artificial intelligence involving the development and use of computational models to process language. Within this, there are two general areas of research: *comprehension,* which deals with processes that extract information from language (e.g., natural language understanding, information retrieval), and *generation,* which deals with processes of conveying information using language. Traditionally, work dealing with speech has been considered separate fields of SPEECH RECOGNITION and SPEECH SYNTHESIS. We will continue with this separation here, and the issues of mapping sound to words and words to sound will not be considered further.

There are two main motivations underlying work in this area. The first is the technological goal of producing automated systems that perform various language-related tasks, such as building automated interactive systems (e.g., automated telephone-operator services) or systems to scan databases of documents to articles on a certain topic (e.g.,

finding relevant pages on the world wide web). The second, the one most relevant to cognitive science, seeks to better understand how language comprehension and generation occurs in humans. Rather than performing experiments on humans as done in psycholinguistics, or developing theories that account for the data with a focus on handling possible counterexamples as in linguistics and philosophy, researchers in natural language processing test theories by building explicit computational models to see how well they behave. Most research in the field is still more in the exploratory stage of this endeavor and trying to construct "existence proofs" (i.e., find any mechanism that can understand language within limited scenarios), rather than building computational models and comparing them to human performance. But once such existence-proof systems are completed, the stage will be set for more detailed comparative study between human and computational models. Whatever the motivation behind the work in this area, however, computational models have provided the inspiration and starting point for much work in psycholinguistics and linguistics in the last twenty years.

Although there is a diverse set of methods used in natural language processing, the techniques can generally be broadly classified in three general approaches: statistical methods, structural/pattern-based methods and reasoning-based methods. It is important to note that these approaches are not mutually exclusive. In fact, the most comprehensive models combine all three techniques. The approaches differ in the kind of processing tasks they can perform and in the degree to which systems require handcrafted rules as opposed to automatic training/learning from language data. A good source that gives an overview of the field involving all three approaches is Allen 1995.

Statistical methods involve using large corpora of language data to compute statistical properties such as word co-occurrence and sequence information (see also STATISTICAL TECHNIQUES IN NATURAL LANGUAGE PROCESSING). For instance, a *bigram* statistic captures the probability of a word with certain properties following a word with other properties. This information can be estimated from a corpus that is labeled with the properties needed, and used to predict what properties a word might have based on its preceding context. Although limited, bigram models can be surprisingly effective in many tasks. For instance, bigram models involving part of speech labels (e.g., noun, verb) can typically accurately predict the right part of speech for over 95 percent of words in general text. Statistical models are not restricted to part of speech tagging, however, and they have been used for semantic disambiguation, structural disambiguation (e.g., prepositional phrase attachment), and many other properties. Much of the initial work in statistical language modeling was performed for automatic speech-recognition systems, where good word prediction can double the word-recognition accuracy rate. The techniques have also proved effective in tasks such as information retrieval and producing rough "first-cut" drafts in machine translation. A big advantage to statistical techniques is that they can be automatically trained from language corpora. The challenge for statistical models concerns how to capture higher level structure, such as semantic information, and

structural properties, such as sentence structure. In general, the most successful approaches to these problems involve combining statistical approaches with other approaches. A good introduction to statistical approaches is Charniak 1993.

Structural and pattern-based approaches have the closest connection to traditional linguistic models. These approaches involve defining structural properties of language, such as defining FORMAL GRAMMARS for natural languages. Active research issues include the design of grammatical formalisms to capture natural language structure yet retain good computational properties, and the design of efficient parsing algorithms to interpret sentences with respect to a grammar. Structural approaches are not limited solely to syntax, however. Many more practical systems use semantically based grammars, where the primitive units in the grammar are semantic classes rather than syntactic. And other approaches dispense with fully analyzing sentence structure altogether, using simpler patterns of lexical, syntactic and semantic information that match sentence fragments. Such techniques are especially useful in limited-domain speech-driven applications where errors in the input can be expected. Because the domain is limited, certain phrases (e.g., a prepositional phrase) may have only one interpretation possible in the application. Structural models also appear at the DISCOURSE level, where models are developed that capture the interrelationships between sentences and build models of topic flow. Structural models provide a capability for detailed analysis of linguistic phenomena, but the more detailed the analysis, the more one must rely on hand-constructed rules rather than automatic training from data. An excellent collection of papers on structural approaches, though missing recent work, is Grosz, Sparck Jones, and Webber 1986.

Reasoning-based approaches involve encoding knowledge and reasoning processes and use these to interpret language. This work has much in common with work in KNOWLEDGE REPRESENTATION as well as work in the philosophy of language. The idea here is that the interpretation of language is highly dependent on the context in which the language appears. By trying to capture the knowledge a human may have in a situation, and model common-sense reasoning, problems such as word sense and sentence-structure disambiguation, analysis of referring expressions, and the recognition of the intentions behind language can be addressed. These techniques become crucial in discourse, whether it be extended text that needs to be understood or a dialogue that needs to be engaged in. Most dialogue-based systems use a speech-act–based approach to language and computational models of PLANNING and plan recognition to define a conversational agent. Specifically, such systems first attempt to recognize the intentions underlying the utterances they hear, and then plan their own utterances based on their goals and knowledge (including what was just recognized about the other agent). The advantage of this approach is that is provides a mechanism for contextual interpretation of language. The disadvantage is the complexity of the models required to define the conversational agent. Two good sources for work in this area are Cohen, Morgan, and Pollack 1990 and Carberry 1991.

There are many applications for natural language processing research, which can be roughly categorized into three main areas:

Information Extraction and Retrieval

Given that much of human knowledge is encoded in textual form, work in this area attempts to analyze such information automatically and develop methods for retrieving information as needed. The most obvious application area today is in developing internet web browsers, where one wants to find web pages that contain specific information. While most web-based techniques today involve little more than sophisticated keyword matching, there is considerable research in using more sophisticated techniques, such as classifying the information in documents based on their statistical properties (e.g., how often certain word patterns appear) as well as techniques that use robust parsing techniques to extract information. A good survey of applications for information retrieval can be found in Lewis and Sparck Jones (1996). Many of the researchers in this area have participated in annual evaluations and present their work at the MUC conferences (Chincor, Hirschman, and Lewis 1993).

Machine Translation

Given the great demand for translation services, automatic translation of text and speech (in simultaneous translation) is a critical application area. This is one area where there is an active market for commercial products, although the most useful products to date have aimed to enhance human translators rather than to replace them. They provide automated dictionary/translation aids and provide rough initial translations that can be post-edited. In applications where the content is stylized, such as technical and user manuals for products, it is becoming feasible to produce reasonable-quality translations automatically. A good reference for the machine-translation area is Hutchins and Somers 1992.

Human-Machine Interfaces

Given the increased availability of computers in all aspects of everyday life, there are immense opportunities for defining language-based interfaces. A prime area for commercial application is in telephone applications for customer service, replacing the touch-tone menu-driven interfaces with speech-driven language-based interfaces. Even the simplest applications, such as a ten-word automated operator service for long-distance calls, can save companies millions of dollars a year. Another important but longer-term application concerns the computer interface itself, replacing current interfaces with multimedia language-based interfaces that enhance the usability and accessibility of personal computers for the general public. Although general systems are a long way off, it will soon be feasible to define such interfaces for limited applications.

Although natural language processing is an area of great practical importance and commercial application, it is important to remember that its main contribution to cognitive science will remain the powerful metaphor that the computer provides for understanding human language processing. It allows us to specify models at a level of detail that would otherwise be unimaginable. We are now at the stage where end-to-end models of conversational agents can be constructed in simple domains. Work in this area will continue to further our knowledge of language processing and suggest novel ideas for experimentation.

Neural Development

Neural development is the mechanistic link between the shaping forces of EVOLUTION and the physical and computational architecture of the mature brain. A growing knowledge of how the genome is expressed in development in the progressive specification of cell fates and neural structures is being combined with a better understanding of the functional organization of the adult brain to define the questions of neural development in a way never before possible. Until recently, questions in neural development were problem-centered—for example, how do axons locate a target?, how is a neuron's neurotransmitter specified?, how are topographic maps made? While most current research remains directed at such empirical problems, advances in our understanding of genetics and evolution have begun to give the questions of neural development a more principled structure.

The most surprising insight of molecular genetics and evolution regarding the brain is the extreme conservation of fundamental genetic and physical structures across vertebrate orders, and even across phyla. Specification of gene expression at the level of the individual neuron is too expensive of the genome; a better solution is to divide areas of the developing nervous system into domains specified by overlapping patterns of gene expression that, in combination, confer unique information to each zone. Such a solution was originally found to be operating in the control of head development in the fruit fly *Drosophila*. Through a mosaic pattern of expression, the HOM-C class of homeotic genes specify segmentation during *Drosophila* development (Lewis 1978), regulating expression of other genes that direct differentiation of structures along the anterior-posterior neuraxis. Since this discovery, these genes or their homologues have been found throughout the animal world; vertebrate homologues of the HOM-C genes, known as Hox genes, were found to delineate various aspects of segmentation of the vertebrate hindbrain and midbrain (Keynes and Krumlauf 1994). An immediate benefit from this descriptive work is a better understanding of the segmental architecture of the forebrain, which had been enigmatic and controversial. The overlapping pattern of Hox and other regulator gene expression allowed the first characterization of a continuous pattern of segmental architecture from spinal cord to olfactory bulb in the vertebrate brain, even in the elaborate forebrain (Puelles and Rubenstein 1993).

This type of conservation of developmental patterning has been apparent not only in fundamental segmental divisions but in many other features of development. In morphogenesis, for example, the same regulator gene (reviewed in Zuker 1994) is implicated in the proper development of eyes both in *Drosophila* and mammals, even though their common ancestor could not have had an image-forming eye. Formation of initial axonal scaffolding and the mechanisms of axon extension are strikingly similar in both vertebrate and complex invertebrate brains (Easter, Ross, and Frankfurter 1993; Goodman 1994; Reichert and Boyan 1997). Within mammals, and possibly most vertebrates, the sequence and relative timing of events in both early neurogenesis and process extension produce extremely predictable alterations in morphology as brains enlarge in various radiations (Finlay and Darlington 1995). That the structures that underlie cognitive processes in complex animals can be found, albeit in reduced form, in animals without such capacities is an important consideration for future theory building in COMPUTATIONAL NEUROSCIENCE.

The actual solutions found in neural development to clearly stated, logical problems seem bound to defy standard hypothesis testing. For example, a central and conspicuous feature of brain organization is the topographic representation of sensory surfaces and the preservation of topographic order as one brain structure maps to the next, though the information-bearing dimensions being mapped are sometimes unclear. How are such maps formed? A number of mechanisms could independently produce an acceptable solution: (1) the spatial relationship of elements in connecting maps could be passively apposed; (2) temporal gradients could map one element to another in an organized sequence; (3) neighboring elements in a map could actively recognize one another so that the map might travel in a coherent pattern of axons to its target; (4) different parts of the map might have different "road maps" to find the target; (5) the elements in the first map might recognize locations in the target map at varying degrees of specificity; (6) the map might develop from trial and error, based on experience; or (7) statistical regularities in the activity pattern of the input array could be used to confer order in the target array. In the highly studied, paradigmatic case of map formation in the retinotectal system begun with the work of Roger SPERRY over fifty years ago, every one of the logical possibilities described above has been shown to contribute to the formation of the adult map (Udin and Fawcett 1988), and unsurprisingly (given the multiplicity of mechanisms), multiple genes are required for its successful development (Karlstrom et al. 1996). The cause of such (at least conceptually) uneconomical solutions is unclear; because this is an evolved system, it could be an accretion of solutions and exaptations, spandrels on spandrels (Gould 1997). Different features of the solution come in at different developmental times, and as a whole this apparent redundancy of mechanism may be responsible for the robust nature of much of neural development.

Conversely, single mechanisms often appear in the solution to multiple developmental problems. Such a mechanism is the Hebbian, activity-dependent stabilization of the synapse. This single mechanism serves in diverse areas such as stabilization of the neuromuscular junction, refinement of topographic maps due to the correlation of firing of neighboring units in a topographic map, sorting of unlike from like inputs in such notable cases as the formation of ocular dominance columns in the VISUAL CORTEX, and basic associative learning both in development and in adulthood (Katz and Shatz 1996). A particularly interesting developmental use of this mechanism is the "retinal waves" described in the ferret where, prior to actual visual experience, the RETINA appears to generate its own highly self-correlated waves of activation that propagate through the nervous system and can initiate the various axonal sorting processes described above (Wong, Meister, and Shatz 1993). A challenge for future work is to describe how this mechanism might function in the creation of neural networks capable of detecting more complex aspects of information structure than temporal association.

The CEREBRAL CORTEX or isocortex has always commanded special attention as the structure of largest volume in the human brain, and the one most closely associated with complex cognitive skills. In this case, the principal developmental questions have been motivated by the adult functional architecture of the isocortex, a structure with a rather uniform architecture which nevertheless carries out a number of distinct and diverse functions. Is the isocortex a structure that performs some sort of standard transformation of its input, with differences in cortical areas (e.g., visual, motor, secondary sensory) arising epigenetically from interaction with the input, or are early regions in some way optimized for their future roles in adult isocortex?

Both positions capture aspects of the true state of affairs, as the following list of features of cortical development will

illustrate. The neurons of the isocortex arise from a sheet of cells in the ventricular zone that is not fully uniform in its neurochemical identity or rate of neurogenesis (reviewed in Levitt, Barbe, and Eagleson 1997). Neuroblasts migrate out on radial glial cells to the cortical plate in a well-described "inside-out" settling pattern, thus potentially retaining positional information of the ventricular zone, though considerable dispersion also occurs (Rakic 1995). The cortical plate shows some neurochemical nonuniformity before it is innervated by any outside structure (Cohen-Tannoudji, Babinet, and Wassef 1994). The innervation of cortex by the THALAMUS is extremely specific and mosaic, while by contrast, the large majority of intracortical connectivity can be accounted for by the generic rule, "connect to your two nearest neighbors" (Scannell, Blakemore, and Young 1995). The specific outputs of discrete cortical areas emerge from a generic set of intracortical and subcortical connections in mid- to late development, dependent on activity. There are several notable examples of plasticity: the isocortex can represent and transform visual input artificially induced to project to the auditory thalamus (Roe et al. 1990), and also, early transplants of one cortical area to another can accept innervation and make connections characteristic of the new area (O'Leary, Schlaggar, and Stanfield 1992). However, neither the new innervation nor the new connectivity is identical to the unaltered state.

Thus, the isocortex does not fall clearly into either the equipotential or modular description, but rather shows evidence of some early channeling of the epigenetic landscape in the context of a great deal of equipotentiality. When the isocortex first encounters the information of the external world, the separation of modalities and the topographic mapping of surfaces available already in the thalamus is preserved and available. Overall, the evolutionarily conservative primary sensory cortices show the most evidence of early morphological and connectional specialization, while those areas of frontal and parietal cortex that proliferate in the largest brains show the least. The specification of intracortical connectivity, both short- and long-range, occurs concurrent with early experience, and it seems likely that it is in this circuitry that the isocortex will represent the predictability and variability of the outside world.

Neural Networks

The study of neural networks is the study of information processing in networks of elementary numerical processors. In some cases these networks are endowed with a certain degree of biological realism and the goal is to build models that account for neurobiological data. In other cases abstract networks are studied and the goal is to develop a computational theory of highly parallel, distributed information-processing systems. In both cases the emphasis is on accounting for intelligence via the statistical and dynamic regularities of highly interconnected, large-scale networks.

Historically, neural networks arose as a number of loosely connected strands, many of which were subsequently absorbed into mainstream engineering disciplines. Some of the earliest research on neural networks (in the 1940s and 1950s) involved the study of interconnected systems of binary switches, or MCCULLOCH-PITTS neurons. This research also contributed to the development of AUTOMATA theory and dynamic systems theory. Links between these fields and neural networks continue to the present day.

Other early research efforts emphasized adaptive systems. In the 1950s and 1960s, Widrow and others studied adaptive linear systems and in particular the *LMS algorithm* (cf. SUPERVISED LEARNING IN MULTILAYER NEURAL NETWORKS). This work led to the field of adaptive signal processing and provided the basis for later extensions to nonlinear neural networks. Adaptive classifiers (systems with a discrete output variable) were also studied during the same period in the form of the "perceptron" algorithm and related schemes; these developments contributed to the development of the engineering field of PATTERN RECOGNITION, which continues to house much neural network research. Finally, efforts in the area of REINFORCEMENT LEARNING formed a strand of neural network research with strong ties to CONTROL THEORY. In the 1980s, these ties were further solidified by research establishing a link between reinforcement learning and optimal control theory, in particular the optimization technique of DYNAMIC PROGRAMMING.

Neural networks received much attention during the 1970s and 1980s, partly as a reaction against the prevailing symbolic approach to the study of intelligence in artificial intelligence (AI). Emphasizing architectures that largely dispense with centralized sequential processing and strict separation between process and data, researchers studied distributed processing in highly parallel architectures (cf. COGNITIVE MODELING, CONNECTIONIST). Intelligence was viewed in terms of mechanisms of CONSTRAINT SATISFACTION and pattern recognition rather than explicit symbol manipulation. A number of technical developments sustained research during this period, two of which stand out.

First, the dynamics of symmetrical networks (networks in which a connection from node A to node B of a given strength implies a connection from B to A of the same strength) was elucidated by the discovery of *energy functions* (see RECURRENT NETWORKS). This allowed network dynamics to be understood in terms of a (generally finite) set of *attractors,* points in the state space toward which tra-

jectories tend as the nodes in the network are updated. This gave a satisfying formal interpretation of constraint satisfaction in neural networks—as the minimization of an energy function—and provided an interesting implementation of an associative memory: the attractors are the memories.

The second important technical development was the discovery of a class of learning algorithms for general networks. The focus on learning algorithms can either be viewed as a natural outgrowth of the earlier research on adaptive algorithms for simple one-layer networks (e.g., the LMS algorithm and the perceptron), or as a necessity born of the fact that general networks are difficult to analyze and accordingly difficult to program. In any case, the algorithms have greatly extended the range of the networks that can be utilized in models and in practical applications, so much so that in AI and engineering the topic of neural networks has become essentially synonymous with the study of numerical learning algorithms.

The earliest successes were obtained with SUPERVISED LEARNING algorithms. These algorithms require an error signal at each of the output nodes of the network. The paradigm case is that of the layered *feedforward network,* a network with no feedback connections between layers and no lateral connections within a layer. Input patterns are presented at the first layer, and each subsequent layer is updated in turn, resulting in an output at the final layer. This output is compared to a desired output pattern, yielding an error signal. Algorithms differ in how they utilize this error signal, but in one way or another the error signal is propagated backward into the network to compute updates to the weights and thereby decrease the error.

A wide variety of theoretical results are available concerning neural network computation. Layered neural networks have been shown to be *universal,* in the sense of being able to represent essentially any function. *Best approximation* results are available for large classes of feedforward networks. Recurrent neural networks have been shown to be TURING-equivalent and have also been shown to be able to represent a wide class of nonlinear dynamic systems. A variety of results are also available for supervised learning in neural networks. In particular, the Vapnik-Chervonenkis (VC) dimension (a measure of the sample complexity of a learning system; see COMPUTATIONAL LEARNING THEORY and STATISTICAL LEARNING THEORY) has been computed for simple networks, and bounds on the VC dimension are available for more complex networks. In classification problems, network learning algorithms have been shown to converge to the posterior probabilities of the classes. Methods from statistical physics have been utilized to characterize learning curves. Finally, Bayesian statistical methods (see BAYESIAN LEARNING) have been exploited both for the analysis of supervised learning and for the design of new algorithms.

Recent years have seen an increase in interest in UNSUPERVISED LEARNING and a concomitant growth in interest in fully probabilistic approaches to neural network design. The unsupervised learning framework is in many ways more powerful and more general than supervised learning, requiring no error signal and no explicit designation of nodes as input nodes or output nodes. One general way to approach

the problem involves specifying a *generative model*—an explicit model of the way in which the environment is assumed to generate data. In the neural network setting, such models are generally realized in the form of a network. The learner's uncertainty about the environment is formalized by annotating the network with probabilities. The learning problem in this setting becomes the classic statistical problem of finding the best model to fit the data. The learner may either explicitly manipulate an instantiation of the generative model, or may utilize a network that is obtained by inverting the generative model (e.g., via an application of Bayes's rule). The latter network is often referred to as a *discriminative* network.

Probabilistic network models are studied in other areas of AI. In particular, BAYESIAN NETWORKS provide a general formalism for designing probabilistic networks. It is interesting to note that essentially all of the unsupervised learning architectures that have been studied in the neural network literature can be obtained by specifying a generative model in the form of a Bayesian network.

This rapprochement between neural networks and Bayesian networks has a number of important consequences that are of current research interest. First, the Bayesian network formalism makes it natural to specify and manipulate prior knowledge, an ability that eluded earlier, nonprobabilistic neural networks. By associating a generative model with a neural network, prior knowledge can be more readily incorporated and posterior knowledge more readily extracted from the network. Second, the relationship between generative models and discriminative models can be exploited, yielding architectures that utilize feedback connections and lateral connectivity. Third, the strengths of the neural network focus on LEARNING—particularly discriminative learning—and the Bayesian network focus on inference can be combined. Indeed, learning and inference can be fruitfully viewed as two sides of the same coin. Finally, the emphasis on approximation techniques and laws of large numbers that is present in the neural network literature can be transferred to the Bayesian network setting, yielding a variety of methods for approximate inference in complex Bayesian networks.

Neural Plasticity

The functional properties of neurons and the functional architecture of the CEREBRAL CORTEX are dynamic, constantly under modification by experience, expectation, and behavioral context. Associated with functional plasticity is a process of modification of circuits, either by altering the strength of a given synaptic input or by axonal sprouting and synaptogenesis. Plasticity has been seen under a number of conditions, including functional recovery following lesions of the sensory periphery of central structures, perceptual learning and learning of object associations, spatial learning, visual-motor adaptation, and context-dependent changes in receptive field properties. This discussion will compare plasticity observed early in development with that seen in adulthood, and then discuss the role of plasticity in recovery of function after lesions, in learning in sensory systems, and in visual-spatial integration.

Much of the original work on neural plasticity in the central nervous system was done in the context of experience-dependent plasticity in the period of postnatal development during which cortical connections, functional architecture, and receptive field properties continue to be refined. Hubel and Wiesel (1977) showed that in the visual system, the balance of input from the two eyes, known as ocular dominance, can be influenced by keeping one eye closed, which shifts the balance toward the open eye, or by induced strabismus (where the two eyes are aimed at different points in the visual field), which blocks the development of binocular cells. The substrate of these changes is an alteration in the extent of thalamocortical axonal arbors, which, immediately after birth, are undergoing a process of collateral sprouting and pruning. The plasticity of these arbors, of ocular dominance columns, and of the ocular dominance of receptive fields, is under experience-dependent regulation for a limited period early in the life of animals that is known as the *critical period.* The length of the critical period is species-dependent, and can extend for the first few months (cats) or years (humans and nonhuman primates) of life. After the end of the critical period the properties involved become fixed for the rest of the life of the animal.

The model of ocular dominance plasticity has been a prime example of the role of activity and of experience in the formation of the functional properties of neurons and of the refinement of connectivity between neurons. Models of cortical development have shown how spontaneous activity in utero can lead to the formation of cortical functional architecture and receptive field properties in the absence of visual experience, and prenatal patterned activity in the RETINA and cortex has been discovered. It has been shown that the effects of monocular deprivation can be prevented by blockade of

retinal activity. Some of the molecular intermediaries implicated in the competition between different populations of cortical afferents and of activity-dependent plasticity include neurotrophins and their receptors and glutamate and *N*-methyl-*d*-aspartate (NMDA) receptors. The fundamental rule underlying this plasticity, originating from work in the HIPPOCAMPUS and the ideas of HEBB, is that *neurons that fire together wire together,* and that LONG-TERM POTENTIATION is involved in the consolidation of connections.

Given this background it had been widely assumed that all cortical areas, at least those involved in early sensory processing, would have fixed properties and connections. Of course, some measure of plasticity would have to accompany the ability to acquire and store new percepts throughout life, but this had been thought to be a special property of higher-order cortical areas, particularly those in the temporal lobe, associated with object memory. A radical change has occurred in this view with the growing body of evidence that experience-dependent plasticity is a universal property of cortex, even primary sensory areas.

Each area of sensory cortex, particularly those at early stages in the sensory pathway, has a representation of the sensory surface on the cortical surface. Somatosensory cortex contains a representation of the body map (somatotopy), auditory cortex of the cochlea (tonotopy), and visual cortex of the retina (visuotopy). The integrity of these maps depends on ongoing stimulation of the periphery. Removal of input from any part of the sensory surface, such as by digit amputation or retinal lesion, leads to a reorganization of the cortical maps. Some of the initial evidence for cortical plasticity in the adult came from changes in somatotopic maps following digit amputation (see Merzenich and Sameshima 1993). Amputation of a body part or transection of a sensory nerve causes the area of cortex initially representing that part to be remapped toward a representation of the adjacent body parts. Retinal lesions lead to a shrinkage of the cortical representation of the lesioned part of retina and an expansion in the representation of the part of retina surrounding the lesion.

The mechanism of the reorganization varies with the sensory pathways involved. Generally, the site of reorganization depends on the existence of exuberant connections linking cells representing widely separated parts of the map. Thus, in the somatosensory system, a measure of lesion-induced plasticity can be observed in the spinal cord, although it is likely that a considerable degree of plasticity is based in the somatosensory cortex. In the plasticity observed in the visual system, most of the changes are intrinsic to the visual cortex, and are likely to involve the long-range horizontal connections formed by cortical pyramidal cells. The unmasking of these connections seen with long-term topographic reorganization involves a sprouting of axonal collaterals and synaptogenesis.

There is a wide range of time scales over which the plasticity of topography takes place. The changes occurring over the largest spatial scales in cortex (topographic shifts of up to a centimeter) require several months or years. Smaller but significant changes can be seen within minutes following a lesion, and this is likely to involve changes in the strength of existing connections. Exuberant connections can be unmasked by a potentiation of excitatory connections or by a suppression of inhibitory connections.

The perceptual consequences of lesion-induced plasticity can include, depending on the site of the lesion, a recovery of function or perceptual distortions. PHANTOM LIMB sensation following limb amputation has been linked by Ramachandran (1993) to experimentally induced somatosensory cortical plasticity. For arm amputations, there is often a sensation of stimulation of the absent hand when stroking the limb stump or the cheek. Human patients suffering a loss of central retinal input (by, e.g., age-related macular degeneration) often adopt a preferred retinal locus in the intact retina for targeting visually guided eye movements. Lesions in area MT, an area that plays a role in the perception of movement and the tracking of moving objects by the eyes, initially leads to a loss of smooth pursuit eye movements, but within a few days this function recovers. It is well known that following stroke there are varying degrees of functional recovery. Though this recovery had been thought to involve a return to health of metabolically compromised but not destroyed tissue, it may well be that intact areas of cortex are taking over the function of adjacent cortical regions that have been destroyed.

The mechanisms available to the cortex for functional recovery following lesions are likely to be used for normal sensory processing. It is likely that perceptual learning involves analogous changes in cortical topography. LEARNING in general has been divided into categories including declarative or explicit learning (including the learning of events, facts, and objects) and nondeclarative or implicit learning (including procedural, classical CONDITIONING, priming, and perceptual learning). These different forms of learning may be distinguished less on the basis of the underlying synaptic mechanisms than on the brain region in which the memory is stored. While one ordinarily associates sensory learning with the acquisition and storage of complex percepts and with the temporal lobe, it has been known for well over a hundred years that it is possible to improve one's ability to discriminate simple sensory attributes. Some characteristics of perceptual learning are suggestive of the involvement of early stages in sensory processing.

Perceptual learning has been shown to apply to a wide range of sensory tasks, including visual acuity, hue discrimination, velocity estimation, acoustic pitch discrimination, and two-point somatosensory acuity. This is a form of implicit learning, generally not reaching conscious awareness or requiring error feedback, but is associated with repetitively performing discrimination tasks.

The evidence supporting the idea that the neural substrate for perceptual learning is found in primary sensory cortex comes from the specificity of the learning and from physiological studies demonstrating cortical changes in animals trained on simple discrimination tasks. Improvement in a visual discrimination task at one position in the visual field, for example, does not transfer to other locations. Since the highest spatial resolution is seen in primary visual cortex, where the receptive fields are the smallest and the topography most highly ordered, one might expect to find the basis for specificity there. The learning also shows no transfer to orthogonal orientations, again indicative of early

cortical stages where selectivity for stimulus orientation is sharpest. On the other hand, the learning is also specific for stimulus configuration or the context within which a feature is embedded during the training period, which may point toward a feedback influence from higher-order cortical areas providing information about more complex features.

The physiological studies show changes in cortical magnification factor, or cortical recruitment, associated with training. Training a monkey to do a texture discrimination task with a particular digit will increase the area of primary somatosensory cortex representing that digit. Similarly, it has been suggested that training on an auditory frequency discrimination task increases the representation of that frequency in primary auditory cortex. Not only these forms of implicit learning but associative learning as well causes changes in the receptive fields of cells in primary sensory cortex. When a tone is associated with an aversive stimulus, cells in auditory cortex tend to shift their critical frequency toward that of the tone. The reward component of the training may come from basal forebrain structures, involving the diffuse ascending cholinergic input to cortex.

The storage of more complex information has been identified in the inferior temporal cortex. There, animals trained to recognize complex forms, particularly in association with other forms, have cells that showed elevated activity when a given form is presented. The acquisition of the trained information may depend on input from more medial structures, such as the perirhinal cortex.

A central focus for studies of neural plasticity is the hippocampus. As a consequence of neuropsychological findings showing that persons with medial temporal lesions suffer an inability to acquire and store recent memories, the hippocampus has been an active area of study for neural mechanisms of MEMORY. At the systems level, the hippocampus was shown by O'Keefe (1976) to play a role in spatial learning, with cells being tuned for an animal's position in its external environment, known as a *place field.* At the synaptic level, the hippocampus has become the prime model for changes in synaptic weight, through the phenomenon of long-term potentiation originally described by Bliss and Lomo (1973), and long-term depression. While it has been presumed that these forms of synaptic plasticity account for the storage of complex information in the hippocampus, the linkage has not yet been established. It is clear, however, that cells in the hippocampus are capable of rapidly changing their place fields as the external environment is altered, and this alteration is associated with changes in effective connectivity between hippocampal neurons.

The functional properties of cells in cerebral cortex and in brain stem have been shown to be modifiable over much shorter time scales, potentially involving neural plasticity in the ongoing processing of sensory information and in sensorimotor integration.

One of the earliest and most active areas of investigation of adult plasticity is the vestibulo-ocular reflex, the compensatory movement of the eyes associated with rotation of the head or body to keep the visual field stabilized on the retina. Melville-Jones and Gonshor (1975) found that if prisms are put on the eyes to reduce the amount of retinal slip associated with a given amount of head rotation, the *gain* of the reflex is reduced, and eventually settles to a level where once again the world is stabilized on the eyes. Various brain structures have been suggested to be involved in this phenomenon, including the CEREBELLUM and pontine nuclei. Another revealing model of sensorimotor adaptation has been studied in the owl by Knudsen and Brainard (1995). In the tectum of the owl (analogous to the mammalian superior colliculus), there are superimposed maps of visual and auditory space. When prisms are placed over the owl's eyes, shifting the visual map, there is a compensatory shift of the auditory map, so that once again there is a registration between the two maps for a given elevation and azimuth in the external world. This enables the owl to make accurate targeting movements for catching prey, as detected by both visual and sound cues.

Within sensory cortex, rapid changes in receptive field properties have been associated with perceptual fill-in. When an occluder, or *artificial scotoma,* is placed within a background of a uniform color or a textured pattern, and when this stimulus is stabilized on the retina, the occluder disappears over a few seconds, becoming filled with the surrounding pattern. It is supposed that this phenomenon may be a manifestation of the process of linkage and segmentation of the visual scene into contours and surfaces belonging to particular objects. At the cellular level, at several stages in the visual pathway, cells tend to change their response properties when their receptive fields are placed within the artificial scotoma. Assuming that each cell represents a line label signaling, when active, the presence of a feature centered within its receptive field, the response of a cell whose receptive field is centered within the artificial scotoma is interpreted by the visual system as a shift of stimulus features toward its center.

A growing body of evidence reveals a remarkable degree of mutability of function in primary sensory cortex that is not limited to the first months of life but extends throughout adulthood. It is becoming increasingly clear that rather than performing a fixed and stereotyped calculation on their input, cells in all cortical areas represent active filters. Various components of cortical circuitry have been implicated as the likely source of the changes, including intrinsic horizontal connections and feedback connections from higher-order cortical areas. Neural plasticity serves a wide variety of functional roles, and the extent to which it plays a role in the ongoing processing of sensory information depends on the rapidity with which cells can alter their response properties. To date, it has been shown that substantial changes can be induced within seconds of exposure to novel stimuli. It remains to be seen whether even shorter-term modifications of cortical circuits and receptive field properties may underlie the recognition of objects as the eyes move from saccade to saccade.

Neural Synchrony

See BINDING BY NEURAL SYNCHRONY

Neuroendocrinology

Neuroendocrinology studies the relationships between the endocrine system and the brain. The endocrine system produces a variety of hormones, which are chemical messengers that signal changes that the body needs to make to adapt to new situations. The brain controls the endocrine system through the hypothalamus and pituitary gland, and the secretions of the gonads, adrenals, and thyroid act on tissues throughout the body, and on the brain and pituitary, to produce a wide variety of effects. Some hormone effects occur during development and are generally long lasting and even permanent for the life of the individual. Other hormone actions take place in the mature nervous system and are usually reversible. Still other hormone actions in adult life are related to permanent changes in brain function associated with disease processes or with aging.

Nerve cells in the hypothalamus produce hormones, called releasing factors, which are released into a portal blood supply and travel to the anterior pituitary gland where they trigger the release of trophic hormones such as adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone

(TSH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin, and growth hormone. These hormones, in turn, regulate endocrine responses—for example, ACTH stimulates glucocorticoid secretion by the adrenal cortex; TSH, thyroid hormone secretion; and LH, sex hormone production. Other hypothalamic neurons produce the hormones vasopressin and oxytocin and release these hormones at nerve terminals located in the posterior lobe of the pituitary gland. Brain activity stimulates the secretion of these hormones; for example, oxytocin and prolactin release are stimulated by suckling, and the sight and sound of an infant can stimulate "milk letdown" in the mother; ACTH is driven by stressful experiences and by an internal clock in the brain that is entrained by the light-dark cycle; and LH and FSH secretion are influenced by season of the year in some animals.

Thyroid hormone and sex hormones act early in life to regulate development and differentiation of the brain, whereas the activity of the stress hormone axis is programmed by early experiences via mechanisms which may depend to some degree on the actions of glucocorticoid hormones.

For thyroid hormone, both excesses and deficiencies of thyroid hormone secretion are associated with altered brain development; extremes in thyroid hormone secretion lead to major deficiencies in cognitive function (e.g., cretinism), whereas smaller deviations in thyroid hormone secretion are linked to more subtle individual variations in brain function and cognitive activity.

For sex hormones, the story is more complicated in that testosterone secretion during midgestation in the human male and then again during the first two years of postnatal life alters brain development and affects cognitive function as well as reproductive function. There are comparable periods of testosterone production in early development in other mammals. Absence of testosterone in females leads to the female behavioral and body phenotype; and absence of androgen receptors or the lack of normal androgen secretion in genetic males leads to a feminine phenotype, whereas exposure of genetic females to androgens early in development produces a masculine phenotype. Sexual differentiation of the brain has been investigated in animals, and there are subtle sex differences in a variety of brain structures, ranging from the hypothalamus (which governs reproduction) to the HIPPOCAMPUS and CEREBRAL CORTEX (which subserve cognitive function). There are also indications for structural and functional sex differences in the human brain that are similar to those found in lower animals. For example, in both animals and humans, sex differences are found in the strategies used for spatial learning and memory, with males using the more global spatial cues and females relying upon local contextual cues.

For stress hormones, early experience has a profound role in shaping the reactivity of the stress hormone axis and the secretion not only of ACTH and glucocorticoids but also the activity of the autonomic nervous system. Prenatal stress and certain types of aversive experience in infant rodents (e.g., several hours of separation from the mother) increase reactivity of the stress hormone axis for the lifetime of the individual. In contrast, handling of newborn rat pups (a much briefer form of separation of the pup from the mother)

produces a lifelong reduction in activity of the stress hormone axis. Actions of glucocorticoid and thyroid hormones play a role in these effects. There is growing evidence that for rodents elevated stress hormone activity over a lifetime increases the rate of brain aging, whereas a lifetime of reduced stress hormone activity reduces the rate of brain aging (see below).

Whereas the developmental actions of hormones on the brain are confined to windows of early development during fetal and neonatal life and the peripubertal period, these same hormones produce reversible effects on brain structure and function throughout the life of the mature nervous system. Sex hormones activate reproductive behaviors, including defense of territory, courtship, and mating, and they regulate neuroendocrine function to ensure successful reproduction; however, reflecting sexual differentiation of the brain and secondary sex characteristics of the body, the activational effects of sex hormones in adult life are often gender-specific.

Thyroid hormone actions maintain normal neuronal excitability and promote a normal range of nerve cell structure and function; excesses or insufficiencies of thyroid hormone have adverse effects on brain function and cognition, which are largely reversible. Among these effects are exacerbation of depressive illness.

There are two types of adrenal steroids—mineralocorticoids and glucocorticoids—which regulate salt intake and food intake, respectively, and also modulate metabolic and cognitive function during the diurnal cycle of activity and rest. Adrenal steroids act to maintain homeostasis and glucocorticoids do so in part by opposing, or containing, the actions of other neural systems that are activated by stress and also by promoting adaptation of the brain to repeatedly stressful experiences. Containment effects of glucocorticoids oppose stress-induced activity of the noradrenergic arousal system and the hypothalamic system that releases ACTH from the pituitary. Adaptational effects of stress hormones during prolonged or repeated stress increase or decrease neurochemicals related to brain excitability and neurotransmission and produce changes in neuronal structure. Adrenal steroids biphasically modulate LONG-TERM POTENTIATION (LTP) in the hippocampus, with high levels of stress hormones also promoting long-term depression (LTD). LTP and LTD may be involved in learning and memory mechanisms.

Primary targets of stress hormones are the hippocampal formation and also the AMYGDALA. Repeated stress causes atrophy of hippocampal pyramidal neurons and inhibits the replacement of neurons of the dentate gyrus by cognitive function, enhancing episodic and declarative memory at low to moderate levels but inhibiting these same functions at high levels or after acute stress. Along with adrenal steroids, the sympathetic nervous system participates in creating the powerful memories associated with traumatic events, in which the amygdala plays an important role. Glucocorticoid hormones act in both the amygdala and hippocampus to promote consolidation.

Steroid hormones and thyroid hormone act on cells throughout the body via intracellular receptors that regulate gene expression. Such intracellular receptors are found het-erogeneously distributed in the brain, with each hormone having a unique regional pattern of localization across brain regions. The hypothalamus and amygdala have receptors for sex hormones, with both sexes expressing receptors for androgens, estrogens, and progestins, although, because of sexual differentiation, there are somewhat different amounts of these receptors expressed in male and female brains. The hippocampus and amygdala have receptors for adrenal steroids, whereas thyroid hormone receptors are widely distributed throughout the nervous system, particularly in the forebrain and CEREBELLUM.

Effects mediated by intracellular receptors are generally slow in onset over minutes to hours and long-lasting because alterations in gene expression produce effects on cells that can last for hours and days, or longer. Steroid hormones also produce rapid effects on the membranes of many brain cells via cell surface receptors that are like the receptors for neurotransmitters. These actions are rapid in onset and short in duration. However, the precise nature of the receptors for these rapid effects is in most cases largely unknown.

Hormones participate in many disease processes, in some cases as protectors and in other cases as promoters of abnormal function. Adrenal steroids exacerbate neural damage from strokes and seizures and mediate damaging effects of severe and prolonged stress. Estrogens enhance normal declarative and episodic memory in estrogen-deficient women, and estrogen replacement therapy appears to reduce the risk of Alzheimer's disease in postmenopausal women. Estrogens also have antidepressant effects; they modulate pain mechanisms; and they regulate the neural pathways involved in movement, with the result that estrogens enhance performance of fine motor skills and enhance reaction times in a driving simulation test in women. Androgen effects are less well studied in these regards.

Age-related decline of gonadal function reduces the beneficial and protective actions of these hormones on brain function. At the same time, age-related increases in adrenal steroid activity promote age-related changes in brain cells that can culminate in neuronal damage or cell death. Lifelong patterns of adrenocortical function, determined by early experience (see above), contribute to rates of brain aging, at least in experimental animals.

Hormones are mediators of change, acting in large part by modulating expression of the genetic code, and they provide an interface between experiences of the individual and the structure and function of the brain, as well as other organs of the body. Hormone action during development and in adult life participates in the processes that determine individual differences in physiology, behavior, and cognitive function.

Neuroimaging

Neuron

The neuron is the main type of cell in the nervous system that, in association with neuroglial cells, mediates the information processing that underlies nervous function. As the main building block of the brain, the nerve cell is fundamental to the neural basis of cognitive abilities. Much of the research in contemporary neuroscience focuses on neuronal structure, function, and pharmacology, using modern techniques of molecular and cell biology. Based on these results, computational models of neurons and neuronal circuits are being constructed to provide increasingly powerful insights into how the brain mediates cognitive functions.

In their speculations on the mind, the ancients knew nothing of cells or neurons, nor did DESCARTES, Locke, or KANT, or any other scientist or natural philosopher until the nineteenth century. The first step toward this understanding was the cell theory of Schwann, in 1839, which stated that all body organs and tissues are composed of individual cells. A nerve cell was recognized to consist of three main parts: the cell body (soma), containing the nucleus; short processes (dendrites); and a single long process (axon) that connects to the dendrites or somata of other nerve cells within the region or of cells in other regions. However, the branches of dendrites and axons could not be clearly visualized, leading to the belief among some workers that nerve cells are different from other cells in that their finest branches form a continuous functional network (called the reticular theory). It was also recognized that numerous non-neuronal cells, called neuroglia, surround the neurons and contribute to their functions.

Led by Ramón y CAJAL, neuroanatomists in the 1880s and 1890s, using the GOLGI stain, showed that most regions of the brain contain several distinctive types of nerve cell with specific axonal and dendritic branching patterns. Dendrites and axons were found not to be continuous, so that the nerve cell belongs under the cell theory, as summarized in the neuron doctrine. How then are signals transferred between neurons? Sherrington in 1897 suggested that this occurs by means of specialized junctions which he termed *synapses*. Electron microscopists in the 1950s showed that such contacts between neurons exist. Since that time, neuroanatomists have elucidated the ultrastructure of the synapse as well as

the patterns of synaptic connections between the different types of neurons. The patterns of connections within a region are called canonical circuits, mediating the main types of information processing within each region. Neurons and their canonical circuits are organized at the next higher level into neural modules, such as the columns found in the CERE-BRAL CORTEX (see also VISUAL CORTEX). At a still higher organization level, the patterns of neuronal connections between regions are called distributed circuits, which constitute the pathways and systems underlying behavior (e.g., see VISUAL ANATOMY AND PHYSIOLOGY).

Physiological studies of neuron properties have paralleled these anatomical developments. The axon generates a nerve impulse (action potential), a wave of depolarization of the surface membrane, which propagates rapidly along the membrane from its site of initiation (the axon hillock) to the axon terminals. Already in 1850 a finite rate of propagation (approximately 100 m per second in the largest axons) was established; this overturned the historical assumption of a mysterious instantaneous "nervous force" underlying the mind.

In the 1950s a slower potential (synaptic potential) was discovered by Katz at the synapse. It was found that an action potential invading a synapse causes it to secrete small vesicles containing a chemical neurotransmitter, which diffuses across the cleft from the presynaptic to the postsynaptic cell. There it acts on a membrane receptor to bring about an opening of membrane channels; this lets electrically charged ions flow across the membrane to change the membrane potential of the postsynaptic site. Membrane proteins that contain both receptor sites and ionic channels are called ionotropic receptors. Depending on which ions flow, the membrane may be depolarized (excitatory postsynaptic potential, EPSP) or hyperpolarized (inhibitory postsynaptic potential, IPSP). Among the cells of the body, chemical synapses are unique to neurons. Thus the study of synapses lies at the heart of the study of brain function at the neuronal level. In addition to these chemical synapses, neurons, like other cells, may be interconnected by gap junctions (electrical synapses), which permit electric currents and small molecules to pass directly between cells. These also connect neuroglial cells, and are especially prevalent during development.

Knowledge of NEUROTRANSMITTERS and how they generate EPSPs and IPSPs began with the study of the autonomic nervous system around 1900. The first neurotransmitter to be identified was acetylcholine, shown by Loewi in the 1920s to mediate the slow action of the vagus nerve in slowing the heart rate, and by Katz in the 1950s to mediate the rapid action of motor nerves in exciting skeletal muscles. Cannon in the 1920s established epinephrine (Adrenaline) as the neurohormone mediating "flight-or-fight" responses, and other biogenic amines acting on autonomic organs were revealed in the 1930s. The introduction of the neuroleptics chlorpromazine and reserpine for the treatment of schizophrenia in the 1950s shifted interest in the pharmacology of neurotransmitters to the central nervous system. The resultant growth of the field of psychopharmacology has generated mechanistic hypotheses for all the major mental disorders. For example, a common action of neuroleptic (antipsychotic) drugs is a blockade of D2 receptors at dopaminergic synapses. And current research on antidepressant drugs is focused on their ability to act as selective serotonin reuptake inhibitors (SSRIs).

Many of the neurotransmitters can activate not only ionotropic receptors but also metabotropic receptors coupled to second messenger systems, which then phosphorylate target proteins or bring about other slower metabolic changes in the postsynaptic neuron (and also can act back on the presynaptic terminal as well). Acetylcholine acting on the heart and epinephrine acting as a hormone are examples, as are a wide range of neuropeptides. These include such molecules as hypothalamic factors (e.g., luteinizing hormone–releasing hormone, corticotropin), opioids (e.g., enkephalins and endorphins), and numerous types found also in the gut and other organs (vasoactive intestinal polypeptide, cholecystokinin, substance P, etc.; see NEUROENDOCRINOLOGY). These molecules, acting as neuromodulators, set behavioral states (e.g., the role of acetylcholine, norepinephrine, and serotonin in waking, sleeping, and levels of consciousness, or the role of neuropeptide Y in feeding behavior and anxiety and stress responses). Another role is in learning and memory; LONG-TERM POTENTIATION (LTP) and long-term depression (LTD) of synaptic responses involve second messengers, calcium, and cyclic nucleotides, and actions on the genome that may implement associative (Hebbian) learning. These latter actions overlap with the activation of receptors controlling growth and differentiation during development.

In summary, a better understanding of the effects of neurotransmitters and neuromodulators on different types of neurons and neuronal circuits is the necessary foundation for an understanding of normal cognition and changes underlying psychotic states.

Analysis of neuronal function has been aided enormously by the development of modern techniques. With the advent of DNA engineering in the 1970s, the molecular basis of neuronal structure and function is being increasingly elucidated. Modern physiological research employs a variety of methods in analyzing neuronal function. These include single- and multiple-neuron recordings in awake behaving animals (SINGLE-NEURON RECORDING); patch pipette recordings from neurons in slices taken from different brain regions (this includes slices of human cerebral cortex in tissue obtained in operations for relief of chronic epilepsy); patch recordings of single membrane channels in isolated cells grown in tissue culture; and different types of functional imaging (including movement of calcium ions, glucose uptake, and voltage-sensitive dyes). A long-term goal is to relate these changes at the neuronal level to changes in blood flow revealed by brain imaging methods (POSITRON EMISSION TOMOGRAPHY, functional MAGNETIC RESONANCE IMAGING, fMRI) at the systems level. This will enable an integrated view of neuronal function and the neural basis of cognition and cognitive disorders to begin to emerge. Databases to support this effort are becoming available on the World Wide Web. Examples are membrane receptors and channels (www.le.ac.uk/csn), canonical neurons and their compartmental models (http://senselab.med.yale.edu/neuron), and brain scans (human brain project).

Experimental approaches to the study of the neuron are being greatly aided by the development of computer models

and the emergence of the new field of COMPUTATIONAL NEUROSCIENCE. This began in the 1950s with the pioneering model of the axonal action potential by Hodgkin and Huxley. In the 1960s Rall showed that complex dendritic trees could be modeled as chains of compartments incorporating properties representing action potentials and synaptic potentials. With the rise of powerful modern desktop computers it is now possible for neuroscientists to construct increasingly accurate models of different types of neurons to aid them in analyzing the neural basis of function of a given neuron in a given region. This work is reported in mainstream neuroscience journals as well as in new journals such as *Neural Computation* and the *Journal of Computational Neuroscience.* In contrast to this approach, connectionist networks reduce the soma and dendrite of a neuron to a single node, thereby excluding most of the interesting properties of neurons as summarized above. A merging of neuron-based compartmental models with NEURAL NETWORKS will therefore be welcome, because it will provide insights into how real brains actually carry out their system functions in mediating cognitive behavior. It is not unreasonable to expect that this will also provide the philosophical foundation for a more profound functional explanation of the relation between the brain and the mind.

Neurotransmitters

Neurotransmitters are chemicals made by neurons and used by them to transmit signals to other neurons or non-neuronal cells (e.g., skeletal muscle, myocardium, pineal glandular cells) that they innervate. The neurotransmitters produce their effects by being released into synapses when their neuron of origin fires (i.e., becomes depolarized) and then attaching to receptors in the membrane of the postsynaptic cells. This causes changes in the fluxes of particular ions across that membrane, making cells more likely to become depolarized if the neurotransmitter happens to be excitatory, or less likely if it is inhibitory. Neurotransmitters can also produce their effects by modulating the production of other signal-transducing molecules (second messengers) in the postsynaptic cells (Cooper, Bloom, and Roth 1996). Nine compounds—belonging to three chemical families—are generally believed to function as neurotransmitters some-

where in the central nervous system (CNS) or periphery. In addition, certain other body chemicals, for example, adenosine, histamine, enkephalins, endorphins, and epinephrine, have neurotransmitter-like properties, and many additional true neurotransmitters may await discovery.

The first of these families, and the group about which most is known, are the amine neurotransmitters, a group of compounds containing a nitrogen molecule that is not part of a ring structure. Among the amine neurotransmitters are acetylcholine, norepinephrine, dopamine, and serotonin. *Acetylcholine* is possibly the most widely used neurotransmitter in the body, and all axons that leave the CNS (e.g., those running to skeletal muscle, or to sympathetic or parasympathetic ganglia) use acetylcholine as their neurotransmitter. Within the brain, acetylcholine is the transmitter of, among other neurons, those generating the tracts that run from the septum to the HIPPOCAMPUS, and from the nucleus basalis to the CEREBRAL CORTEX—both of which seem to be needed to sustain memory and learning. It is also the neurotransmitter released by short-axon interneurons of the BASAL GANGLIA. *Norepinephrine* is the neurotransmitter released by sympathetic nerves (e.g., those innervating the heart and blood vessels) and, within the brain, those of the locus ceruleus, a nucleus activated in the process of focusing attention. *Dopamine* and *serotonin* apparently are neurotransmitters only within the CNS. Some dopaminergic (i.e., dopamine-releasing) neurons run from the substantia nigra to the corpus striatum; their loss gives rise to the clinical manifestations of Parkinson's disease (Korczyn 1994); others, involved in the rewarding effects of drugs and natural stimuli, run from the mesencephalon to the nucleus accumbens. Dopaminergic neurons involved in the actions of most antipsychotic drugs (which antagonize the effects of dopamine on its receptors) run from the brain stem to limbic cortical structures in the frontal region, while the dopamine released from hypothalamic cells travels via a private blood supply, the pituitary portal vascular system, to the anterior pituitary gland, where it tonically suppresses release of the hormone prolactin. (Drugs that interfere with the release or actions of this dopamine can cause lactation as a side effect, even in men.)

The cell bodies, or perikarya, of serotoninergic (serotonin-releasing) neurons reside in the brain stem; their axons can descend in the spinal cord (where they "gate" incoming sensory inputs and also decrease sympathetic nervous outflow, thus lowering blood pressure) or ascend to other parts of the brain. Within the brain such serotoninergic nerve terminals are found in virtually all regions, enabling this transmitter to modulate a wide variety of behavioral and nonbehavioral functions, including, among others, mood, sleep, total food intake and macronutrient (carbohydrate vs. protein) selection (Wurtman and Wurtman 1989), aggressive behaviors, and PAIN sensitivity (Frazer, Molinoff, and Winokur 1994). Brains of women produce only about two thirds as much serotonin as those of men (Nishizawa et al. 1997); this may explain their greater vulnerability to serotonin-related diseases like depression and obesity. Within the pineal gland serotonin is also the precursor of the sleep-inducing hormone melatonin (Dollins et al. 1994).

The second neurotransmitter family includes amino acids, compounds that contain both an amino group (NH_2) and a carboxylic acid group (COOH) and which are also the building blocks of peptides and proteins. The amino acids known to serve as neurotransmitters are glycine, and glutamic and aspartic acids, present in all proteins, and γ-aminobutyric acid (GABA), produced only in brain neurons. Glutamic acid and GABA are the most abundant neurotransmitters within the CNS, particularly in the cerebral cortex; glutamic acid tends to be excitatory and GABA inhibitory. Aspartic acid and glycine subserve these functions in the spinal cord (Cooper et al. 1996).

The third neurotransmitter family is composed of peptides, compounds that contain at least two and sometimes as many as 100 amino acids. Peptide neurotransmitters are poorly understood: evidence that they are, in fact, transmitters tends to be incomplete and restricted to their location within nerve terminals and to the physiological effects produced when they are applied to neurons. Probably the best understood peptide neurotransmitter is substance P, a compound that transmits signals generated by pain.

In general each neuron uses only a single compound as its neurotransmitter. However some neurons contain both an amine and a peptide and may release both into synapses. Moreover, many neurons release adenosine, an inhibitory compound, along with their "true" transmitter, for instance, norepinephrine or acetylcholine. The stimulant effect of caffeine results from its ability to block receptors for this adenosine.

Neurotransmitters are manufactured from circulating precursor compounds like amino acids, glucose, and the dietary amine choline. Neurons modify the structure of these precursor compounds through a series of enzymatic reactions that often are limited not by the amount of enzyme present but by the concentration of the precursor, which can change, for example, as a consequence of eating (Wurtman 1988). Neurotransmitters that come from amino acids include serotonin, which is derived from tryptophan; dopamine and norepinephrine, which are derived from tyrosine; and glycine, which is derived from threonine. Among the neurotransmitters made from glucose are glutamate, aspartate, and GABA. Choline serves as the precursor of acetylcholine.

Once released into the synapse, each neurotransmitter combines chemically with one or more highly specific receptors; these are protein molecules which are embedded in the postsynaptic membrane. As noted above, this interaction can affect the electrical properties of the postsynaptic cell, its chemical properties, or both. When a NEURON is in its resting state, it sustains a voltage of about –70 mV as the consequence of differences between the concentrations of certain ions at the internal and external sides of its bounding membrane. Excitatory neurotransmitters either open protein-lined channels in this membrane, allowing extracellular ions, like sodium, to move into the cell, or close channels for potassium. This raises the neuron's voltage toward zero, and makes it more likely that—if enough such receptors are occupied—the cell will become depolarized. If the postsynaptic cell happens also to be a neuron (i.e., as opposed to a muscle cell), this depolarization will cause it to release its own neurotransmitter from its terminals. Inhibitory neurotransmitters like GABA activate receptors that cause other ions—usually chloride—to pass through the membrane; this usually hyperpolarizes the postsynaptic cell, and decreases the likelihood that it will become depolarized. (The neurotransmitter glutamic acid, acting via its *N*-methyl-*d*-aspartate (NMDA) receptor, can also open channels for calcium ions. Some investigators believe that excessive activation of these receptors in neurological diseases can cause toxic quantities of calcium to enter the cells and kill them.)

If the postsynaptic cell is a muscle cell rather than a neuron, an excitatory neurotransmitter will cause the muscle to contract. If the postsynaptic cell is a glandular cell, an excitatory neurotransmitter will cause the cell to secrete its contents.

While most neurotransmitters interact with their receptors to change the voltage of postsynaptic cells, some neurotransmitter interactions, involving a different type of receptor, modify the chemical composition of the postsynaptic cell by either causing or blocking the formation of second messenger molecules. These second messengers regulate many of the postsynaptic cell's biochemical processes, including gene expression; they generally produce their effects by activating enzymes that add high-energy phosphate groups to specific cellular proteins. Examples of second messengers formed within the postsynaptic cell include cyclic adenosine monophosphate, diacylglycerol, and inositol phosphates. Once neurotransmitters have been secreted into synapses and have acted on their receptors, they are cleared from the synapse either by enzymatic breakdown—for example, acetylcholine, which is converted by the enzyme acetylcholinesterase to choline and acetate, neither of which has neurotransmitter activity—or, for neurotransmitters like dopamine, serotonin, and GABA, by a physical process called *reuptake*. In reuptake, a protein in the presynaptic membrane acts as a sort of sponge, causing the neurotransmitter molecules to reenter their neuron of origin, where they can be broken down by other enzymes (e.g., monoamine oxidase, in dopaminergic, serotoninergic, or noradrenergic neurons) or repackaged for reuse.

As indicated above, particular neurotransmitters are now known to be involved in many neurological and behavioral disorders. For example, in Alzheimer's disease, whose victims exhibit loss of intellectual capacity (particularly short-term memory), disintegration of personality, mental confusion, hallucinations, and aggressive—even violent—behaviors, many families of neurons, utilizing many neurotransmitters, die (Wurtman et al. 1996). However, the most heavily damaged family seems to be the long-axon acetylcholine-releasing neurons, originating in the septum and the nucleus basalis, which innervate the hippocampal and cerebral cortices. Acetylcholinesterase inhibitors, which increase brain levels of acetylcholine, can improve short-term memory, albeit transiently, in some Alzheimer's disease patients.

Most drugs—therapeutic or recreational—that affect brain and behavior do so by acting at synapses to affect the production, release, effects on receptors, or inactivation of neurotransmitter molecules (Bernstein 1988). Such drugs can also constitute important and specific probes for understanding cognition and other brain functions.

Newell, Allen

Allen Newell (1927–1992), cognitive psychologist and
computer scientist, made profound contributions to fields
ranging from computer architecture and programming soft-
ware to artificial intelligence, cognitive science, and psy-
chology. One of the founding fathers of the new domains of
artificial intelligence and cognitive science, his work con-
tinues to exercise a major influence on these developing
fields.

Newell was born on March 19, 1927, in San Francisco,
the son of Dr. Robert R. Newell, a distinguished radiologist
on the faculty of the Stanford Medical School, and Jeanette
LeValley Newell. He attended San Francisco public schools,
and served in the Navy after World War II, assisting in map-
ping radiation intensities at the Eniwetok A-bomb tests, an
experience that awoke his interest in science. In 1949, he
received a B.S. degree in Physics at Stanford, then spent a
postgraduate year studying mathematics at Princeton Uni-
versity. A desire to learn more about applications domains
led him to a position studying logistics and air defense orga-
nization at Rand in Santa Monica, a "think tank" supported
by the U.S. Air Force, and gave him early contact with the
then emerging electronic digital computers.

At almost the beginning of the computer era, Newell, col-
laborating with J. C. Shaw and H. A. Simon, conceived that
computers might solve problems, non-numerical or numeri-
cal, by selective HEURISTIC SEARCH, as people do. Needing
programming languages that would provide flexible memory
structures, they invented list processing languages (or Infor-
mation Processing Languages, IPLs) in 1956. Today, list pro-
cessing is an indispensable tool for artificial intelligence and
computer science, central to such widely used languages as
LISP and OPS5, and providing a basis for structured pro-
gramming.

The research continued at Carnegie Institute of Technol-
ogy (after 1965, Carnegie Mellon University), where New-
ell enrolled in 1955 to pursue a Ph.D. in Industrial
Administration, with a thesis—probably the first—in artifi-
cial intelligence. Over the next few years, Newell and his
associates at Rand and Carnegie used the IPLs to create the
first artificial intelligence programs, including the Logic
Theorist (1956), the General Problem Solver (1959), and the
NSS chess program (1958), introducing fundamental ideas
that are still at the core of PROBLEM SOLVING theory, includ-
ing means-ends analysis and PLANNING. To test how well
these simulations accounted for human problem solving, the
group used thinking-aloud protocols. Newell received his
doctorate in 1958, joined the faculty of Carnegie Tech in
1961 as a full professor, and retained this position for the
remaining three decades of his life.

In 1972, Newell and Simon summarized their psychologi-
cal research, which employed verbal protocols and computer
simulation, in their book *Human Problem Solving.* Recog-
nizing the potential of PRODUCTION SYSTEMS (programs con-
sisting of condition-action statements, employed in most AI
programs and expert systems), in 1981, Newell designed the
language OPS5.

To generalize psychological simulations and endow them
with a more realistic control structure, Newell's research
focused increasingly on devising a powerful and veridical
cognitive architecture that would provide a framework for
general cognitive theories. A major product of this work
was the Soar system, developed with Paul Rosenbloom and
John Laird, a substantial extension of GPS that operates in
multiple problem spaces and has powerful learning capabil-
ities. Dozens of investigators are now using Soar as the
architecture for intelligent systems, both simulations of
human thinking and expert systems for AI. Soar and the
future of unified theories were the subject of Newell's last
book, *Unified Theories of Cognition* (1990), based on his
William James Lectures at Harvard.

Apart from the Soar research, much of Newell's produc-
tive effort went into what he called his "diversions," which
almost all produced important contributions to cognitive sci-
ence. These included investigations with Gordon Bell of
computer architectures, reported in *Computer Structures*
(1971), and participation in a team at CMU designing paral-
lel computer architectures. He also served as chair of the
committee that monitored the research in computer SPEECH
RECOGNITION sponsored by the Defense Department's
Advanced Research Projects Agency (ARPA). Yet another
"diversion" was research with Card and Moran (*The Psy-
chology of Human-Computer Interaction,* 1983) that rein-
vigorated human factors studies, extending them to complex
cognitive processes.

In addition to his scientific work, Newell provided leadership in such organizations as the American Association for Artificial Intelligence, and the Cognitive Science Society (serving as president of both), and he provided advice to agencies of the national government. He played a leading role in creating and developing the School of Computer Science at Carnegie Mellon University and the innovations in computing and electronic networking of its campus.

For his scientific and professional contributions, Newell received numerous honors and awards, including the U.S. National Medal of Science, the Lifetime Contributions Award of the International Joint Conference on Artificial Intelligence, the Distinguished Scientific Contributions Award of the American Psychological Association, and the A. M. Turing Award of the Association for Computing Machinery, and honorary degrees from the Universities of Groningen (Netherlands) and Pennsylvania. He was elected to both the National Academy of Engineering and the National Academy of Sciences.

Nonmonotonic Logics

Nonmonotonic logics are used to formalize plausible reasoning. They allow more general reasoning than standard logics, which deal with universal statements. For example,

standard logics can easily represent the argument:

All men are mortal
Socrates is a man
_____

Therefore, Socrates is mortal

$(\forall x)(Man(x) \Rightarrow Mortal(x)); Man(Socrates)$
_____

Mortal(Socrates)

but cannot represent reasoning such as:

Birds typically fly
Tweety is a bird
_____

Therefore, Tweety (presumably) flies

Such arguments are characteristic of commonsense reasoning, where *default* rules and the absence of complete information are prevalent.

The most salient feature of nonmonotonic reasoning is that the conclusion of a nonmonotonic argument may not be correct. For example, if Tweety is a penguin, it is incorrect to conclude that Tweety flies. Nonmonotonic reasoning often requires jumping to a conclusion and subsequently retracting that conclusion as further information becomes available. Thus, as the set of assumptions grows, the set of conclusions (theorems) may shrink. This reasoning is called *nonmonotonic* in contrast to standard logic, which is *monotonic:* as one's set of assumptions grows, one's set of theorems grows as well. (Formally, a system is monotonic if for any two theories A and B, whenever A is a subset of B, the theorems of A are a subset of the theorems of B.)

All systems of nonmonotonic reasoning are fundamentally concerned with the issue of consistency: ensuring that conclusions drawn are consistent with one another and with the assumptions.

Major Systems of Nonmonotonic Reasoning

Default Logic (Reiter 1980) introduces a *default rule,* an inference rule consisting of an assumption, an appeal to the consistency of some formula, and a conclusion. For example, the rule *Birds typically fly* could be written as

Bird(x):Fly(x)
_____

Fly(x)

which reads: if x is a bird, and it is consistent that x flies, then conclude that x flies.

Default rules must be applied with care, since conflicting default rules could cause inconsistency if used together. For example, the default *Quakers are usually pacifists* conflicts with the default *Republicans are usually nonpacifists* in the case of Richard Nixon, who was both a Quaker and a Republican. Applying the first default yields the conclusion that Nixon was a pacifist; applying the second default yields the conclusion that Nixon was a nonpacifist; applying both yields inconsistency. One generates *extensions* of a default theory by applying as many default rules as possible. Multiple extensions, or their equivalent, arise in all nonmonotonic logics. The existence of multiple extensions may be seen as

a feature or a problem. On the one hand, they allow the expression of reasonable but conflicting arguments within one system, and thus model well commonsense reasoning and discourse. However, conflicting defaults may give rise to unexpected extensions, corresponding to arguments that seem odd or unreasonable. An example of problematic multiple extensions is the Yale shooting problem, discussed below.

Autoepistemic Logic (Moore 1985) formalizes nonmonotonicity using sentences of a MODAL LOGIC of belief with belief operator *L*. Autoepistemic Logic focuses on *stable sets* of sentences (Stalnaker 1980)—sets of sentences that can be viewed as the beliefs of a rational agent—and the *stable expansions* of a premise set. Properties of stable sets include consistency and a version of negative introspection: if a sentence *P* does not belong to a belief set, then the sentence $\neg L P$ belongs to the belief set. This corresponds to the principle that if an agent does not believe a particular fact, he believes that he does not believe it. To formalize the Tweety example, one represents the rule that birds typically fly as an appeal to an agent's beliefs: $L(Bird\ (x)) \wedge \neg L\ (\neg Fly\ (x)) \Rightarrow Fly\ (x)$. If I believe that *x* is a bird and I don't believe that *x* cannot fly, then (I will conclude that) *x* flies. Any stable expansion of the premise set consisting of this premise and the premise that Tweety is a bird will contain the conclusion that Tweety flies.

Circumscription (McCarthy 1980, 1986) seeks to formalize nonmonotonic reasoning within classical logic by circumscribing, or limiting the extension of, certain predicates. The logic limits the objects in a particular class to those that *must be* in the class. For example, consider the theory containing assumptions that typical birds fly, atypical (usually called *abnormal*) birds do not fly, penguins are atypical, Opus is a penguin, and Tweety is a bird. Opus *must* be in the class of atypical, nonflying birds, but there is no reason for Tweety to be in that class; thus we conclude that Tweety can fly. The circumscription of a theory is achieved by adding a second-order axiom (or, in a first-order theory, an axiom schema), limiting the extension of certain predicates, to a set of axioms.

The systems above describe different ways of determining the nonmonotonic consequences of a set of assumptions. *Entailment Relations* (Kraus, Lehmann, and Magidor 1990) generalize these approaches by considering a nonmonotonic entailment operator |∼, where P |∼ Q means that Q is a nonmonotonic consequence of P, and by formulating general principles characterizing the behavior of |∼. These principles specify how |∼ relates to the standard entailment operator ⊢ of classical logic, and how meta-statements referring to the entailment operator can be combined.

Belief Revision (Alchourron, Gardenfors, and Makinson 1985) studies nonmonotonic reasoning from the dynamic point of view, focusing on how old beliefs are retracted as new beliefs are added to a knowledge base. There are four interconnected operators of interest: contraction, withdrawal, expansion, and revision. In general, revising a knowledge base follows the principle of minimal change: one conserves as much information as possible.

Integrating Nonmonotonic Reasoning with Other Theories

Nonmonotonic reasoning systems are useful only if they can be successfully *integrated* with other theories of commonsense reasoning. Attempts at integration are often surprisingly difficult. For example, the Yale shooting problem (Hanks and McDermott 1987) showed that integrating nonmonotonic reasoning with TEMPORAL REASONING was complicated by the multiple extension problem. The Yale shooting problem consists of determining what happens to a turkey when we know that

1. a gun is loaded at 1:00 and fired at 3:00
2. firing a loaded gun at a turkey results in the turkey's immediate death
3. guns typically stay loaded (default rule D1)
4. turkeys typically stay alive (default rule D2)

Two extensions arise, only one of which is expected. In the expected extension, D1 is applied, the gun remains loaded at 3:00, and the turkey dies. In the unexpected extension, D2 is applied and the turkey is therefore alive after 3:00. This entails that the gun mysteriously becomes unloaded between 1:00 and 3:00. The problem of formalizing a system of temporal reasoning so that these unexpected extensions do not arise has become a central topic in nonmonotonic research. In nonmonotonic temporal reasoning, it has resulted in the development of theories of CAUSATION and EXPLANATION (Morgenstern 1996 and Shanahan 1997 give summaries and analyses).

Integrating nonmonotonic logics with MULTIAGENT SYSTEMS is also difficult. The major problem is modeling nested nonmonotonic reasoning: agents must reason about other agents' nonmonotonic reasoning processes. Most nonmonotonic formalisms are not expressive enough to model such reasoning. Moreover, nested nonmonotonic reasoning requires that agents know what other agents do *not* believe, a difficult requirement to satisfy (Morgenstern and Guerreiro 1993).

In general, integration may require extending both the nonmonotonic formalism and the particular theory of commonsense reasoning.

Implementations and Applications

Applications of nonmonotonic systems are scarce. Implementors run into several difficulties. First, most nonmonotonic logics explicitly refer to the notion of consistency of a set of sentences. Determining consistency is in general undecidable for first-order theories; thus predicate nonmonotonic logic is undecidable. Determining inconsistency is decidable but *intractable* for propositional logic; thus performing propositional nonmonotonic reasoning takes exponential time. This precludes the development of general efficient nonmonotonic reasoning systems (Selman and Levesque 1993).

However, efficient systems have been developed for limited cases. LOGIC PROGRAMMING, the technique of programming using a set of logical sentences in clausal form, uses a nonmonotonic technique known as "negation as failure": a literal, consisting of an atomic formula preceded by

a nonclassical negation operator, is considered true if the atomic formula cannot be proven. Although logic programs cannot express all types of nonmonotonic reasoning, they can be very efficient (Gottlob 1992). Likewise, inheritance with exceptions is an efficient, although limited, form of nonmonotonic reasoning (Horty, Thomason, and Touretzky 1990; Stein 1992). These limited cases handle many common types of nonmonotonic reasoning.

Due to its efficiency, logic programming has been used for many applications, ranging from railway control to medical diagnosis (*Proceedings of the Conference on Practical Applications of Prolog* 1996, 1997), although few applications exploit logic programming's nonmonotonic reasoning abilities. Aside from logic programming, nonmonotonic logic is still rarely used in the commercial world. This may be because the nonmonotonic reasoning community and the commercial world focus on different problems, and because there are few industrial-strength nonmonotonic tools (Morgenstern 1998).

There are similarities between nonmonotonic logics and other areas of research that seek to formalize reasoning under UNCERTAINTY, such as FUZZY LOGIC and PROBABILISTIC REASONING (especially BAYESIAN NETWORKS). These fields are united in their attempt to represent and reason with incomplete knowledge. The character of nonmonotonic reasoning is different in that it uses a qualitative rather than a quantitative approach to uncertainty. Attempts to investigate the connections between these areas include the work of Goldszmidt and Pearl (1992, 1996).

Numeracy and Culture

Numeracy is a term that has been used in a variety of ways. It encompasses formal and informal mathematics, cultural practices with mathematical content, and behavior mediated by mathematical properties even when these properties are not verbally accessible. The study of numeracy explores a broad range of mathematical competencies across species, cultures, and the human lifespan. Human numeracy has universal characteristics based on biological mechanisms and developmental trajectories as well as culturally variable representation systems, practices, and values.

Studies with diverse species show that animals are sensitive to number (see Gallistel 1990 for a review). This literature suggests that there are innate capabilities that have evolved to support numeracy in humans (Gallistel and Gelman 1992). A variety of sources of evidence point to early numerical abilities in human infants (see INFANT COGNITION). For example, infants as early as the first week of life have been shown to discriminate between different small numbers (Antell and Keating 1983). The possibility that this discrimination is carried out by a cognitive mechanism encompassing several modalities has been debated (Starkey, Spelke, and Gelman 1990). In addition, studies have shown that infants have some knowledge of the effects of numerical transformations such as addition and subtraction (Wynn 1992).

Numerical competencies evident in the human infant are strong candidates for universal aspects of human numeracy. However, this does not necessarily discount the role of culture in developing human numeracy. Within the framework of EVOLUTIONARY PSYCHOLOGY, it is argued that universal characteristics of numeracy provide innate starting points for numeracy development, which, in turn, is influenced by culturally specific systems of knowledge (Cosmides and Tooby 1994). Similarly, within the neo-Piagetian framework, children are seen not simply as passing through a universal set of stages, but also as setting out on a unique cognitive journey that is guided by cultural practices (Case and Okamoto 1996). In this sense, numeracy is viewed as a cultural practice that builds on innate mechanisms for understanding quantities. The result is a conceptual structure for numeracy that reflects both universal and culture-sensitive characteristics. These conceptual structures are relatively similar across cultures that provide similar problem-solving experiences in terms of schooling and everyday life. On the other hand, mastery levels of particular tasks or skills may differ from one culture to another depending on the degree to which they are valued in each culture (Okamoto et al. 1996). In addition, cultures influence mathematical practices through the belief systems associated with numeracy, as well as through tools and artifacts (e.g., symbol systems) that support numeracy. A broad array of human activities to which mathematical thinking is applied are interwoven with cultural artifacts, social conventions, and social interactions (Nunes, Schliemann, and Carraher 1993; Saxe 1991).

Cultures have developed systems of signs that provide ways of thinking about quantitative information (see LANGUAGE AND CULTURE). Different systems shed light on different aspects of knowing. That is, they provide a means to extend the ability to deal with numbers; at the same time, they constrain numerical activities. For example, the Oksapmin of Papua New Guinea have a counting system using body parts, with no base structure, that only goes up to 27 (Saxe 1982). This way of quantifying is fully adequate for the numerical tasks of traditional life. It does not, however, facilitate easy computation or the counting of objects beyond 27. In contrast, the perfectly regular base-10 system of many Asian languages appears to make the mastery of base-10 concepts easier for children beginning school than the less regular base-10 systems of many European languages, including English (Miura et al. 1993). These various representational systems are culture-specific tools to deal with counting and computing, and all cultures seem to have them. Other culture-specific representation systems have been identified for locating (geometry, navigation), measuring, designing (form, shape, pattern), playing (rules, strategies), and explaining (Bishop 1991).

Further cultural variations in mathematical behavior are manifest in the ways that people use mathematical representations in the context of everyday activities (see SITUATED COGNITION AND LEARNING). Although they use the same counting numbers for different activities, child street vendors in Brazil were observed to use different computational strategies when selling than when doing school-like problems (Nunes, Schliemann, and Carraher 1993). While selling, they chose to use oral computation and strategies such as decomposition and repeated groupings. On school-like problems, they chose to use paper and pencil with standard algorithms and showed a markedly higher rate of error. Research in other domains, for example measurement (Gay and Cole 1967) and proportional reasoning (Nunes, Schliemann, and Carraher 1993), further confirms that informal mathematics can be effective and does not depend upon schooling for its development.

One characteristic of ethnomathematics, as informal mathematics or NAIVE MATHEMATICS is commonly called, is that the mathematics is used in pursuit of other goals rather than solely for the sake of the mathematics as in school or among professional mathematicians. As new goals arise, representational systems and practices develop to address the emergent goals. For instance, as the Oksapmin became more involved with the money economy, their "body" counting system began to change toward a base system (Saxe 1982). Although the differences between informal and school mathematics are often stressed (Bishop 1991), skills developed in the informal domain can be used to address new goals and practices in the school setting. In Liberian schools it was found that the most successful elementary students were those who combined the strategies from their indigenous mathematics with the algorithms taught in

school (Brenner 1985). Similarly, Oksapmin and Brazilian children benefit from using their informal mathematics to learn school mathematics (Saxe 1985, 1991). Because conflicts between informal and school mathematics frequently arise, a number of authors have argued for building bridges between these different cultures of mathematics (Bishop 1991; Gay and Cole 1967; Gerdes 1988).

In addition to the overt mathematical practices already described, Gerdes (1988) has described *frozen* mathematics as the mathematics embodied in the products of a culture such as baskets, toys, and houses. Although the history of these objects has typically been lost, the original designers of these cultural artifacts employed mathematical principles in their design, according to Gerdes. Mathematical traditions embodied in these artifacts can provide interesting mathematical investigations that help children understand their own cultural heritage as well as contemporary school mathematics.

The study of numeracy and culture draws from diverse disciplines within the cognitive sciences including psychology, linguistics, biology, and anthropology. The strengths of each discipline should be utilized to provide a more coherent view of what numeracy is and how it interacts with culture. Much future work remains to be done to better understand the universal and culture-specific aspects of numeracy.

Object Recognition, Animal Studies

One of the major problems which must be solved by a visual system used for object recognition is the building of a representation of visual information which allows recognition to occur relatively independently of size, contrast, spatial frequency, position on the RETINA, and angle of view, etc. It is important that invariance in the visual system is made explicit in the neuronal responses, for this simplifies greatly the output of the visual system to memory systems such as the HIPPOCAMPUS and AMYGDALA, which can then remember or form associations about *objects* (Rolls 1999). The function of these memory systems would be almost impossible if there were no consistent output from the visual system about objects (including faces), for then the memory systems would need to learn about all possible sizes, positions, etc. of each object, and there would be no easy generalization from one size or position of an object to that object when seen with another retinal size, position, or view (see Rolls and Treves 1998).

The primate inferior temporal visual cortex is implicated by lesion evidence in providing invariance. For example, Weiskrantz and Saunders (1984; see also Weiskrantz 1990) showed that macaques with inferior temporal cortex lesions performed especially poorly in visual discrimination tasks when one of the objects was shown in a different size or in different lighting.

Using the population of neurons in the cortex in the superior temporal sulcus and inferior temporal cortex with responses selective for faces, it has been found that the responses are relatively invariant with respect to size and contrast (Rolls and Baylis 1986); spatial frequency (Rolls, Baylis, and Leonard, 1985; Rolls, Baylis, and Hasselmo, 1987) and retinal translation, that is, position in the visual field (Tovee, Rolls, and Azzopardi 1994; cf. earlier work by Gross 1973; Gross et al. 1985). Some of these neurons even have relatively view-invariant responses, responding to different views of the same face but not of other faces (Hasselmo et al. 1989; see FACE RECOGNITION).

To investigate whether view-invariant representations of objects are also encoded by some neurons in the inferior temporal cortex (area TE) of the rhesus macaque, the activity of single neurons was recorded while monkeys were shown very different views of ten objects (Booth and Rolls 1998). The stimuli were presented for 0.5 sec on a color video monitor while the monkey performed a visual fixation task. The stimuli were images of ten real plastic objects which had been in the monkey's cage for several weeks to enable him to build view-invariant representations of the objects. Control stimuli were views of objects which had never been seen as real objects. The neurons analyzed were in the TE cortex in and close to the ventral lip of the anterior part of the superior temporal sulcus. Many neurons were found that responded to some views of some objects. However, for a smaller number of neurons, the responses occurred only to a subset of the objects, irrespective of the viewing angle. These latter neurons thus conveyed information about which object had been seen, independently of

view, as confirmed by information-theoretic analysis of the neuronal responses.

The representation of objects or faces provided by these neurons is distributed, in that each NEURON does not, in general, respond to only one object or face, but instead responds to a subset of the faces or objects. They thus showed ensemble, sparsely distributed, encoding (Rolls and Tovee 1995; Rolls et al. 1997). One advantage of this encoding is that it allows receiving neurons to generalize to somewhat similar exemplars of the stimuli, because effectively it is the activity of the population vector of neuronal firing which can be read out by receiving neurons (Rolls and Treves 1998). A second advantage is that the information available from such a population about which face or object was seen increases approximately linearly with the number of neurons in the sample (Abbott, Rolls, and Tovee 1996; Rolls et al. 1997). This means that the number of stimuli that can be represented increases exponentially with the number of cells in the sample (because information is a logarithmic measure). This has major implications for brain operation, for it means that a receiving neuron or neurons can receive a great deal of information from a sending population if each receiving neuron receives only a limited number of afferents (100–1000) from a sending population.

A way in which artificial vision systems might encode information about objects is to store the relative coordinates in 3-D object-based space of parts of objects in a database, and to use general-purpose algorithms on the inputs to perform transforms such as translation, rotation, and scale change in 3-D space to see if there is any match to a stored 3-D representation (e.g., Marr 1982). One problem (see also Rolls and Treves 1998) with implementing such a scheme in the brain is that a detailed syntactical description of the relations between the parts of the 3-D object is required, for example, body > thigh > shin > foot > toes. Such syntactical networks are difficult to implement in neuronal networks, because if the representations of all the features just mentioned were active simultaneously, how would the spatial relations between the features also be encoded? (How would it be apparent just from the firing of neurons that the toes were linked to the rest of foot but not to the body?) Another more recent suggestion for a syntactically linked set of descriptors is that of Biederman (1987; see also Hummel and Biederman 1992).

An alternative, more biologically plausible scheme is that the brain might store a few associated 2-D views of objects, with generalization within each 2-D view, in order to perform invariant object and face recognition (Koenderink and Van Doorn 1979; Poggio and Edelman 1990; Rolls 1992, 1994; Logothetis et al. 1994; Wallis and Rolls 1997). The way in which the brain could learn and access such representations is described next.

Cortical visual processing for object recognition is considered to be organized as a set of hierarchically connected cortical regions consisting at least of V1, V2, V4, posterior inferior temporal cortex (TEO), inferior temporal cortex (e.g., TE3, TEa, and TEm), and anterior temporal cortical areas (e.g., TE2 and TE1). There is convergence from each small part of a region to the succeeding region (or layer in the hierarchy) in such a way that the receptive field sizes of

neurons (e.g., one degree near the fovea in V1) become larger by a factor of approximately 2.5 with each succeeding stage (and the typical parafoveal receptive field sizes found would not be inconsistent with the calculated approximations of, for example, eight degrees in V4, twenty degrees in TEO, and fifty degrees in inferior temporal cortex; Boussaoud, Desimone, and Ungerleider 1991; see figure 1). Such zones of convergence would overlap continuously with each other. This connectivity would be part of the architecture by which translation-invariant representations are computed. Each layer is considered to act partly as a set of local self-organizing competitive neuronal networks with overlapping inputs. These competitive nets (described, e.g, by Rolls and Treves 1998) operate to detect correlations between the activity of the input neurons, and to allocate output neurons to respond to each cluster of such correlated inputs. These networks thus act as categorizers, and help to build feature analyzers. In relation to visual information processing, they would remove redundancy from the input representation.

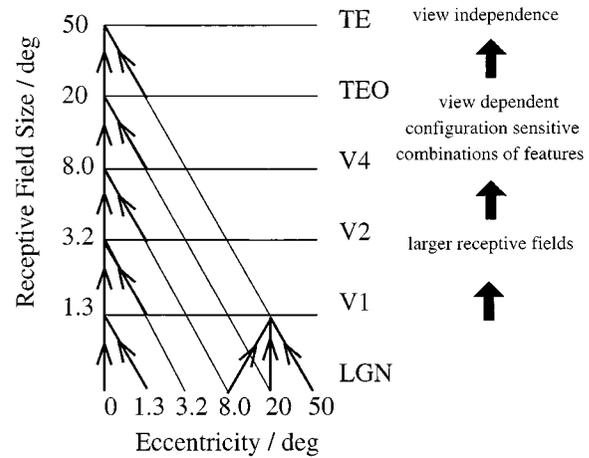
Translation invariance would be computed in such a system by utilizing competitive learning to detect statistical regularities in inputs when real objects are translated in the physical world. The hypothesis is that because objects have continuous properties in space and time in the world, an object at one place on the retina might activate feature analyzers at the next stage of cortical processing, and when the object was translated to a nearby position, because this would occur in a short period (e.g., 0.5 sec), the membrane of the postsynaptic neuron would still be in its "Hebb-modifiable" state (caused for example by calcium entry as a result of the voltage-dependent activation of N-methyl-d-aspartate receptors), and the presynaptic afferents activated with the object in its new position would thus become strengthened on the still-activated postsynaptic neuron. It is proposed that the short temporal window (e.g., 0.5 sec) of Hebb modifiability helps neurons to learn the statistics of objects moving in the physical world, and at the same time to form different representations of different feature combinations or objects, as these are physically discontinuous and present less regular statistical correlations to the visual system. Foldiak (1991) has proposed computing an average activation of the postsynaptic neuron to assist with the same problem. The idea here is that the temporal properties of the biologically implemented learning mechanism are such that it is well suited to detecting the relevant continuities in the world of real objects. Rolls (1992, 1994) has also suggested that other invariances, for example, size, spatial frequency, and rotation invariance, could be learned by a comparable process. (Early processing in V1, which enables different neurons to represent inputs at different spatial scales, would allow combinations of the outputs of such neurons to be formed at later stages. Scale invariance would then result from detecting at a later stage which neurons are almost conjunctively active as the size of an object alters.) It is proposed that this process takes place at each stage of the multiple-layer cortical-processing hierarchy, so that invariances are learned first over small regions of space, and then over successively larger regions. This limits the size of the connection space within which correlations must be sought.


Figure 1. Schematic diagram showing convergence achieved by the forward projections in the visual system, and the types of representation that may be built by competitive networks operating at each stage of the system, from the primary visual cortex (V1) to the inferior temporal visual cortex (area TE; see text). LGN—lateral geniculate nucleus. Area TEO forms the posterior inferior temporal cortex. The receptive fields in the inferior temporal visual cortex (e.g., in the TE areas) cross the vertical midline (not shown).

View-independent representations could be formed by the same type of computation, operating to combine a limited set of views of objects. Consistent with the suggestion that the view-independent representations are formed by combining view-dependent representations in the primate visual system is the fact that in the temporal cortical areas, neurons with view-independent representations of faces are present in the same cortical areas as neurons with view-dependent representations (from which the view-independent neurons could receive inputs; Hasselmo et al. 1989; Perrett, Mistlin, and Chitty 1987).

This hypothesis about the computation of invariant representations has been implemented in a computational model by Wallis and Rolls (1997), and a related model with a trace version of the Hebb rule implemented in recurrent collateral connections has been analyzed using the methods of statistical physics (Parga and Rolls 1998).

Another suggestion for the computation of translation invariance is that the image of an object is translated to standard coordinates using a circuit in V1 that has connections for every possible translation, and switching on in a multiplication operation just the correct set of connections (Olshausen, Anderson, and Van Essen 1993). This scheme does not appear to be fully plausible biologically, in that all possible sets of connections do not appear to be present (in the brain), the required multiplier inputs and multiplication synapses do not appear to be present; and such a scheme could perform translation-invariant mapping in one stage, whereas in the brain it takes place gradually over the whole series of visual cortical areas V1, V2, V4, posterior inferior temporal, and anterior inferior temporal, with an expansion of the receptive field size (and thus of translation invariance) of approximately 2.5 at each stage (see figure 1 and Rolls 1992, 1994; Wallis and Rolls 1997; Rolls and Treves 1998).

Object Recognition, Human Neuropsychology

Most of what we know about the neural mechanisms of object recognition in humans has come from the study of *agnosia*, or impaired object recognition following brain damage. In addition, in recent years, functional neuroimaging in normal humans has begun to offer insights into object recognition. This article reviews both literatures, with greater emphasis accorded to agnosia because of its currently greater contribution to our understanding of human object recognition.

To be considered agnosia, an object recognition impairment must be selective in the sense of not being attributable to impaired elementary perceptual function or general intellectual decline. It must also be a true impairment of recognition, as opposed to an impairment of naming. Agnosias are generally confined to a single perceptual modality, such as auditory (Vignolo 1969), tactile (Reed, Caselli, and Farah 1996), or visual (Farah 1990), suggesting that for each perceptual modality there is a stage of processing beyond elementary perceptual processes that is nevertheless modality-specific, and that represents learned information about objects' sounds, tactile qualities, and visual appearances. In the case of visual agnosia, which is the focus of this article, this stage presumably corresponds to the inferior temporal regions that have been studied using physiological techniques in the monkey

(see also OBJECT RECOGNITION, ANIMAL STUDIES). The different types of visual agnosia provide insights into the organization of high-level visual object representations in humans, by showing us the "fracture lines" of the system.

Lissauer (1890) introduced a fundamental distinction between two broad classes of agnosia: those in which perception seemed clearly at fault, which he termed *apperceptive*, and those in which perception seemed at least roughly intact, which he termed *associative*. Lissauer hypothesized that the latter type of patient suffered from an inability to associate percepts with meaning. Although the theory behind this classification system is now widely questioned, the classification itself—that is, the separation of patients with obvious perceptual disorders from patients without obvious perceptual disorders—has proved useful.

The apperceptive agnosias have received less attention than the associative agnosias, perhaps because they are less surprising or counterintuitive. Although such elementary visual functions as acuity and color perception are roughly intact, higher levels of perception such as visual grouping appear to be disrupted, and the object recognition impairment is secondary to these perceptual impairments. In this article I focus on the associative agnosias because they are the most directly relevant to object recognition per se. Readers may consult chapters 2 and 3 of Farah (1990) for further information on the apperceptive agnosias.

In contrast to the apperceptive agnosias, perception seems roughly normal in associative agnosia, and yet patients cannot recognize much of what they see. Most often, associative agnosia follows bilateral inferior occipitotemporal lesions, although unilateral lesions of either the left or right hemisphere are sometimes sufficient (see the final section). The classic case of Rubens and Benson (1971) shows all of the cardinal signs of associative agnosia, including preserved recognition of objects through modalities other than vision, failure to indicate visual recognition verbally and nonverbally, and apparently good visual perception.

The patient could not identify common objects presented visually, and did not know what was on his plate until he tasted it. He identified objects immediately on touching them. When shown a stethoscope, he described it as "a long cord with a round thing at the end," and asked if it could be a watch. He identified a can opener as "could be a key. . . ." He was never able to describe or demonstrate the use of an object if he could not name it. . . . He could match identical objects but not group objects by categories (clothing, food). He could draw the outlines of objects which he could not identify. . . . Remarkably, he could make excellent copies of line drawings and still fail to name the subject.

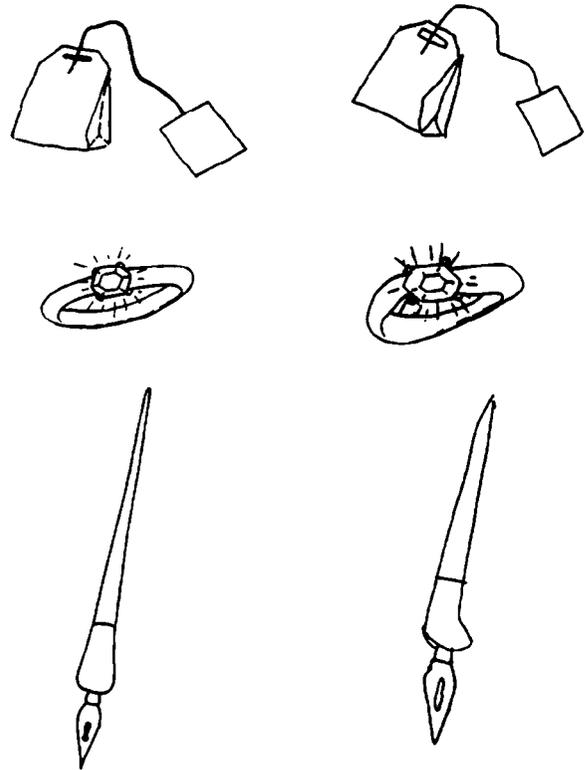
The modality-specific failure of object recognition, in the context of normal intellect, is what one would expect following destruction of the kinds of object representations found at higher levels of the primate visual system, and indeed the most common lesion locations are roughly consistent with this hypothesis (the human lesions are perhaps a bit more posterior). Although the good copies and successful matching performance of associative agnosic patients might seem inconsistent with the hypothesis of a visual perceptual impairment, these perceptual tasks do not require the use of object representations per se. Indeed, the manner


Figure 1. Three drawings that an associative agnosic patient could not recognize (left) and the good-quality copies that he was nevertheless able to produce (right).

in which associative agnosic patients copy and match is consistent with the use of lower-level visual representations in which objects per se are not explicitly represented: they copy line by line, and match feature by feature, unlike normal subjects who organize their copying and matching of these local elements into more global, object-based units (see Farah 1990, chaps. 4 and 5 for a review). The left side of figure 1 shows three drawings that an associative agnosic patient was unable to recognize. When I asked him to copy the drawings, he produced the very adequate copies shown on the right, but only after a laborious, line-by-line process.

Studies using POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI) have confirmed the most basic conclusion to be drawn from the agnosia literature, namely, that there are visual modality-specific brain regions in inferior temporo-occipital cortex whose function is object perception. Relative to baselines involving the viewing of gratings, random lines, or disconnected object pieces, the viewing of objects is generally associated with temporal or occipital activation, or both, in both hemispheres (e.g., see Menard et al. 1996; Kanwisher et al. 1996, 1997; Sergent, Ohta, and MacDonald 1992; see Aguirre and Farah 1998 for a review). Furthermore, this localization held both for studies that required subjects to perform active information retrieval (e.g., is the depicted object living or nonliving?) and for others that required only passive viewing, suggesting that the critical determinant of the region's activation is object perception,

rather than the association of stored memory knowledge with a percept. Indeed, Kanwisher et al. (1997) found no greater activation for unfamiliar objects than for familiar objects, which have a preexisting memory representation.

Agnosia does not always affect all types of stimuli equally. The scope of the deficit varies from case to case, with recognition of faces, objects, and printed words all pairwise dissociable. These dissociations provide us with insights into the internal organization of high-level visual object representation. Similarly, neuroimaging studies have sometimes found differing patterns of activation for different stimulus types (Aguirre and Farah 1998).

When agnosia is confined to faces or is disproportionately severe for faces, it is prosopagnosia. There are many cases of profound FACE RECOGNITION impairment, with little or no evident object agnosia, in the literature. Pallis (1955) provides a detailed case study of a patient whose impairment of face recognition was so severe, he mistook his own reflection in a mirror for a rude stranger staring at him.

Are faces really disproportionately impaired in prosopagnosia, consistent with a distinct subsystem for face recognition, or does the appearance of a selective deficit result from the need for exceedingly fine discrimination among visually similar members of a single category? Recent evidence suggests that there is specialization within the visual system for faces. McNeill and Warrington (1993) showed that a prosopagnosic patient was better able to recognize individual sheep faces than individual human faces, even though normal subjects find the human faces easier to recognize. Farah, Klein, and Levinson (1995) showed that a prosopagnosic patient was disproportionately impaired at face recognition relative to common object recognition, taking into account the difficulty of the stimulus sets for normal subjects. This was true even when the common objects were all eyeglass frames, a large and visually homogeneous category. Farah et al. (1995) showed that the same subject was impaired at upright face perception relative to inverted face perception, even though normal subjects find the latter harder. The existence of patients who are more impaired with objects than with faces also supports the independence of prosopagnosia and object agnosia. Feinberg et al. (1994) documented impaired object recognition in a series of patients with preserved face recognition.

Attempts to dissociate face and object perception using neuroimaging have produced variable results, although in at least some studies the patterns of activation were different (Sergent et al. 1992; Kanwisher et al. 1996).

Orthography-specific processing systems? So-called pure alexics typically read words letter by letter, in a slow and generally error-prone manner. Their impairment is called "pure" because they are able to comprehend spoken words, they have no problem writing words, and their recognition of objects and faces seems normal. Although pure alexia is generally discussed in the context of language and reading disorders, it is clearly also an impairment of visual recognition affecting printed words. Furthermore, in all the cases so far examined, the visual recognition impairment is not confined to words, but also affects the processing of nonorthographic stimuli whenever rapid processing of multiple shapes is required, be they letters in words or sets of abstract shapes (Farah and Wallace 1991; Kinsbourne and Warrington 1962; Levine and Calvanio 1978; Sekuler and Behrmann 1996; see Farah and Wallace 1991 for a discussion of some apparently conflicting data). Although clinical descriptions suggest that in some cases orthographic stimuli may be disproportionately affected, for example, relative to numerical stimuli, this can be understood in terms of segregation of representations for orthographic stimuli within a visual area dedicated to rapid encoding of multiple shapes in general (Farah in press). Polk and Farah (1995) describe and test a mechanism by which such segregation could occur in a self-organizing network, based on the statistics of co-occurrence among letter and nonletter stimuli in the environment.

Just as pure alexia is an impairment of printed word recognition in the absence of obvious impairments of single-object recognition, there are cases of object recognition impairment with preserved reading. For example, the case of Gomori and Hawryluk (1984) was impaired at recognizing a variety of objects and the faces of his friends and family. He nevertheless continued to read with ease, even when interfering lines were drawn across the words. Thus, like prosopagnosia and object agnosia, pure alexia and object agnosia are doubly dissociable.

Only one neuroimaging study has directly compared the patterns of activation evoked by printed words and objects, and did find a degree of separation (Menard et al. 1996).

Localization of high-level object representation in the human visual system: Ironically, although the primary goal of neuroimaging is localization, and agnosia research is subject to the vagaries of naturally occurring lesions, the clearest evidence concerning the anatomy of object recognition comes from patient research. In general, the intrahemispheric location of damage is generally occipitotemporal, involving both gray and white matter. In order to understand the laterality of visual recognition processes, it is crucial to distinguish between subtypes of agnosia. Cases of associative agnosia have been reported following unilateral right hemisphere lesions, unilateral left hemisphere lesions, and bilateral lesions. The dual systems hypothesis presented above helps reduce the variability in lesion site. Agnosic patients presumed to have an impairment of just the first ability (in mild form affecting just faces, in more severe form affecting faces and objects but not words) usually have bilateral inferior lesions, although occasionally unilateral right hemisphere lesions are reported (Farah 1991). Agnosic patients presumed to have an impairment of just the second ability (in mild form affecting just words, in more severe form affecting words and objects but not faces) generally have unilateral left inferior lesions (Farah 1991; Feinberg et al. 1994). Agnosic patients presumed to have an impairment in both abilities (affecting faces, objects, and words) generally have bilateral lesions.

Aside from confirming the generalization that face, object, and VISUAL WORD RECOGNITION tasks involve posterior cortices, the neuroimaging literature tells us little about the localization of different subtypes of object recognition (Aguirre and Farah 1998). The precise locations of areas responsive to faces, nonface objects, and words differ widely, from study to study, within posterior association cortex.

Whether this reflects individual variability in brain organization, problems with normalization and statistical procedures for analyzing images of brain activity, or the difference between localizing areas that are activated (as revealed by neuroimaging) vs. areas that are necessary (as revealed by lesions) for visual recognition remains to be discovered.

Oculomotor Control

Eye movements fall into two broad classes. *Gaze-stabilization* movements shift the lines of sight of the two eyes to precisely compensate for an animal's self-motion, stabilizing the visual world on the RETINA. *Gaze-aligning* movements point a portion of the retina specialized for high resolution (the *fovea* in primates) at objects of interest in the visual world.

In mammals, gaze-stabilization movements are accomplished by two partially independent brain systems. The *vestibulo-ocular system* employs the inertial velocity sensors attached to the skull (the *semicircular canals*) to determine how quickly and in what direction the head is moving and then rotates the eyes an equal and opposite amount to keep the visual world stable on the retina. The *optokinetic system* extracts information from the visual signals of the retina to determine how quickly and in what direction to rotate the eyes to stabilize the visual world.

Gaze-aligning movements also fall into two broad classes: *saccades* and *smooth pursuit* movements. Saccadic eye movements rapidly shift the lines of sight of the two eyes, with regard to the head, from one place in the visual world to another at rotational velocities up to 1000°/sec. Smooth pursuit eye movements rotate the eyes at a velocity and in a direction identical to those of a moving visual target, stabilizing that moving image on the retina. In humans and other binocular animals, a third class of gaze-shifting movements, *vergence* movements, operates to shift the lines of sight of the two eyes with regard to each other so that both eyes can remain fixated on a visual stimulus at different distances from the head.

In humans, all eye movements are rotations accomplished by just six muscles operating in three antagonistic pairs. One pair of muscles located on either side of each eyeball controls the horizontal orientation of each eye. A second pair controls vertical orientation and a third pair controls rotations of the eye around the line of sight (*torsional movements*). These torsional movements are actually quite common, though usually less than 10° in amplitude.

These six muscles are controlled by three brain stem nuclei. These nuclei contain the cell bodies for all of the motor neurons that innervate the oculomotor muscles and thus serve as a final common path through which all eye

movement control must be accomplished. Engineering models of the eye and its muscles indicate that motor neurons must generate two classes of muscle forces to accomplish any eye rotation: a pulsatile burst of force that regulates the *velocity* of an eye movement and a long-lasting increment or decrement in maintained force that, after the movement is complete, holds the eye stationary by resisting the elasticity of the muscles which would slowly draw the eye back to a straight-ahead position (Robinson 1964). Physiological experiments have demonstrated that all motor neurons participate in the generation of both of these two types of forces.

These two forces, in turn, appear to be generated by separable neural circuits. In the 1960s it was suggested that changes to the long-lasting force required after each eye rotation could be computed from the pulse, or velocity, signal by the mathematical operation of integration. In the 1980s the lesion of a discrete brain area, the nucleus prepositus hypoglossi, was shown to eliminate from the motor neurons the long-lasting force change required for leftward and rightward movements without affecting eye velocity during these movements (Cannon and Robinson 1987). This, in turn, suggested that most or all eye movements are specified as velocity commands and that brain stem circuits involving the nucleus prepositus hypoglossi compute, by integration, the long-lasting force required by a particular velocity command. More recently, a similar circuit has been identified that appears to generate the holding force required for upward, downward, and torsional movements.

The saccadic system, in order to achieve a precise gaze shift, must supply these brain stem circuits with a command that controls the *amplitude and direction* of a movement. Considerable research now focuses on how this signal is generated. Current evidence indicates that this command can originate in either of two brain structures: the *superior colliculus* of the midbrain or the *frontal eye fields* of the neocortex. Both of these structures contain laminar sheets of neurons that code all possible saccadic amplitudes and directions in a topographic maplike organization (Robinson 1972; Wurtz and Goldberg 1972; Bruce and Goldberg 1985). Activation of neurons at a particular location in these maps is associated with a particular saccade, and activation of neurons adjacent to that location is associated with saccades having adjacent coordinates. Lesion experiments indicate that either of these structures can be removed without permanently preventing the generation of saccades. How these signals that topographically encode the amplitude and direction of a saccade are translated into a form appropriate for the control of the oculomotor brain stem is not known. One group of theories proposes that these signals govern a brain stem feedback loop which accelerates the eye to a high velocity and keeps the eye in motion until the desired eye movement is complete (cf. Robinson 1975). Other theories place this feedback loop outside the brain stem or generate saccadic commands without the explicit use of a feedback loop. In any case, it seems clear that the superior colliculus and frontal eye fields are important sources of these signals because if both of these structures are removed, no further

saccades are possible (Shiller, True, and Conway 1980). The superior colliculus and frontal eye fields, in turn, receive input from many areas within the VISUAL PROCESSING STREAMS, including the VISUAL CORTEX, as well as the BASAL GANGLIA and brain structures involved in audition and somatosensation. These areas are presumed to participate in the processes that must precede the decision to make a saccade, processes like ATTENTION.

In the smooth pursuit system, signals carrying information about target MOTION are extracted by motion-processing areas in visual cortex and then passed to the dorsolateral pontine nucleus of the brain stem. There, neurons have been identified which code either the direction and velocity of pursuit eye movements, the direction and velocity of visual target motion, or both. These signals proceed to the cerebellum where neurons have been shown to specifically encode the velocity of pursuit eye movements (Suzuki and Keller 1984). These neurons, in turn, make connections with cells known to be upstream of the nucleus prepositus hypoglossi (the integrator of the oculomotor system described above). As in the saccadic system, the brain stem integrator appears to compute the long-term holding force from this signal and then to pass the sum of these signals to the motor neurons.

All eye movement control signals must pass through the ocular motor neurons which serve as a final common path. In all cases these neurons carry signals associated both with the instantaneous velocity of the eye and the holding force required at the end of the movement. Eye movement systems must provide control signals of this type, presumably by first specifying a velocity command from which changes in holding force can be computed. In the case of saccades, this command is produced by brain structures that topographically map all permissible saccades in amplitude and direction coordinates. In the case of pursuit, the brain appears to extract target motion and to use this signal as the oculomotor control input. Together these systems allow humans to redirect the lines of sight to stimuli of interest and to stabilize moving objects on the retina for maximum acuity.

Optimality Theory

Optimality Theory ("OT," Prince and Smolensky 1991, 1993) is a theory of LINGUISTIC UNIVERSALS AND UNIVERSAL GRAMMAR. According to OT, the grammars of all human languages share a set of constraints, denoted *Con.* These constraints are sufficiently simple and general that they conflict in many contexts: they cannot all be satisfied simultaneously. The grammar of an individual language resolves these conflicts: it ranks the universal constraints of *Con* into a *constraint hierarchy,* conflicts being resolved in favor of higher-ranked constraints, with each constraint having absolute priority over all lower-ranked constraints. Grammars may differ *only* in how they rank the universal constraints; the TYPOLOGY of all possible human languages may be computed as the result of all possible rankings of these constraints. An OT analysis explains why some grammatical patterns are possible while others are not. (That a particular language happens to have a particular constraint ranking is not considered a fact to be explained within grammatical theory proper.)

Consider, for example, the difference between the simple English sentence *it rains* and its Italian counterpart *piove*—literally, "rains." What do these sentences reveal about the commonalities and differences between the two grammars? According to the OT analysis of Grimshaw and Samek-Lodovici (1995, 1998), at issue here is a conflict between two constraints—SUBJECT: "Every sentence has a subject," and FULL-INT(ERPRETATION): "Every element of a linguistic expression contributes to its interpretation." In English, the conflict is resolved in favor of SUBJECT: to provide a subject, *it* must appear, even though it has no referent and contributes nothing to the interpretation of the sentence, violating FULL-INT. In Italian, the conflict is resolved the other way: no meaningless subject may appear, and FULL-INT prevails over SUBJECT.

In many other contexts, SUBJECT and FULL-INT do not conflict, and both constraints must be satisfied in both languages. Both constraints are parts of the grammars of both languages, but they do not have equal status: in English, SUBJECT has priority, or *dominates*; we write: SUBJECT >> FULL-INT. In Italian, the reverse *constraint ranking* holds. The lower-ranked constraint in each language must be obeyed, except in contexts in which doing so would violate the higher-ranked constraint; in this sense, constraints in OT are *minimally violable.* OT thus differs from earlier grammatical theories employing *inviolable* constraints, where any violation of a constraint renders a structure

ungrammatical (e.g., RELATIONAL GRAMMAR, LEXICAL FUNCTIONAL GRAMMAR, HEAD-DRIVEN PHRASE STRUCTURE GRAMMAR).

To sketch the broad outline of the OT picture of cross-linguistic variation, we fix attention on a universal constraint C (e.g., FULL-INT). In some languages, C is very highly ranked (e.g., Italian); the effect is that those linguistic structures (e.g., meaningless *it*) that violate the constraint—those that are *marked* by it—are altogether banned from the language. In other languages, C is somewhat lower ranked, so that the structures it marks (e.g., *it*) now appear—but only in those highly restricted contexts in which the marked element is needed to satisfy one of the few constraints more highly ranked than C (e.g., SUBJECT in English). Looking across still other languages, C is ranked lower and lower, so that the structures it marks appear in more and more contexts, as more and more other constraints force violations of because they outrank it. The OT literature documents many specific cases of this general cross-linguistic pattern, which can be captured entirely by the simple statement: C ∈ *Con*. Once this has been stated, the rest of the pattern follows from the formal structure of OT: languages differ in how they rank C, and depending on this ranking, those structures marked by C will be either banned altogether (highest ranking), allowed but only in a highly restricted set of contexts, or allowed in a wide range of contexts (lowest ranking).

Each universal constraint C defines a class of dispreferred or *marked* structures: those that violate it. Through the single mechanism of constraint ranking, such marked elements are banned in some languages, and restricted in their distribution in all languages. OT thus builds on the notion of *markedness* developed in the 1930s by N. S. Trubetzkoy, Roman JAKOBSON, and others of the Prague Linguistics Circle; OT provides a formal, general markedness-based calculus within the tradition of GENERATIVE GRAMMAR. OT's formalization of markedness computation brings into sharp focus a number of issues otherwise obscure.

Competition

To say that a linguistic structure *S* is grammatical in a language *L* because it optimally satisfies *L*'s constraint hierarchy is to exploit a *comparative* property: even though *S* might not satisfy all the universal constraints, *every alternative* incurs more serious violations of *L*'s hierarchy than does *S*. Specifying an OT grammar includes specifying the *candidate sets* of linguistic structures that compete for optimality. This must be universal, for in OT, only constraint ranking varies across grammars.

Aggregation of Multiple Dimensions of Markedness

What defines optimality when the constraints defining different dimensions of markedness disagree on which candidate is preferred? OT's answer is constraint ranking. *S* is optimal if and only if it is *more harmonic* than all other members *S'* of its candidate set, written S ≻ S': this means that, of the constraints differentiating the markedness of *S* and *S'*, *S* is favored by the highest ranked. It is perhaps sur-

prising that within such a simple mechanism, reranking can succeed in accounting for such a diversity of observed grammatical patterns.

Faithfulness to Targets

Why is *it rains* optimal, when its violation of FULL-INT could be avoided by selecting another candidate with an interpreted subject, say, *John smiles*? Implicit thus far in the competition for optimality is the *target* proposition, <rain(), tense = present>, to which *it rains,* but not *John smiles,* is *faithful*. In OT, each candidate is evaluated relative to a target, faithfulness to which is demanded by constraints in *Con* collectively called FAITHFULNESS. *John smiles* is indeed optimal, but for a different target, <smile(x), x = John, tense = present>. The multiplicity of grammatical—optimal—structures in a single language arises from the multiplicity of possible targets. In PHONOLOGY, the target is a sequence of phones, an *underlying form* such as /bat + d/ for the past tense of *to bat*. Optimal for this target is [batɪd] "batted"; this includes a vowel ([ɪ]) not present in the target, so it violates a FAITHFULNESS constraint, F. This minimally unfaithful candidate is optimal because of a universal constraint against certain word-final consonant clusters, including *td;* this constraint is higher ranked than F in the phonological component of the English grammar. That a morpheme (like past-tense /d/) receives different (but closely related) pronunciations, depending on its context, follows in OT from a fixed underlying form for the morpheme, FAITHFULNESS to which is (minimally) violated in many optimal forms, forced by higher-ranked well-formedness constraints governing phones in various contexts. Violability of FAITHFULNESS plays a less obvious role in SYNTAX; Legendre, Smolensky, and Wilson (1998) use it to explain why some syntactic targets have *no* grammatical expression in a particular language: for such an ineffable target, every faithful candidate violates sufficiently high-ranking constraints that an unfaithful candidate, with a different interpretation, is optimal.

The candidates competing for a target *I* form a set written *Gen(I); I* is often called the *input,* and sometimes the *index,* of this candidate set. The set of targets and the candidate-generating function *Gen* are universal.

Implications

A framework employing a novel type of grammatical computation, optimization, OT has cognitive implications for the classic questions of generative grammar that concern the nature of knowledge of language, its use, its acquisition, and its neural realization.

Violable constraints profoundly alter the analytic options in syntactic theory. When a grammatical sentence *S appears* to violate a putative simple, general, universal constraint C, it becomes possible to simply say that it *actually does*; with inviolable constraints, it is typically necessary to posit invisible structures that allow *S* to covertly satisfy C, or to complicate C, often via language-particular parameters, so that it is no longer violated by *S*. Topics of OT syntactic analyses include grammatical voice alternations (GRAMMATICAL

RELATIONS and THEMATIC ROLES), case, ANAPHORA, HEAD MOVEMENT, subject distribution, *wh*-questions (WH-MOVEMENT), scrambling, and clitic inventories and placement.

In phonological theory, the shift from serial, process-oriented frameworks (PHONOLOGICAL RULES AND PROCESSES) to OT's parallel, violable constraint optimization has enabled explanation of typological variation in a number of areas: segmental inventories, syllable structure, STRESS, TONE, vowel harmony, reduplicative and templatic MORPHOLOGY, phonology-morphology relations, the phonology-PHONETICS interface, and many others. (For an extensive bibliography and on-line database of OT papers and software, see the Rutgers Optimality Archive ROA at http://ruccs.rutgers.edu/roa.html.)

A unified grammatical framework for syntax and phonology, OT also provides results that span both these modules, including the relation of general to more specific constraints, the compatibility among related grammatical processes, and the computation and learnability of grammars. Formal results on the latter topics address algorithms for learning constraint rankings from positive examples, algorithms for computing optimal forms, and the complexity of formal languages specified by OT grammars. Empirical findings on the course of acquisition of PHONOLOGY in children, and on real-time SENTENCE PROCESSING, have been analyzed within OT. While detailed OT proposals for the neural basis of language and the neural basis of phonology do not currently exist, theoretical connections between optimization in OT and in NEURAL NETWORK models have proved fruitful for the continuing development of both OT and the theory of complex symbol processing in neural networks (Prince and Smolensky 1997).

Pain

To a degree matched by no other component of somatic sensation and by no other sensory system, pain carries with it an emotional quality. From one person to the next, differences in personal traits and past experience play major roles

in the perception of pain. For any individual, changes in mood or expectation are similarly important for judging and reacting to pain. Moreover, thresholds for a stimulus perceived as painful vary across the body surface, as every person can attest to by comparing how he or she reacts to one grain of sand under the eyelid vs. thousands of grains under the feet. These variations in the perception of pain and its strong affective component make it difficult to study clinically and experimentally.

The anatomy and physiology of pain (nociception) begin with two types of specialized receptors in the skin, muscles, and viscera. One responds only to very forceful mechanical energy and the other to noxious stimuli of many kinds. The first of these is the mechanical nociceptor, a type of afferent that responds only to physical force intense enough to produce tissue damage. Far more general is the response of polymodal nociceptors, as seen by comparing the response of the two receptor types to heat: mechanical nociceptors have a very high threshold for the initial application of heat, whereas polymodal nociceptors begin responding to stimuli of 40° C and show a linear increase in response to stimuli up to 60° C. Both receptor types are notable for the fact that, unlike all other somatosensory receptors, they are left uncovered by specialized cells or connective tissue sheaths and are thus unprotected from the diffusion of chemical agents released by surrounding cells. These agents include a variety of small molecules such as amines and peptides that can produce or change activity in nociceptors over a distance of several millimeters.

Whereas other somatosensory receptors adapt to repeated stimulation by becoming less sensitive and less responsive to each subsequent stimulus, nociceptors participate in a heightened response to repeated noxious stimulation, referred to as hyperalgesia. Both neural and non-neuronal mechanisms appear to participate in this phenomenon by which application of noxious thermal or mechanical stimuli produces a lower threshold for and a greater response to other noxious stimuli. Primary hyperalgesia occurs at the site of injury through the local release of chemical agents, such as bradykinin, which directly stimulate nociceptors to become active. Other chemical agents, including prostaglandin E_2, also play a role in primary hyperalgesia, not by directly driving nociceptors, but by making them much more responsive to subsequent non-noxious mechanical stimuli. It is through inhibition of these chemical agents that aspirin and ibuprofen work as analgesics. A second type of hyperalgesia is of strictly neural origin and probably includes a component that originates in the spinal cord rather than in the periphery.

The two nociceptor types send their responses into the central nervous system (CNS) by way of different kinds of peripheral axons. Larger, lightly myelinated (Aδ) axons end as mechanical nociceptors, whereas the smallest, unmyelinated (C) axons end as polymodal nociceptors. These differences in axon diameter and level of myelination necessarily translate into differences of conduction velocity and thus in the time over which signals from the two nociceptor types reach the CNS. Pricking pain, carried by Aδ fibers, is the more rapidly transmitted, better localized, and more easily tolerated component of pain. The perception of pricking pain is followed after a substantial delay by second or burning pain, a poorly localized, agonizing pain carried by C fibers.

Pain afferents are segregated from other somatosensory afferents that carry discriminative information of touch and body position. They enter the spinal cord in the dorsal root as a more lateral bundle and synapse directly upon neurons of the cord's dorsal and intermediate horns. Convergence of inputs from many pain afferents at this level produces a situation amplified at higher levels in which painful stimuli are localized very poorly when unaccompanied by information from other cutaneous afferents. Further synaptic convergence at higher levels between cutaneous nociceptors and visceral nociceptors leads to the misplacement of pain occurring in viscera to sites that are more peripheral. This referred pain is a common part of abnormal situations, such as those that occur during heart attacks.

Many spinal neurons driven by nociceptive afferents send their axons across the spinal cord, where they ascend to various locations in the brain stem and THALAMUS. That immediate crossing in the cord of pain information contrasts with the delayed crossing of fine touch and proprioceptive axons, which occurs in the medulla. Such a wide difference in the site of crossing produces a situation in which hemisection of the cord leads to a loss of pain sensation on the contralateral side of the body but loss of discriminative sensation on the ipsilateral side. Other neurons directly driven by nociceptive afferents have intraspinal axons that end on spinal motor neurons. These synapses are part of a rapid reflex that produces withdrawal of a limb from the location of a painful stimulus.

Much of the ascending pain information reaches a region of the midbrain around the cerebral aqueduct of the ventricular system. This periaqueductal gray (PAG) region is a principal component of a descending system, stimulation of which relieves pain. Axons from the PAG innervate a collection of serotonin-synthesizing and -secreting neurons of the medulla, the nucleus raphe magnus. These neurons, in turn, send long, descending axons into the dorsal horn of the spinal cord, where they form synapses with interneurons that use opiate-like peptides, the enkephalins, as NEUROTRANSMITTERS. By modulating the activity of nociceptor afferents and of spinal pain neurons, the enkephalinergic interneurons control the perception of the intensity of a noxious stimulus. Opiates and other pharmacological agents that mimic the effects of enkephalins are effective as analgesics in part because of their action at these spinal synapses.

A fraction of spinal neurons that respond to nociceptive inputs send their axons to the contralateral thalamus. Part of that spinothalamic system reaches nuclei of the intralaminar group, which provides the great mass of the cerebral cortex with a diffuse innervation. That system and the projection of spinal nociceptive neurons to the brain stem reticular formation are the anatomical substrates for the generally arousing and motivating qualities of pain. Most spinothalamic axons, however, synapse on clusters of small cells in the ventral posterior lateral (VPL) nucleus, which together make up a complete body representation of pain. A comparable group of cells in the ventral posterior medial (VPM) nucleus is innervated by neurons in the pars caudalis of the spinal trigeminal system and includes a nociceptive representation

of the face. Both VPL and VPM send axons to the first somatosensory area of the cerebral cortex, found in the postcentral gyrus of monkeys, apes, and humans. By this route and by a separate innervation of the second somatosensory area, nociceptive information reaches the CEREBRAL CORTEX in a way that it can be compared with other somatosensory information and localized with some precision to particular sites along the body. Neurological studies of soldiers suffering head wounds in the two world wars clearly demonstrate that injuries confined to the postcentral gyrus produce permanent analgesia along the contralateral body surface.

Where the affective quality to pain arises is poorly understood. Those few studies to have addressed the question have focused on areas of temporal and orbitofrontal cortex in humans and nonhuman primates. Perhaps the best current guess is that more than one area of cerebral cortex is involved in the agony that accompanies extreme pain such as that produced by solid tumors or burns. These extreme cases of pain and the need to control them and other lesser or more acute nociceptive events often raise questions of the advantage conferred by painful affect. Rare clinical cases of patients who perceive a painful event as differing from an innocuous stimulus but who experience no affect accompanying that event are test cases for such a question. Most of these patients die at an early age, victims of numerous destructive wounds and crippling conditions of joints. Apparently the failure of these patients to avoid or discontinue actions that are painful significantly shortens their lives despite intensive training in detecting and responding to painful stimuli. From these cases, then, it can be concluded that both precise localization and emotional reaction to pain are parts of successful strategies for survival.

Parameter-Setting Approaches to Acquisition, Creolization, and Diachrony

How is knowledge of one's idiolect—*I(nternal)-language,* in Noam Chomsky's (1986) terminology—represented in the mind/brain? How is such knowledge acquired by children? Answers to these questions are intricately and constructively related. In the principles and parameters/minimalist approach (Chomsky 1981, 1986, 1995; see SYNTAX, ACQUISITION OF and MINIMALISM), linguistic knowledge, in addition to a (language-specific) LEXICON (see WORD MEANING, ACQUISITION OF and COMPUTATIONAL LEXICONS), consists of a computational system that is subject to an innate set of formal constraints, partitioned into *principles* and *parameters.* The *principles* are argued to be universal; they formalize constraints obeyed by *all* languages (see LINGUISTIC UNIVERSALS). Alongside these principles—and perhaps *within* some of these principles (e.g., Rizzi 1982)—what allows for diversity in TYPOLOGY (possibly, in addition to the lexicon proper) are the *parameters.* These parameters constitute an innate and finite set of "switches," each with a fixed range of settings. These switches give the learner a restricted number of options in determining the complete shape of the attained I-language. In such a framework, syntax acquisition reduces to fixing the values of parameters on the basis of primary linguistic data (PLD) (cf. LANGUAGE ACQUISITION). Taken together, principles and parameters bring a solution to the "logical problem of language acquisition":

(1) UG / S_0
(universal principles cum *UNSET* parameters)

+

PLD / "triggers"

=

Idiolect-Specific Grammar / S_f
(universal principles cum SET parameters)

Per (1), language acquisition is the process in which exposure to PLD transforms our innately specified *faculté de langage* (from an initial state S_0) into a language-specific grammar (at the final state S_f) by assigning values (settings) to an array of (initially unset) parameters (see Chomsky 1981, HISTORICAL LINGUISTICS, and INNATENESS OF LANGUAGE).

The schema just sketched delineates a fascinating and productive research program. Yet our understanding is still very incomplete as to how (which aspects of) the PLD "lead" the learner to adopt (what) settings for (what) parameters. What are the major questions raised by this program? In order to flesh out the structure in (1), generativists are advancing on three complementary theoretical fronts toward:

1. A characterization of parameters. For example, are parameters distributed across various grammatical principles (cf. Rizzi 1982; Chomsky 1986) or are parameters restricted to "inflectional systems" (Borer 1983; Chomsky 1995: ch 2), to the inventory and properties of functional heads (Ouhalla 1991; cf. SYNTAX and HEAD

MOVEMENT), or to ("weak" vs. "strong") morphological features of functional heads (see Chomsky 1995: ch. 3)?
2. A theory that would delineate what (kinds and amounts of) forms from the PLD are used by the learner in what contexts and at what stages as *triggers* or *cues* for assigning particular settings to particular parameters (cf. Gibson and Wexler 1994; Lightfoot 1999; Roberts 1999; also see further readings below).
3. A proposal as to how (i.e., by what chains of deductions) the triggering in (2) takes place.

Current approaches to 1–3 still remain controversial and in need of refinements. Here I discuss one proposal with *some* promise regarding certain (diachronic and ontogenetic) developmental data. Rohrbacher (1994), following insights from works by, among others, Borer, Pollock, Platzack and Holmberg, Roberts, and Chomsky, proposes that "rich" verbal inflections constitute a trigger for verb displacement (V-raising) because such MORPHOLOGY is listed in the lexicon and inserted in the syntax outside of the verbal phrase (VP): as affixal heads, such verbal inflection induces the verb to raise outside VP via head movement in order for the verb stem to become bound with its affixes. Such verb raising is diagnosed by, for example, placement of the finite verb to the left of certain adverbs, as in French. In languages with "poor" verbal inflection, affixes (if any) generally do not behave as independent *syntactic* elements that induce V-raising; they are introduced post-syntactically in the morpho-phonological component. Such proposals for the morphology-syntax interface in parameter-setting are not unproblematic. Yet they make interesting predictions that can (in principle, if not always in practice) be tested against phenomena in language acquisition, creolization, and language change. In turn, research in these three areas has brought forward data and insights that may prove useful in elucidating parameter setting.

Starting with CREOLES, there has been much recent work by young creolists proceeding from the hunch that paths of creolization may provide much needed hints toward understanding: the mechanics of parameter-setting in acquisition and through language change; and whether parameter settings are hierarchically organized along a cline of (un)markedness (with unmarked settings being those that are attained with few or no triggers of the appropriate type). The hunch that creolization phenomena should shed light on parameter setting essentially goes back to Derek Bickerton's language bioprogram hypothesis. In Bickerton's hypothesis, creoles by and large manifest the sort of properties a language learner would attain in the absence of reliable PLD, for example, in the presence of the overly impoverished and unstable patterns that are typical of speakers in (early) pidgin/interlanguage stages. Thus creole settings tend to indicate values accessible with few or no triggers in the PLD. Why should this state of affairs hold?

For Bickerton, structural similarities across creoles arise as creole grammars tend to instantiate genetically specified *default* values of parameter settings due to: (1) the restricted nature of the PLD: the source of the PLD that gave rise to the creole is a pidgin that is itself the outcome of adult language acquisition under duress, that is, with restricted input in contact situations that are unfriendly toward the learner;

thus, pidgin grammatical morphologies tend to be impoverished; (2) the privileged role of children in creole genesis: in acquiring their native language with pidgin PLD, such children appear to stabilize and expand inconsistent, unstable, and restricted patterns in their PLD.

Regarding the morphologies of contact languages, it was noted long ago (e.g., by Meillet 1919) that inflectional paradigms are singularly susceptible to the vagaries of language learning in contact situations. Thus, in a theory where parameter settings are derived from the properties of inflectional morphemes (cf. Borer 1983; see e.g., Rohrbacher 1994), the question arises as to what settings are attainable in an environment that causes attrition to the PLD's inflectional morphemes. Bickerton's proposal is that, in the absence of the relevant (morphological) triggers, certain parameters are assigned default settings by UG. Although various creole structures are inherited from the parent languages, contra Bickerton (see e.g., Chaudenson 1992; Lumsden 1999), Bickerton's intuition seems partly confirmed in certain domains of creole syntax, for example, for Haitian Creole, in the domains of nonverbal predication (*sans* verbal copulas; DeGraff 1992), and of verb and object-pronoun syntax (with adverb-verb-pronoun order; DeGraff 1994, 1997). These are among patterns that distinguish Haitian Creole both from its European ancestor (French) and from its West-African ancestors (e.g., Kwa). Much recent work in this vein (see further readings below) is preliminary and exploratory, but appears to hold promise toward understanding the mechanics of parameter-setting and of creole genesis.

Beyond creolization, Bickerton's proposal, once embedded in a parameter-setting framework, also has ramifications for the relationship between acquisition and language change. Given (1) and some implementation thereof, the language acquisition device with the appropriate parameter-setting algorithm is one locus of confluence for creolization and language-change data (cf. DeGraff 1999b; Lightfoot 1999). As language learners and field and historical linguists often experience (the learners more successfully than the linguists), "language data do not wear their grammars on their sleeves," and parameter values must be fixed anew each time an I-language is attained, that is, at each instantiation of (1). This is in keeping with Meillet's (1929: 74) and others' classic idea that the transmission of language is inherently discontinuous: the grammar of each speaker is an individual re-creation, based on limited evidence. Furthermore, parameter-setting takes the learner through parametric configurations distinct from the target grammar(s) (see e.g., the papers in Roeper and Williams 1987). One must also remark that PLD sets—as uttered by the learner's various model speakers (caretakers, older peers, etc.)—are themselves determined by parameter-setting arrays that, although overlapping, are in most cases (subtly) distinct from one another idiolect-wise. Thus, even in unexceptional instances of acquisition, target grammars, and the final grammars attained by the learners ineluctably diverge, if only along relatively few parameters. Yet such localized parametric shifts are noticeable via the innovative structural patterns they give rise to. In any case, it has been claimed (e.g., in DeGraff 1999b) that such innovation is of the same

character as that found in creolization and in the early stages of language acquisition (modulo the degree of divergence); they all are rooted in (1), which is a modern rendering of Meillet's observation about the discontinuity of language transmission. As for the more radical nature of the changes observed in creolization, this stems from the unusual nature of the PLD.

Thus, it should not come as surprise that creolization patterns (e.g., in Haitian Creole's verbal syntax and morphology; see DeGraff 1997) present uncanny parallels with: (1) patterns in language acquisition, as with children who, in the initial stages of acquiring V-raising languages like French, (optionally) use noninflected unraised verbs in contexts where the target language requires inflected raised verbs (Pierce 1992); and (2) patterns in language change, as for example in the history of English where V-raising in Middle English gave way to V-in-situ in Modern English with a prior decrease in verbal inflections (Rohrbacher 1994; Vikner 1997; Roberts 1999; Lightfoot 1999).

Results of this sort would then confirm the view that morphology is one major source of syntactic variations and that functional categories and their associated morphemes are the locus for parameter-setting. In this view, the learner, unlike the linguist, need not consult actual "constructions" in order to set parameters. Instead, inflectional paradigms (once their "richness" and frequencies exceed certain thresholds) serve as triggers for syntax-related settings such as V-raising vs V-in-situ, possibly alongside *syntactic* triggers qua robust and localized distributional patterns (e.g., verb-negation/adverb orders; see, e.g., Roberts 1999; Lightfoot 1999). (As noted by Rohrbacher 1994: 274, the inflectional paradigms may be key because they must be learned anyway.) In absence of relatively copious morphological (and syntactic) triggers, the learner initially falls back on default options (e.g., V-in-situ) as in the earliest stages of acquisition and in the linguistic environments that produced Haitian Creole and Modern English—and other languages that lost V-raising through language contact.

The hypothesis sketched above regarding parameter-setting (in verbal syntax) has been much debated; see, inter alios, Vikner 1997 for counterexamples, and Thráinsson 1996 and Lightfoot 1999 for alternative proposals. Yet, to advance our understanding of parameter-setting within current (provisional) assumptions in syntax (particularly minimalism), one may ask whether morphological triggering (or any other triggering that relies on narrowly defined, easily accessible paradigms) *must* be the null hypothesis in any theory that both assumes "constructions" to be epiphenomenal (see Chomsky 1995) and potentially ambiguous parameter-wise (e.g., Gibson and Wexler 1994), and seeks to solve the logical problem of language acquisition by keeping learning and induction from PLD to a strict minimum (see POVERTY OF THE STIMULUS ARGUMENTS).

Parsimony and Simplicity

The law of parsimony, or Ockham's razor (also spelled "Occam"), is named after William of Ockham (1285–1347/49). His statement that "entities are not to be multiplied beyond necessity" is notoriously vague. What counts as an entity? For what purpose are they necessary? Most agree that the aim of postulated entities is to represent reality, or to "get at the truth" in some sense. But when are entities postulated *beyond* necessity?

The role of parsimony and simplicity is important in all forms of INDUCTION, LEARNING, STATISTICAL LEARNING THEORY, and in the debate about RATIONALISM VS. EMPIRICISM. However, Ockham's razor is better known in scientific theorizing, where it has two aspects. First, there is the idea that one should not postulate entities that make *no* observable difference. For example, Gottfried Wilhelm Leibniz objected to Isaac Newton's absolute space because one absolute velocity of the solar system would produce the same observable behavior as any other absolute velocity.

The second aspect of Ockham's razor is that the *number* of postulated entities should be minimized. One of the earliest known examples was when Copernicus (1473–1543) argued in favor of his stationary-sun theory of planetary motion by arguing that it endowed one cause (the motion of the earth around the sun) with many effects (the apparent motions of the planets). In contrast, his predecessor (Ptolemy) unwittingly duplicated the Earth's motion many times in order to "explain" the same effects. Newton's version of Ockham's razor appeared in his first and second rules of philosophizing: "We are to admit no more causes of natural things than such as are both true and sufficient to explain their appearances. Therefore, to the same natural effects we must, as far as possible, assign the same causes."

Both aspects arise in modern empirical science, including psychology. When data are modeled by an equation or set of equations, they are usually designed so that all theoretical parameters can be *uniquely* estimated for the data using standard statistical estimation techniques (like the method of least squares, or maximum likelihood estimation). When this condition is satisfied, the parameters are said to be *identifiable.* This practice ensures the satisfaction of Ockham's razor in its first aspect. For example, suppose we have a set of data consisting in n pairs of (x, y) values: $\{(x_1, y_1), (x_2, y_2), \ldots (x_n, y_n)\}$. The model $y_i = a + b\, x_i$, for $i = 1, 2, \ldots n$, is identifiable because the parameters a and b can be uniquely estimated by sufficiently varied data. But a model like $y_i = a + (b + c)\, x_i$ is not identifiable, because many pairs of values of b and c fit the data equally well. Different parameter values make no empirical difference.

Normally, this desideratum is so natural and common-sensical that nonidentifiable models are not used. B. F. Skinner resisted the introduction of intervening variables in BEHAVIORISM for this reason. However, they do arise in NEURAL NETWORKS (see also COGNITIVE MODELING, CONNECTIONIST). In the simplest possible two-layered network, one would have one input neuron, or node, with an activation x, one hidden node, with activation y, and an output node, with activation z, where the output is a function of the hidden node activation, which is in turn a function of the input activation. In a simple linear network, this would mean that $z = a.y$, and $y = b.x$, where a and b are the connection weights between the layers. The connection weights are the parameters of the model. But the hidden activations are not observed, and so the only testable consequence of the model is the input-output function, $z = (ab)x$. Different pairs of values of the parameters a and b lead to the same input-output function. Therefore, the model is not identifiable.

Perhaps the more difficult problem is to understand how to draw the line in cases in which extra parameters make a difference, but a very little difference. This is the second aspect of Ockham's razor. For example, how do we select between competing models like $y = a + b x_1$ and $y = a + b x_1 + c x_2$, where the parameters a, b, and c are *adjustable* parameters that range over a set of possible values? Each equation represents a different model, which may be thought of as a *family* of curves. Under one common notion of simplicity, the first *model* is simpler than the second model because it has fewer adjustable parameters. Simplicity is measured by the size, or dimension, of the *family* of curves. (Note that, in this definition, models are of greater or lesser simplicity, but all curves are equally simple because their equations have zero adjustable parameters.)

How does one decide when an additional parameter makes "enough" of an empirical difference to justify its inclusion, or when an additional parameter is "beyond necessity"? If the choice is among models that fit the data *equally well* (where the fit of a model is given by the fit of its best case), then the answer is that simplicity should break the tie. But in practice, competing models do not fit equally well. For instance, when one model is a special case of, or nested in, another (as in the previous example), the more complex model will always fit better (if only because it is able to better fit the noise in the data).

So, the real question is: How much better must the complex model fit before we say that the extra parameter is necessary? Or, when should the better fit of the complex model be "explained away" as arising from the greater tendency of complex models to fit noise? How do we trade off fit with simplicity? That is the motivation for standard significance testing in statistics. Notice that significance testing does not always favor the simpler model. Nor is the practice motivated by any belief in the simplicity of nature. In fact, when enough data accumulates, the choice will favor the complex model eventually even if the added parameters have very small (but nonzero) values.

In recent years, there have been many new model selection criteria developed in statistics, all of which define simplicity in terms of the paucity of parameters, or the dimension of a model (see Forster and Sober 1994 for a nontechnical introduction). These include Akaike's Information Criterion (AIC; Akaike 1974, 1985), the Bayesian Information Criterion (BIC; Schwarz 1978), and MINIMUM DESCRIPTION LENGTH (MDL; Rissanen 1989). They trade off simplicity and fit a little differently, but all of them address the same problem as significance testing: Which of the estimated "curves" from competing models best represents reality? This work has led to a clear understanding of why this form of simplicity is relevant to that question.

However, the paucity of parameters is a limited notion. It does not mark a difference in simplicity between a wiggly curve and a straight curve. Nor does it capture the idea of simpler theories having fewer numbers of fundamental principles or laws. Nor does it reward the repeated use of equations of the same *form*. A natural response is to insist that there must be other kinds of simplicity or unification that are relevant to theory choice. But there are well-known problems in defining these alternative notions of simplicity (e.g., Priest 1976; Kitcher 1976). Moreover, there are no precise proposals about how these notions of simplicity are traded off with fit. Nor are there any compelling ideas about why such properties *should* count in favor of one theory being closer to the truth than another.

Pattern Recognition and Feedforward Networks

A feedforward network can be viewed as a graphical representation of a parametric function which takes a set of input values and maps them to a corresponding set of output values (Bishop 1995). Figure 1 shows an example of a feedforward network of a kind that is widely used in practical applications.

Vertices in the graph represent either inputs, outputs, or "hidden" variables, while the edges of the graph correspond to the adaptive parameters. We can write down the analytic function corresponding to this network as follows. The output of the jth hidden node is obtained by first forming a weighted linear combination of the d input values x_i to give

$$a_j = \sum_{i=1}^{d} u_{ji} x_i + b_j. \tag{1}$$

The value of hidden variable j is then obtained by transforming the linear sum in (1) using an activation function $g(\cdot)$ to give

$$z_j = g(a_j). \tag{2}$$

Finally, the outputs of the network are obtained by forming linear combinations of the hidden variables to give

$$a_k = \sum_{j=1}^{M} v_{kj} z_j + c_k. \tag{3}$$

The parameters $\{u_{ji}, v_{kj}\}$ are called *weights* while $\{b_j, c_k\}$ are called *biases,* and together they constitute the adaptive parameters in the network. There is a one-to-one correspondence between the variables and parameters in the analytic function and the nodes and edges respectively in the graph.

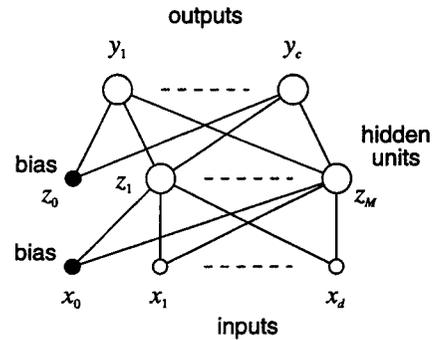
Historically, feedforward networks were introduced as models of biological neural networks (McCulloch and Pitts 1943), in which nodes corresponded to neurons and edges corresponded to synapses, and with an activation function $g(a)$ given by a simple threshold. The recent development of feedforward networks for pattern recognition applications has, however, proceeded largely independently of any biological modeling considerations.


Figure 1. A feedforward network having two layers of adaptive parameters.

The goal in pattern recognition is to use a set of example solutions to some problem to infer an underlying regularity which can subsequently be used to solve new instances of the problem. Examples include handwritten digit recognition, medical image screening, and fingerprint identification. In the case of feedforward networks, the set of example solutions (called a training set) comprises instances of input values together with corresponding desired output values. The training set is used to define an error function in terms of the discrepancy between the predictions of the network for given inputs and the desired values of the outputs given by the training set. A common example of an error function would be the squared difference between desired and actual output, summed over all outputs and summed over all patterns in the training set. The learning process then involves adjusting the values of the parameters to minimize the value of the error function. Once the network has been trained, that is, once suitable values for the parameters have been determined, new inputs can be applied and the corresponding predictions (i.e., network outputs) calculated.

The use of layered feedforward networks for pattern recognition was widely studied in the 1960s. However, effective learning algorithms were only known for the case of networks in which, at most, one of the layers comprised adaptive interconnections. Such networks were known variously as perceptrons (Rosenblatt 1962) and adalines (Widrow and Lehr 1990), and were seriously limited in their capabilities (Minsky and Papert 1969/1990). Research into artificial NEURAL NETWORKS was stimulated during the 1980s by the development of new algorithms capable of training networks with more than one layer of adaptive parameters (Rumelhart, Hinton, and Williams 1986). A key development involved the replacement of the nondifferentiable threshold activation function by a differentiable nonlinearity, which allows gradient-based optimization algorithms to be applied to the minimization of the error function. The second key step was to note that the derivatives could be calculated in a computationally efficient manner using a technique called backpropagation, so called because it has a graphical interpretation in terms of a propagation of error signals from the output nodes backward through the network. Originally these gradients were used in simple steepest-descent algorithms to minimize the error

function. More recently, however, this has given way to the use of more sophisticated algorithms, such as conjugate gradients, borrowed from the field of nonlinear optimization (Gill, Murray, and Wright 1981).

During the late 1980s and early 1990s, research into feedforward networks emphasized their role as function approximators. For example, it was shown that a network consisting of two layers of adaptive parameters could approximate any continuous function from the inputs to the outputs with arbitrary accuracy provided the number of hidden units is sufficiently large and provided the network parameters are set appropriately (Hornik, Stinchcombe, and White 1989). More recently, however, feedforward networks have been studied from the much richer probabilistic perspective (see PROBABILITY, FOUNDATIONS OF), which sets neural networks firmly within the field of *statistical pattern recognition* (Fukunaga 1990). For instance, the outputs of the network can be given a probabilistic interpretation, and the role of network training is then to model the probability distribution of the target data, conditioned on the input variables. Similarly, the minimization of an error function can be motivated from the well-established principle of maximum likelihood that is widely used in statistics. An important advantage of this probabilistic viewpoint is that it provides a theoretical foundation for the study and application of feedforward networks (see STATISTICAL LEARNING THEORY), as well as motivating the development of new models and new learning algorithms.

A central issue in any pattern recognition application is that of generalization, in other words the performance of the trained model when applied to previously unseen data. It should be emphasized that a small value of the error function for the training data set does not guarantee that future predictions will be similarly accurate. For example, a large network with many parameters may be capable of achieving a small error on the training set, and yet fail to model the underlying distribution of the data and hence achieve poor performance on new data (a phenomenon sometimes called "overfitting"). This problem can be approached by limiting the complexity of the model, thereby forcing it to extract regularities in the data rather than simply memorizing the training set. From a fully probabilistic viewpoint, learning in feedforward networks involves using the network to define a *prior* distribution over functions, which is converted to a *posterior* distribution once the training data have been observed. It can be formalized through the framework of BAYESIAN LEARNING, or equivalently through the MINIMUM DESCRIPTION LENGTH approach (MacKay 1992; Neal 1996).

In practical applications of feedforward networks, attention must be paid to the representation used for the data. For example, it is common to perform some kind of preprocessing on the raw input data (perhaps in the form of "feature extraction") before they are used as inputs to the network. Often this preprocessing takes into consideration any prior knowledge we might have about the desired properties of the solution. For instance, in the case of digit recognition we know that the identity of the digit should be invariant to the position of the digit within the input image.

Feedforward neural networks are now well established as an important technique for solving pattern recognition problems, and indeed there are already many commercial applications of feedforward neural networks in routine use.

Penfield, Wilder

Our knowledge about the organization of the CEREBRAL CORTEX is derived, in part, from the search for a therapeutic intervention for a particular disease—*epilepsy*. Wilder Penfield (1891–1976), stimulated by his postgraduate work with Otfrid Foerster, a pioneer in the development of modern neurosurgical procedures to relieve seizures in epileptic patients, began a prolonged scientific study of the surgical treatment of epilepsy at McGill University in 1928. By 1934, Penfield had founded Montreal Neurological Institute (MNI), which he served as director until his retirement in 1960. Penfield was soon joined by others, including Herbert Jasper, who introduced the EEG to the operating room, and by D. O. HEBB and Brenda Milner, who introduced the idea of systematic neuropsychological assessment of surgical patients. The foundation and the establishment of the endowment for the MNI, or "Neuro," which has become an international center for training, research, and treatment related to the brain and diseases of the nervous system, may be Penfield's most lasting legacy. The idea of a neurological hospital, integrated with a multidisciplinary brain research complex, providing a center where a mutidisciplinary team of both scientists and physicians might study the brain, has served as a model for the establishment of similar units throughout the world.

By the mid-1930s, Penfield and his colleagues were employing electrical stimulation and systematic mapping techniques adapted from physiological work with animals. These procedures were employed to aid in excising those regions of brain tissue that served as the focus of epileptic activity in patients whose seizures were not adequately controlled by available drugs. Electrical brain stimulation provided the "gold standard" by which the functional properties of brain regions might be determined. This *Montreal Procedure* was used both to localize the epileptogenic tissue itself and to minimize surgical damage by first mapping critical motor, somatosensory, language-related brain tissue by applying brief, low-voltage electrical current through thin wire electrodes to sites on the cortical surface of the brains of fully conscious human patients. It was then noted which parts of the body moved, or what bodily sensations were reported in response to each stimulus. By the late 1930s, Penfield and his coworkers had created the first systematic maps of both the human primary motor and somatosensory cortex. Their data indicated there was a point-to-point relation between parts of the body and these neocortical regions (i.e., that motor and somatosensory cortex were both somatotopically organized) and that these distributions of the body surface were distorted, leading to the construction of his famous sensory and motor homunculistylized cartoons of the body surface with the relative prominence of different body parts reflecting the extent of their representation in the cortex. A *sensorimotor* integrative conception of brain organization was also promoted by his finding that 25 percent of the stimulation points yielding sensory experiences were located in precentral *motor* cortical regions. Subsequent investigation of nonhuman subjects led to identification of analogous maps or representations of visual and auditory external worlds and, together with Penfield's own mapping work, helped shape our view of cortical organization for decades. While his original work suggested that there were several somatosensory cortical representations of the external environment, it was not until the late 1970s that more refined anatomical and physiological techniques revealed dozens of maps in each modality, rather than just one or two.

Careful study of hundreds of patients by Penfield and his coworkers (and more recently by George Ojemann and his colleagues at the University of Washington) also provided clear evidence of cerebral asymmetry or HEMISPHERIC SPECIALIZATION. For example, the pooled data from many patients yielded the first direct confirmation of conclusions inferred from previous postmortem correlations, by establishing a map of language-related zones of the left hemisphere that included not only the traditional areas of Paul BROCA and Carl Wernicke, but also the supplementary speech zone. Stimulation in these regions of the left hemisphere usually arrested (or initiated) speech during the stimulation period or produced other forms of language interference such as misnaming and impaired word repetition, whereas stimulation of the right hemisphere seldom did. Penfield's research also furnished other evidence that did not support traditional localizationist models of language. For example, stimulation of anterior and posterior speech zones had remarkably similar effects on speech function, and the extent of these cortical language zones varied considerably among patients.

Accounts of apparent awaking of long-lost childhood and other memories by temporal lobe epileptics during electrical stimulation of the region were recorded by Penfield in the 1930s. This data, together with evidence provided in the

neuropsychological studies of such patients after surgery by Brenda Milner and others, made it clear to Penfield that the medial temporal region, including the HIPPOCAMPUS, was of special importance in respect to human MEMORY (and emotion).

Penfield's early observations on seizures arising from deep midline portions of the brain also had an important impact on the development of ideas about the neural substrate of CONSCIOUSNESS. In 1938 he proposed a "*centrencephalic*" system that stressed the role of the upper brain stem in the integration of higher functions. In arguing that consciousness is more closely related to the brainstem than the cortex, he foreshadowed Moruzzi and Magouns's (1949) conception about the role of the midbrain reticular formation. "Consciousness," he later wrote, "exists only in association with the passage of impulses through ever-changing circuits between the brainstem and cortex. One can not say that consciousness is here or there. But certainly without centrencephalic integration, it is nonexistent." Penfield's lifelong search for a better understanding of the functional organization of the brain and its disorders during epileptic seizures is symbolized by this hypothesis of the central integrating mechanism. Never localized in any specific area of gray matter, but "in wider-ranging mechanisms," it represented a conceptual bridge he envisaged between brain and mind (cf. MIND-BODY PROBLEM).

Perceptual Development

Just a century ago it was widely believed that the world perceived by newborn infants was, in the words of WILLIAM JAMES, a "blooming, buzzing confusion." In the decades since then, developmental research has demonstrated dramatically that James's view was erroneous. The shift in view was prompted by research from various domains. In the 1930s, Piaget's detailed descriptions of his infant children and Gesell's charting of infants' motor milestones created a climate of interest in infants as research subjects and in developmental questions. The work of ethologists studying the behavior of animals in their natural habitats (COMPARATIVE PSYCHOLOGY) paved the way for careful observations of spontaneous activity in even the youngest animals. Observation of spontaneous activity ran counter to theories of stimulus-response (S-R) chaining and the radical BEHAVIORISM fashionable in the 1930s; at the same time, it inspired the design of new methods for studying infants, including methods for asking what infants perceive.

By the 1960s, methods for studying infant perception had multiplied as psychologists exploited infants' natural exploratory behaviors, especially looking. Preferential looking at one of two displays, habituation to one display followed by a new display, and a paired comparison test of old and new displays were highly effective methods for studying visual discrimination of simple contrasting properties and even more complex patterns. Spontaneous exploratory behavior was also the basis for research methods, particularly operant conditioning of responses such as sucking, head turning, or moving a limb. Methods which provide infants with opportunities to control their environment (e.g., operant conditioning, infant-controlled habituation) were shown to be more effective than methods without consequences for changing behavior (Horowitz et al. 1972). Psychologists found that they could also investigate what is perceived utilizing natural actions in controlled experimental situations, such as reaching for objects varying in bulk or attainability, and locomotion across surfaces varying in rigidity, pitfalls, obstacles, and slope. Methods borrowed from physiological research,

including heart rate and electrophysiological responses, have been used effectively in studying sensitivity to change in stimulus dimensions. These measures, along with psychophysical procedures, have revealed impressive discriminatory abilities in very young infants. (See VISION AND LEARNING; AUDITION; TASTE; and SMELL.) Researchers are now discovering the precursors of some of these competencies during the fetal period of prenatal development.

Major research topics include development of perception of events, the persistent properties of objects, and the larger layout of surfaces. Five key points that emerge are the following:

1. The perception of events is prospective or forward-looking. One example is infants' differential response to approaching obstacles and apertures, the so-called looming studies (Yonas, Petterson, and Lockman 1979). Infants respond with defensive blinking and head retraction to approaching objects, but not to approaching apertures or to withdrawing objects. Studies of neonates reaching out to catch moving objects provide another compelling demonstration of anticipatory perception as skilled reaching develops (Hofsten 1983). Infants also anticipate occurrence of environmental happenings, for example, by looking toward the locus of a predictable event (Haith 1993).

2. Motion is important for revealing the persistent properties of events, objects, and layout of the world. A striking example is the perception of biological motion when visual information is minimized. When spots of light are placed on key joints (e.g., elbows, ankles, hips), and all other illumination is eliminated, observers immediately perceive a person engaging in a uniquely specified activity, such as walking, dancing, or lifting a heavy box, but only when the actor is moving. Infants differentiate these biological motion displays from inverted displays and from spots of light moving in a random fashion (Bertenthal 1993). Motion makes possible pickup of information about social (communicative) events, such as smiling and talking, at an early age. The role of motion is also critical in visual detection of constant properties of objects, such as unity, size, shape (SHAPE PERCEPTION), and substance. At four months of age, infants perceive the unity of an object despite partial occlusion by another object, provided that the occluded object is in motion (Kellman and Spelke 1983). Constant size of an object is given in changes in distance relative to self and background, and neonates appear to detect size as invariant (Slater, Mattock, and Brown 1990). Shape constancy, invariant over changes in orientation of an object, is perceived by five months (Gibson et al. 1979). Rigidity or elasticity of substance is differentiated via mouthing in neonates (Rochat 1983), and visually by five months (Gibson and Walker 1984). Methods of visual habituation and observation of grasping skills converge on evidence for perceiving these properties. Such convergence is not surprising, since exploration of object properties is naturally multimodal. Surface properties of objects, such as color (see COLOR VISION), are not necessarily dependent on motion, but texture of an object's surface is accessed by haptic as well as visual information and is differentiated early in the first year (SURFACE PERCEPTION; see also HAPTIC PERCEPTION).

3. Perception is multimodally unified (MULTISENSORY INTEGRATION). From the earliest moments of life, infants orient to sounds, particularly human voices, and they engage in active visual exploration of faces and sounding objects (Gibson 1988). In fact, infants as young as five months can match the sounds and visible motions of faces and voices in a bimodal matching task (Kuhl and Meltzoff 1982; Walker 1982). Infants can also match the sounds and visible motions of object events (Spelke 1976), evidently perceiving a unified event. At one month, infants appear to detect and unify haptic and visual information for object substance (Gibson and Walker 1984).

4. Properties of the larger layout are made available multimodally as motor skills and new action patterns develop. Experience and practice play an important role in this development. How far away things are must be perceived in units of body scale by infants. Observation of the hands, in relation to surrounding objects, occurs spontaneously within the first month (van der Meer, van der Weel, and Lee 1995). When reaching for objects emerges as a skill, judging not only the distance of an object but its size improves rapidly. Information for the major properties of the layout is best accessed when babies begin locomotion. While recognition of obstacles, approaching objects, and surface properties is not unprepared, experience in traversing the ground surface brings new lessons. Crawling infants tend to avoid a steep drop in the surface of support (Gibson and Walk 1960). The affordance of falling is perceived early in locomotor history, but becomes more dependable with experience in locomotion. Properties of the surface of support that afford locomotion (its rigidity, smoothness, slope, etc.) are detected by experienced crawling infants. They learn to cope effectively with steep slopes by avoiding them or adopting safe methods of travel, but the same infants as novice upright walkers attempt dangerous slopes and must learn new strategies (Adolph 1997). Bipedal locomotion requires extensive adjustments of perceptual and locomotor skills, as infants learn a new balancing act, using multimodal information from ankles, joints, and visual cues provided by flow patterns created by their own movements. Novice walkers fall down in a "moving room," despite a firm and stable unmoving ground surface (Lee and Aronson 1974). Flow patterns created by the room's motion give false information that they are falling forward or backward. Perceiving the world entails coperception of the self; in this case, via visual information from perspective changes in the room's walls in relation to vestibular information about one's own upright posture.

5. Infants perceive the SELF as a unit distinct from the world (see SELF-KNOWLEDGE). By four to five months, infants watch their own legs moving currently on a television screen, contrasted with views of similarly clad legs of another infant or their own at an earlier moment

(Bahrick and Watson 1985). They reliably prefer to gaze at the novel display rather than their own ongoing movements. However, introduction of a target that can be kicked changes the preference to monitoring the ongoing self kicking at the target (Morgan and Rochat 1995). An opportunity for making contact with an object provides motivation for controlling the encounter. Considerable other research in a contingent reinforcement situation (e.g., kicking to rotate a mobile) confirms infants' perception of a self in control. Disruption of control results in frustration and emotional disturbance (Lewis, Sullivan, and Brooks-Gunn 1985).

Early reaction to the explosion of knowledge about the perceptual abilities of young infants was a burst of astonished admiration ("Aren't babies wonderful?"), and little concern was given to how development progresses, although previously popular Piagetian views were questioned. Three current views vary in their assumptions about processes involved in perceptual development. Two are construction theories: (1) The information processing view assumes that bare sensory input is subject to cognitive processing that constructs meaningful perception. (2) The nativist view assumes that rules about order governing events in the world are inherently given and used to interpret observed events. (3) The third view combines an ecological approach to perception and a systems view. Infants actively seek information that comes to specify identities, places, and affordances in the world. Processes that influence development are the progressive growth and use of action systems, and learning through experience. Perceptual learning is viewed as a selective process, beginning with exploratory activity, leading to observation of consequences, and to selection based on two criteria, an affordance fit and reduction of uncertainty, exemplified by detection of order and unity in what is perceived.

We know much less about perceptual development after the first two years. After infancy, perceptual development takes place mainly in complex tasks such as athletic skills, tool use, way-finding, steering vehicles, using language, and READING—all tasks in which experience and learning become more and more specialized (cf. COGNITIVE DEVELOPMENT). Theoretical applications to specialized tasks involving perceptual learning can be profitable (Abernathy 1993).

Phantom Limb

Phantom limbs occur in 95 to 100 percent of amputees who lose an arm or leg. The phantom is usually described as having a tingling feeling and a definite shape that resembles the somatosensory experience of the physical limb before amputation. It is reported to move through space in much the same way as the normal limb would move when the person walks, sits down, or stretches out on a bed. At first, the phantom limb feels perfectly normal in size and shape —so much so that the amputee may reach out for objects with the phantom hand, or try to step onto the floor with the phantom leg. As time passes, however, the phantom limb begins to change shape. The arm or leg becomes less distinct and may fade away altogether, so that the phantom hand or foot seems to be hanging in midair. Sometimes, the limb is slowly "telescoped" into the stump until only the hand or foot remains at the stump tip.

Amputation is not essential to the occurrence of a phantom. After avulsion of the brachial plexus of the arm, without injury to the arm itself, most patients report a phantom arm that is usually extremely painful. Even nerve destruction is not necessary. About 95 percent of patients who receive an anesthetic block of the brachial plexus for surgery of the arm report a vivid phantom, usually at the side or over the chest, which is unrelated to the position of the real arm when the eyes are closed but "jumps" into it when the patient looks at the arm. Similarly, a spinal anesthetic block of the lower body produces reports of phantom legs in most patients, and total section of the spinal cord at thoracic levels leads to reports of a phantom body, including genitalia and many other body parts, in virtually all patients.

The most astonishing feature of the phantom limb is its "reality" to the amputee, which is enhanced by wearing an artificial arm or leg; the prosthesis feels real, "fleshed out." Amputees in whom the phantom leg has begun to "telescope" into the stump, so that the foot is felt to be above floor level, report that the phantom fills the artificial leg when it is strapped on and the phantom foot now occupies the space of the artificial foot in its shoe. The reality of the phantom is reinforced by the experience of details of the limb before amputation. For example, the person may feel a painful bunion that had been on the foot or even a tight ring on a phantom finger.

Phantoms of other body parts feel just as real as limbs do. Heusner describes two men who underwent amputation of the penis. One of them, during a four-year period, was intermittently aware of a painless but always erect phantom penis. The other man had severe PAIN of the phantom penis. Phantom bladders and rectums have the same quality of reality. The bladder may feel so real that patients, after a bladder removal, sometimes complain of a full bladder and even report that they are urinating. Patients with a phantom rectum may actually feel that they are passing gas or feces. Menstrual cramps may continue to be felt after a hysterectomy. A painless phantom breast, in which the nipple is the most vivid part, is reported by about 25 percent of women after a mastectomy and 13 percent feel pain in the phantom.

The reality of the phantom body is evident in paraplegic patients who suffer a complete break of the spinal cord. Even though they have no somatic sensation or voluntary movement below the level of the break, they often report that they still feel their legs and lower body. The phantom appears to inhabit the body when the person's eyes are open and usually moves coordinately with visually perceived movements of the body. Initially, patients may realize the dissociation between the two when they see their legs stretched out on the road after an accident yet feel them to be over the chest or head. Later, the phantom becomes coordinate with the body, and dissociation is rare.

Descriptions given by amputees and paraplegic patients indicate the range of qualities of experience of phantom body parts. Touch, pressure, warmth, cold, and many kinds of pain are common. There are also feelings of itch, tickle, wetness, sweatiness, and tactile texture. Even the experience of fatigue due to movement of the phantom limb is reported. Furthermore, male paraplegics with total spinal sections report feeling erections, and paraplegic women describe sexual sensations in the perineal area. Both describe feelings of pleasure, including orgasms.

A further striking feature of the phantom limb or any other body part, including half of the body in many paraplegics, is that it is perceived as an integral part of one's SELF. Even when a phantom foot dangles "in midair" (without a connecting leg) a few inches below the stump, it still moves appropriately with the other limbs and is unmistakably felt to be part of one's body-self. The fact that the experience of "self" is subserved by specific brain mechanisms is demonstrated by the converse of a phantom limb —the denial that a part of one's body belongs to one's self. Typically, the person, after a lesion of the right parietal lobe or any of several other brain areas, denies that a side of the body is part of himself.

There is convincing evidence that a substantial number of children who are born without all or part of a limb feel a vivid phantom of the missing part. The long-held belief that phantoms are experienced only when an amputation has occurred after the age of six or seven years is not true. Phantoms are experienced by about 20 percent of children who are born without all or part of a limb (congenital limb deficiency), and 20 percent of these children report pain in their

phantom. Persons with congenital limb deficiency sometimes perceive a phantom for the first time after minor surgery or an injury of the stump when they are adults.

The innate neural substrate implied by these data does not mean that sensory experience is irrelevant. Learning obviously plays a role because persons' phantoms often assume the shape of the prosthesis, and persons with a deformed leg or a painful corn may report, after amputation, that the phantom is deformed or has a corn. That is, sensory inputs play an important role in the experience of the phantom limb. Heredity and environment clearly act together to produce the phenomena of phantom limbs.

Phonetics

Speech is the most common medium by which language is transmitted. Phonetics is the science or study of the physical aspects of speech events. It has a long history. For centuries, phonetic descriptions of particular languages have been undertaken to preserve or reconstruct their pronunciation. Phonetics developed rapidly in the nineteenth century in connection with spelling reform, language (pronunciation) teaching, speech training for the deaf, stenographic shorthands, and the study of historical sound changes. Today phonetics is an interdisciplinary field combining aspects of linguistics, psychology (including perception and motor control), computer science, and engineering. However, in the United States especially, "phonetics" is commonly considered a subfield of linguistics, and "speech science" or "speech" is the more general term.

A common question among linguists and nonlinguists alike is, "What is the difference between phonetics and phonology?" One answer is that phonetics is concerned with actual physical properties that are measured or described with some precision, whereas phonology is concerned with (symbolic) categories. For example, the phonology of a language might describe and explain the allowed sequences of consonants in the language, and the phonetics of the language would describe and explain the physical properties of a given consonant in these different allowed sequences. Nonetheless, even though phonetics deals with physical properties, it is just as much concerned with linguistic knowledge as with behavior. It is not the case that phonology can be identified with "competence" and phonetics with "performance," for example.

Phonetics is usually divided into three areas: speech production, acoustics, and perception. Phoneticians want to understand not only how speech is produced, perceived, and acoustically structured, but how these mechanisms shape the sound systems of human languages. What is the range of speech sounds found in human languages? Why do languages prefer certain sounds and combinations of sounds? How does speech convey linguistic structure to listeners? These are some of the key questions in phonetics. Phoneticians stress that only if the array of sounds used across languages is studied can complete models of speech be developed.

Speech production is the basis of traditional phonetic transcription systems such as the International Phonetic Alphabet (IPA), as well as some phonological feature systems (Catford 1977; Ladefoged 1993; Laver 1994; see PHONOLOGY and DISTINCTIVE FEATURES). The components of speech production are the airstream mechanism (the process by which air flow for speech is initiated), phonation or voicing (production of a sound source by the vibrating vocal cords inside the larynx—this is the most important sound source in speech), ARTICULATION (modification of the phonation sound source, and introduction of additional sound sources, by the movements of articulators), and the oronasal process (modification of the sound source by the flow of air through the nose). Speech sounds are traditionally described as combinations of these components. On the other hand, PROSODY (the suprasegmental variation of loudness, length, and pitch that makes some segments, or larger groupings of segments, more prominent or otherwise set off from others) is traditionally described not in speech-production terms but more in terms of the dimensions of amplitude, duration, and frequency (Lehiste 1970; see STRESS, LINGUISTICS; TONE).

Speech acoustics concerns the properties of speech transmitted from speaker to hearer. Speech sounds are usually described in terms of their prominent frequency components and the durations of intervals within each sound. The source-filter theory of speech production and acoustics (Fant 1960; Stevens, forthcoming) describes speech as the result of modifying acoustic sources by vocal-tract filter functions. The acoustic sources in speech include phonation (described above), noise produced in the larynx (such as for aspiration and breathiness), and noise produced by air flowing through a constriction anywhere in the vocal tract (such as for a fricative sound or after the release of a stop). Every speech sound must involve one or more such sources. The source(s) is then modified by the filter function of the vocal tract. The most important aspect of this filtering is that the airways of the vocal tract have particular resonances, called formants, which serve to enhance any corresponding frequencies in a source. The resonance frequencies depend on the size and shape of the airway, which in turn depend on the positions of all the articulators; thus, as the articulators move during speech, the formant frequencies are varied.

At the same time, phonetics can be divided into practical, experimental, and theoretical approaches. Practical phonetics concerns skills of aural transcription and oral production of speech sounds, usually in conjunction with a descriptive system like the IPA. Different levels of phonetic transcription are traditionally recognized. In a phonemic transcription, the only phonetic symbols used are those representing the phonemes, or basic sounds, of the language being transcribed. In an allophonic transcription, additional symbols are used, to represent more detailed variants (or allophones) of the phonemes. The more such detail included, the narrower the allophonic transcription.

Experimental phonetics is based on the use of laboratory equipment. Laboratory techniques (see Hardcastle and Laver 1997) are generally needed to understand exactly how some sound is produced and to detail its acoustic and/or perceptually relevant properties. When experimental phonetic methods are used to answer questions of interest to phonologists, it is sometimes called "laboratory phonology".

Certain acoustic measurements of speech sounds have become common, especially since the advent of the sound spectrograph, which produces visual displays (spectrograms) of frequency and intensity over time. The most common frequency measurements are the frequencies of vowel formants, of the formant transitions between consonants and vowels, and of the fundamental frequency of phonation. Changes in the source, and the durations of intervals with different sources, are also important in speech; for example the duration between the release of a stop and the onset of voicing (an interval filled with aspiration) is called voice onset time (VOT). There is now a wide range of the world's languages receiving detailed experimental descriptions in terms of these and other measures (e.g., Ladefoged and Maddieson 1996), although of course there remain many languages with unusual sounds whose production, acoustics, and/or perception are not well understood. Furthermore, manipulation of such measures to provide a range of artificial speech stimuli is an important tool of SPEECH PERCEPTION, in determining which acoustic properties matter most to listeners. Experimental phonetics

also contributes to the development of speech technology (see SPEECH SYNTHESIS and SPEECH RECOGNITION IN MACHINES).

Theoretical phonetics is concerned not only with theories of speech production, acoustics, and perception but also with theories to explain why languages have the sounds, grammatical structures, and historical sound changes that they do, and theories to describe the interrelationship of the more abstract patterns of phonology and the physical forms of speech sounds. Phoneticians look for recurring patterns of variation in sounds (see PHONOLOGICAL RULES AND PROCESSES), and then try to understand why they should occur. Phonetic constraints on phonology may be proposed as part of either a reductionist program (see REDUCTIONISM), in which phonology is reduced to phonetics, or an interface program, in which phonetics and phonology are usually recognized as separate components of a grammar.

Phonological Rules and Processes

Phonological processes were first systematically studied in the nineteenth century under the rubric of sound laws relating

the various Indo-European languages. In the twentieth century, attention shifted to a synchronic perspective, prompted by observations such as Edward SAPIR's that as part of their grammatical competence mature speakers unconsciously and effortlessly assign (sometimes radically) different pronunciations to a lexical item drawn from memory and inserted in different grammatical or prosodic contexts. For example, in the pronunciation of the word *átom* American English speakers "flap" the intervocalic consonant to [ɾ] and reduce the unstressed vowel to schwa [ə] so that it merges with *Adam*: ['ærəm]. The underlying phonemes emerge when the stress is shifted under affixation: *atóm-ic* [ətʰam-ɪk]. Processes also figure in the neutralizations found in child language such as the loss of the tongue-tip articulation of *r* so that *room* merges with *womb*.

Phonological processes fall into two broad categories: sound change and prosodic grouping. We briefly illustrate each type. In *in-articulate* versus *im-possible* the prefixal nasal *assimilates* the labial feature of the [p] thereby changing from [n] to [m]. *Dissimilation* alters neighboring sounds that share the same feature so that they become more distinct from one another (see DISTINCTIVE FEATURES). For example, the vocalic nucleus and offglide comprising the [au] diphthong of *how* share a retracted tongue position in most English dialects. In broad Australian English the nucleus is fronted to the [æ] vowel of *cat: h[æu]*. Assimilation and dissimilation are subject to a strict locality condition requiring that they apply in the context of the closest sound with the appropriate feature. The phonological features that define a sound are also subject to *deletion* and *insertion*: the former typically operates in prosodically weak contexts (reduction of unstressed vowels to schwa in *át[ə]m* but *[ə]tóm-ic)* and the latter in strong contexts (aspiration of [t] before stress in *a[tʰ]ómic)*.

Processes of prosodic grouping include the organization of phonemes into syllables. In English a consonant cluster such as [rt] easily combines with the preceding vowel into a single syllable: monosyllabic *mart*. But in order to syllabify the inverse cluster [tr], a helping schwa is required: disyllabic *me.t[ə]r* (cf. *metr-ic*). Languages such as Japanese have simpler syllabic structures that bar syllable-internal consonant clusters and place rigid restrictions on syllable-final consonants. Accordingly, the [rt] cluster in a loanword such as French *courte* [kurt] 'short' receives two extra syllables when it is adapted into Japanese: *kuruto* (Shinohara 1997). At the next level of prosodic organization, syllables are grouped into strong-weak (trochaic) or weak-strong (iambic) rhythmic units known as metrical feet. Native Australian languages impose trochaic rhythm so that words have a canonical SsSsSs . . . syllabic structure in comparison to the iambic grouping sSsSsS . . . found in many Native American languages. English has trochaic grouping as shown by the strong-weak template imposed on nickname formation: *Elízabeth* shortens to Ss *Lísa*; sS *Elí* is impossible.

Some linguists (e.g., Stampe 1979) distinguish between "processes" that reflect phonetically motivated limitations on which sounds can appear where in pronunciation and more arbitrary and conventional "rules" that are typically restricted to particular morphological or lexical contexts

such as the voicing of [f] in the plural of *leaf*: *leaves* but *reefs* (*reeves*) and verbal *he leafs* (*leaves) through the paper*). A plausible but unsubstantiated hypothesis is that rules relate different lexical items stored in memory while processes operate online.

Phonological processes are often phonetically motivated, seeming either to enhance the perceptibility of a sound, especially in "strong" contexts or more formal speaking styles (aspiration of prestressed [t] in *a[tʰ]ómic*), or to minimize articulatory gestures, especially in "weak" contexts or fast tempos (flapping of the stop and reduction of the unstressed vowel of *átom* ['ærəm]). Besides a typology based on their formal properties, phonological processes are also usefully viewed as different solutions to a common phonetic difficulty. For example, the transition from the nasal to the fricative in the consonant cluster of *dense* is relatively complex because it requires synchronization of two independent gestures: raising the velum to shut off nasal airflow and shifting the tongue tip from a closure to a constriction. Common responses include insertion of a transitional stop *den[t]se* (to rhyme with *dents*) or deletion of the tongue-tip closure d[ɛ̃]s. An example from prosody is provided by the widespread tendency to avoid syllables beginning with a vowel. When morphological or syntactic rules juxtapose vowels, a variety of processes come into play to avoid a syllable break between the vowels. These include deletion of one of the vowels (Slavic), contraction of the vowels into a diphthong (Polynesian) or long vowel (Sanskrit), or insertion of a consonantal onset (British English intrusive [r] as in *the idea [r] is*).

Processes are characteristically myopic in the sense that in solving one phonetic problem they often create another. Popular London (Cockney) deletion of initial [h] creates a vowel cluster with the indefinite article ("a hedge" [ə ɛdʒ]— a situation that is otherwise avoided by substitution of the *an* allomorph (cf. "an edge" [ən ɛdʒ]; Wells 1982). To take another example (data from Bethin 1992), in Polish [n] assimilates the place of articulation of a following velar: *ba[ŋ]k* 'bank'. In the Southwestern dialect, the process is extended to clusters arising from the deletion of a weak vowel, whereas in the Northeastern dialect, such derived *nk* clusters remain unassimilated: *ganek* 'porch', *ga[ŋ]ka* SW versus *ga[n]ka* NE genitive singular. Many phonologists (e.g., Halle 1962) conclude from examples like this that processes apply in a linear sequence: in the Southwestern dialect, vowel deletion precedes nasal assimilation, whereas in the Northeastern dialect, nasal assimilation precedes vowel deletion (and so sees /ganek+a/ at its point of application). An alternative interpretation (Donegan and Stampe 1979) sees all processes as applying simultaneously to the input with each given the option to iterate (Southwestern) or not (Northeastern).

Although myopic, phonological processes are typically not self-defeating in the sense of recreating the same problem they are called upon to solve. An example is provided by the liquid [l,r] dissimilation inherited from Latin (Steriade 1995), in which the suffixal [l] of *nav-al, fat-al, mor-al* is turned into [r] when the stem contains an [l]: *stell-ar, lun-ar, column-ar, nucle-ar*. The process systematically blocks when an [r] intervenes between the suffixal and stem [l]'s:

flor-al, *plur-al*, *later-al*. If the point of the change is to avoid successive identical liquids, an output such as **flor-ar* is no better than the input *flor-al* and hence the process is suspended.

Providing empirical substantiation to the notion "phonetic motivation" as well as determining the principles that underlie the interaction of rules and constraints remain outstanding research objectives.

Phonology

Phonology addresses the question of how the words, phrases, and sentences of a language are transmitted from speaker to hearer through the medium of speech. It is easy to observe that languages differ considerably from one another in their choice of speech sounds and in the rhythmic and melodic patterns that bind them together into units of structure and sense. Less evident to casual observation, but equally important, is the fact that languages differ greatly in the way their basic sounds can be combined to form sound patterns. The phonological system of a given language is the part of its grammar that determines what its basic phonic units are and how they are put together to create intelligible and natural-sounding spoken utterances.

Let us consider what goes into making up the sound system of a language. One ingredient, obviously enough, is its choice of speech sounds. All languages deploy a small set of consonants and vowels, called *phonemes*, as the basic sequential units from which the minimal units of word structure are constructed. The phonemes of a language typically average around 30, although many have considerably more or less. The Rotokas language of Papua New Guinea has just 11 phonemes, for example, whereas the !Xũ language of Namibia has 141. English has about 43, depending on how we count and what variety of English we are describing. Although this number may seem relatively small, it is sufficient to distinguish the 50,000 or so items that make up the normal adult LEXICON. This is due to the distinctive role of order: thus, for example, the word s*tep* is linked to a sequence of phonemes that we can represent as /stɛp/, whereas *pest* is composed of the same phonemes in a different order, /pɛst/.

Phonemes are not freely combinable as a maximally efficient system would require but are sequenced according to strict patterns that are largely specific to each language. One important organizing principle is *syllabification.* In most languages, all words can be exhaustively analyzable into syllables. Furthermore, many languages require all their syllables to have vowels. The reason why a fictional patronymic like *Btfsplk* is hard for most English speakers to pronounce is that it violates these principles—it has no vowels, and so cannot be syllabified. In contrast, in one variety of the Berber language spoken in Morocco, syllables need not have vowels, and utterances like *tsqssft stt* ("you shrank it") are quite unexceptional. Here is a typical, if extreme, example of how sound patterns can differ among languages.

Speech sounds themselves are made up of smaller components called DISTINCTIVE FEATURES, which recur in one sound after another. For example, a feature of tongue-front ARTICULATION (or *coronality,* to use the technical term) characterizes the initial phoneme in words like *tie, do, see, zoo, though, lie, new, shoe, chow,* and *jay,* all of which are made by raising the tip or front of the tongue. This feature minimally distinguishes the initial phoneme of *tie* from that of *pie,* which has the feature of labiality (lip articulation). Features play an important role in defining the permissible sound sequences of a language. In English, for instance, only coronal sounds like those just mentioned may occur after the diphthong spelled *ou* or *ow*: We consequently find words like *out, loud, house, owl, gown,* and *ouch,* all words ending in coronal sounds, but no words ending in sound sequences like *owb, owf, owp, owk,* or *owg.* All speech sounds and their regular patterns can be described in terms of a small set of such features.

A further essential component of a sound system is its choice of "suprasegmental" or prosodic features such as LINGUISTIC STRESS, by which certain syllables are highlighted with extra force or prominence; TONE, by which vowels or syllables bear contrastive pitches; and intonation, the overall "tune" aligned with phrases and sentences. Stress and tone may be used to distinguish different words. In some varieties of Cantonese, for example, only

tone distinguishes *si* "poem" (with high pitch), *si* "cause" (with rising pitch), and *si* "silk" (with falling pitch). Prosodic features may also play an important role in distinguishing different sentence types, as in conversational French where only intonation distinguishes the statement *tu viens* "you come" (with falling intonation) from the corresponding question *tu viens?* (with rising intonation). In many languages, stress is used to highlight the part of the sentence that answers a question or provides new information (cf. FOCUS). Thus in English, an appropriate reply to the question "Where did Calvin go?" is *He went to the STORE*, with main stress on the part of the sentence providing the answer, whereas an appropriate reply to the question "Did you see Calvin with Laura?" might be *No, I saw FRED with her*, where the new information is emphasized. Though this use of stress seems natural enough to the English speaker, it is by no means universal, and Korean and Yoruba, to take two examples, make the same distinctions with differences in word order.

Although phonological systems make speech communication possible, there is often no straightforward correspondence between underlying phoneme sequences and their phonetic realization. This is due to the cumulative effects of sound changes on a language, many of them ongoing, that show up not only in systematic gaps such as the restriction on vowel + consonant sequences in English noted above but also in regular alternations between different forms of the same word or morpheme. For example, many English speakers commonly pronounce *fields* the same way as *feels*, while keeping *field* distinct from *feel*. This is not a matter of sloppy pronunciation but of a regular principle of English phonology that disallows the sound [d] between [l] and [z]. Many speakers of American English pronounce *sense* in the same way as *cents*, following another principle requiring the sound [t] to appear between [n] and [s]. These principles are fully productive in the sense that they apply to any word that contains the underlying phonological sequence in question. Hosts of PHONOLOGICAL RULES AND PROCESSES such as these, some easily detected by the untrained ear and others much more subtle, make up the phonological component of English grammar, and taken together may create a significant "mismatch" between mentally represented phoneme sequences and their actual pronunciation. As a result, the speech signal often provides an imperfect or misleading cue to the lexical identity of spoken words. One of the major goals of speech analysis—one that has driven much research over the past few decades—is to work out the complex patterns of interacting rules and constraints that define the full set of mappings between the underlying phonemic forms of a language and the way these forms are realized in actual speech.

Why should phonological systems include principles that are so obviously dysfunctional from the point of view of the hearer (not to mention the language learner)? The answer appears to lie in the constraints imposed "from above" by the brain and "from below" by the size, shape, and muscular structure of the speech-producing apparatus (the lungs, the larynx, the lips, and the tongue). The fact that languages so commonly group their phonemes into syllables and their syllables into higher-level prosodic groupings (metrical feet, phrases, etc.) may reflect a higher-order disposition to group serially ordered units into hierarchically organized structures, reflected in many other complex activities such as memorization, versification (see METER AND POETRY), and jazz improvisation. On the other hand, human biology imposes quite different demands, often requiring that complex phonemes and phoneme sequences be simplified to forms that are more readily articulated or that can be more easily distinguished by the ear.

Research on phonology dates back to the ancient Sanskrit, Greek, and Roman grammarians, but it received its modern foundations in the work of Henry Sweet, Jan Baudouin de Courtenay, Ferdinand de SAUSSURE, and others in the late nineteenth century. Principles of phonemic analysis were subsequently worked out in detail by linguists such as BLOOMFIELD, SAPIR, Harris, Pike, and Hockett in the United States and Trubetzkoy, Hjelmslev, and Martinet in Europe. Feature theory was elaborated principally by Roman JAKOBSON and his associates in the United States, and the study of suprasegmental and prosodic features by Kenneth Pike as well as by J. R. Firth and his associates in London. Since mid-century, linguists have increasingly attempted to develop explicit formal models of phonological structure, including patterns of phonologically conditioned morpheme alternation. In their watershed work *The Sound Pattern of English* (1968), Noam Chomsky and Morris Halle proposed to characterize the phonological competence of English speakers in terms of an ordered set of rewrite rules, applying in strict order to transform underlying representations into surface realizations. More recent trends taking such an approach as their point of departure have included the development of so-called nonlinear (autosegmental, metrical, prosodic) models for the representation of tone, stress, syllables, feature structure, and prosodic organization, and the study of the interfaces between phonology and other areas of language, including SYNTAX; MORPHOLOGY; AND PHONETICS. At the present time, newer phonological models emphasizing the role of constraints over rewrite rules have become especially prominent, and include principles-and-parameters models, constraint-and-repair phonology, declarative phonology, connectionist-inspired approaches, and most recently OPTIMALITY THEORY.

Viewed from a cognitive perspective, the task of phonology is to find the mental representations that underlie the production and perception of speech and the principles that relate these representations to the physical events of speech. This task is addressed hand-in-hand with research in related areas such as LANGUAGE ACQUISITION and language pathology, acoustic and articulatory phonetics, PSYCHOLINGUISTICS, neurology, and computational modeling. The next decades are likely to witness increased cross-disciplinary collaboration in these areas.

As one of the basic areas of grammar, phonology lies at the heart of all linguistic description. Practical applications of phonology include the development of orthographies for unwritten languages, literacy projects, foreign language teaching, speech therapy, and man-machine communication (see SPEECH SYNTHESIS and SPEECH RECOGNITION IN MACHINES).

Phonology, Acquisition of

The acquisition of PHONOLOGY—or rather its development—may be divided into two fields: SPEECH PERCEPTION and speech production. There are two reasons why the development of perception is prior to the development of production. One is that although the human ear is almost completely formed when the fetus is 7 months, the oral cavity of a human at birth is very different from the adult's oral cavity. The second reason is that in order to produce the sounds of a given language, a child must be exposed to the relevant linguistic experience. Babbling infants, in fact, produce all sorts of linguistic sounds, even ones they have never heard in their linguistic environment. Although the first reason why perception is prior to production holds exclusively for the acquisition of the mother tongue (L1), the second holds both for the acquisition of L1 and of whichever language comes after L1 (L2).

A child comes into life well equipped to hear subtle differences in sounds (Eisenberg 1976). Though it is conceivable that some speech perception development starts before birth, because newborns discriminate the mother language from a foreign one (Mehler et al. 1988), it is generally assumed that the development of language perception starts at birth.

The most widely accepted theory of speech perception is the innatist theory, first proposed by JAKOBSON and much influenced by the work of Chomsky and other generative linguists. A mechanism, called the LANGUAGE ACQUISITION device (LAD), is assumed to be responsible for the ability humans have to analyze linguistic inputs and to construct grammars that generate them (see GENERATIVE GRAMMAR). Given that some properties of language are common to all languages of the world, it may be assumed that these are the consequences of the innate human endowment. The development of a specific language is achieved through the setting of the values of a set of parameters on the basis of the linguistic data one is exposed to.

According to the innatist hypothesis, a newborn can discriminate between pairs of segments (consonant and vowels) attested in at least one language of the world, even if they are not distinctive in the language they are exposed to (Jakobson 1941). Testing what infants hear has become possible only in the last twenty years. The methodology to test young infants' perception is the nonnutritive (or high amplitude) sucking method (Eimas et al. 1971). When infants are 6 months or older, the preferential headturn procedure is commonly used to test sound discrimination (Moore, Wilson, and Thomson 1977). It has been shown

that, indeed, for the newborn, the ability to discriminate does not appear to be related to the language he or she is exposed to (Streeter 1976). At a later stage of development, around 10 months, infants start losing the ability to discriminate sounds that are not distinctive in the language(s) they are exposed to (Werker and Tees 1984; Kuhl et al. 1992). This is in line with the learning by selection theory of neurological development (Changeux, Heidmann, and Patte 1984). It has also been shown that already from 1 month, infants represent linguistic sounds categorically, that is, different acoustic variants of a sound are identified with one category (Eimas, Miller, and Jusczyk 1987; Kuhl 1993).

Perceiving phonological distinctions is not only relevant to the acquisition of a phonological system but is also essential to the development of both LEXICON and SYNTAX. Newborns are in a position similar to that of adults when they hear a language unrelated to any other language of which they have some experience. One of the problems in constructing a lexicon is segmenting a continuous stream of sounds. In order to build a lexicon, a child must come to understand where each word ends and the next one begins. Because newborns are sensitive to edges of phonological or prosodic constituents (Christophe et al. 1994) and to LINGUISTIC STRESS (Sansavini et al. 1995), it is conceivable that they use these prosodic cues to segment the continuous input (cf. PROSODY AND INTONATION).

According to the theory of language initialization known as prosodic bootstrapping, the prosody of a language also provides a cue to its syntactic structure (Gerken, Jusczyk, and Mandel 1994). Given its sensitivity to prosody, an infant should thus be capable of setting certain syntactic parameters long before the period in which he or she shows some knowledge of the lexicon (Mazuka 1996; Nespor, Guasti, and Christophe 1996). The early setting of parameters responsible for word order accounts for the fact that the monolingual child hardly makes any mistakes in the relative order of words when he or she starts combining them into small sentences.

Speech production starts with babbling, the first approximation to language. The vocal apparatus approaches an adult state at about 6 months of age, so it is only from this period that it is safe to talk about babbling. Though the segmental categories in babbling do not resemble those of the adult language (de Boysson-Bardies 1993), even at this first stage, speech production is influenced by speech perception: babbling does not develop normally without an auditory input (Oller and Eilers 1988). In auditorily unimpaired infants, suprasegmentals (i.e., rhythm and intonation) are acquired before segments are, as early as at 6 months (Whalen, Levitt, and Wang 1991). Around the first year of age, both the vowel quality and the syllabic structure of auditorily unimpaired babbling infants is much influenced by that of the adult language (de Boysson-Bardies et al. 1989; Vihman 1992). The first syllable type produced throughout the languages of the world is one formed by a consonant (C) followed by a vowel (V). This is also the only syllable type universally present. The segmental content of the first syllables is such that C and V are as far apart as possible in sonority—that is, C is pronounced with high air pressure in the oral cavity compared to the external air pressure, as in [p], whereas in the pronunciation of V, the internal pressure is similar to the external one, as in [a]. Subsequently different CV combinations develop and different parameters are set to give the full range of adult syllables such as whether a prevocalic consonant is obligatory or not or whether a postvocalic consonant is allowed or not. PHONOLOGICAL RULES AND PROCESSES also develop with time. For example, the centralization to schwa of unstressed vowels in English is not part of early productions.

The acquisition of the phonology (and of grammar in general) of L1 appears to be impaired after the fifth year of life. This claim is based on the experience of humans who have not been in contact with a speaking community and have been found at age 5 or more. The acquisition of the phonology of L2 appears to be impaired after puberty, as witnessed by the foreign-accent phenomenon, responsible for the fact that we can distinguish a native speaker from a nonnative one. Interestingly, the acquisition of syntax (i.e., the computational system) is not so impaired.

Phonology, Neural Basis of

PHONOLOGY refers to the sound structure of language. As such, the study of phonology includes investigation of the representations and organizational principles underlying the sound systems of language, as well as the exploration of the mechanisms and processes used by the listener in speech perception or by the speaker in speech production. The study of the neural basis of phonology is guided by an attempt to understand the neural mechanisms contributing to the perception and production of speech. This domain of inquiry has largely focused on investigations of adult aphasics who have language deficits subsequent to brain damage, exploring their language impairments and accompanying lesion localization. These "experiments in nature" provide the traditional approach to the study of the neural bases of phonology. More recently, neuorimaging techniques, such as POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI), have provided a new window into the neural mechanisms contributing to phonology, allowing for investigation of neural activity in normal subjects as well as brain-damaged patients.

It has been long known that the left hemisphere is dominant for language for most speakers, and that the peri-sylvian regions of the left hemisphere are most directly involved in LANGUAGE PRODUCTION and SPEECH PERCEPTION. The classical view has characterized speech/language deficits in APHASIA in terms of broad anatomical (left anterior and left posterior) and functional (expressive and receptive) dichotomies (Geschwind 1965). In this view, expressive language deficits occur as a result of damage to the motor (anterior) areas, and receptive language deficits occur as a result of damage to the auditory association (posterior) areas. Nonetheless, the processing components involved in both speech production and perception are complex and appear to involve more extensive neural structures than originally proposed.

In order to produce a word or group of words, a speaker must select the word(s) from the set of words in long-term memory, encode its phonological form in a short-term buffer in order to plan the phonetic shape, which will vary as a function of the context (*articulatory phonological planning*), and convert this phonetic string into a set of motor commands or motor programs to the vocal tract (*articulatory implementation*). Results from studies with aphasic patients show that all patients, regardless of clinical syndrome and accompanying lesion localization, display deficits in the processes of selection and planning (Blumstein 1994). That is, they may produce the wrong sound segment, a selection error, such as "keams" for "teams", or they may produce the wrong sound segment because of the influence of a neighboring sound, a planning error, such as "rof beef" for "roast beef." The patterns of errors that occur show that the sounds of speech are organized in terms of smaller units called phonetic features (cf. DISTINCTIVE FEATURES), and that patients tend to make errors involving a change in the value of a phonetic feature. For example, the production of "keams" for "teams" reflects a change in the place of articulation of the initial stop consonant. Of importance, phonetic

features are not "lost," but the patterns of errors reflect statistical tendencies. Sometimes the patients produce a word correctly, sometimes not; and sometimes they may make one type of error on a word, and other times a different type of error on the same word. These phonological deficits arise in nearly all aphasic patients including Broca's aphasics who may have brain damage in Broca's area and other anterior brain structures such as the precentral gyrus and the BASAL GANGLIA, and Wernicke's aphasics who may have brain damage in the third temporal gyrus and other posterior structures such as the second temporal gyrus and the supramarginal gyrus.

Although speech-production deficits that relate to selection and planning may not have a distinct neural locus, speech-production impairments that relate to articulatory implementation processes do. Such deficits seem to stem from impaired timing and coordination of articulatory movements (Ryalls 1987). The correct sound may be selected, but the articulatory system cannot implement it normally. For example, for "teams" the patient may produce an overly aspirated initial /t/. Lesion data from aphasic patients and evoked potential and PET data from normal subjects implicate the left inferior frontal gyrus (including Broca's area), the precentral gyrus, the basal ganglia, the precentral gyrus of the insula, and the supplementary motor areas, in the articulatory implementation of speech (Baum et al. 1990; Dronkers 1996; Petersen et al. 1989). Interestingly, although the speech musculature is bilaterally innervated, speech-production deficits emerge only as a consequence of left-brain damage and not right-brain damage to these structures.

Speech perception processes are also complex. They require a transformation of the auditory input from the peripheral auditory system to a spectral representation based on more generalized auditory patterns or properties, followed by the conversion of this spectral representation to a more abstract feature (phonological) representation, and ultimately the mapping of this sound structure onto its lexical representation. Presumably, the word is selected from a set of potential word candidates that are phonologically similar. Speech perception studies support the view that the neural basis of speech perception is dominant in the left hemisphere. However, they challenge the classical view that these deficits underlie the auditory comprehension impairments of Wernicke's aphasics and that speech perception impairments are restricted to patients with temporal lobe pathology. Nearly all aphasic patients, regardless of their lesion localization, display some deficits in perceiving the sounds of speech, as demonstrated by discrimination experiments with words, "pear" versus "bear," or nonwords, "pa" versus "ba." These patients do not seem to have impairments in transforming the auditory input into a phonological form nor do they show impairments in phonological structure. Differences among aphasic patients relate to the quantity of errors, not the patterns of errors. The basis for the different quantity of errors might reflect a greater involvement of posterior structures in such speech processing tasks. Nonetheless, differential patterns of performance do emerge in studies exploring the mapping of sound structure onto lexical representations, implicating lexical processing deficits for Broca's and Wernicke's aphasics rather than speech

processing impairments (Milberg, Blumstein, and Dworetzky 1988).

PET and fMRI studies provide converging evidence consistent with the results from studies with aphasic patients. These studies have shown activation in a number of posterior and anterior structures when passively listening to words or in making phonetic judgments. These structures include the first and second temporal gyri, the supramarginal gyrus, the inferior frontal gyrus, as well as premotor areas. Nonetheless, direct comparisons between the behavioral/lesion studies and the neuroimaging studies are difficult because the experimental tasks used have not been comparable. For example, patients may be required to listen to pairs of words and make same/different judgments, whereas normal subjects may be required to listen to pairs of words and determine whether the final consonant of the stimuli is the same. Even so, it seems clear that the processes involved in the perception of speech are complex and invoke a neural system that encompasses both anterior and posterior brain structures.

Physicalism

Physicalism is the doctrine that everything that exists in the spacetime world is a physical thing, and that every property of a physical thing is either a physical property or a property that is related in some intimate way to its physical nature. Stated this way, the doctrine is an ontological claim, but it has important epistemological and methodological corollaries.

Physicalists in general will accept the following thesis of "ontological physicalism" (Hellman and Thompson 1975): Every object in spacetime is wholly material—that is, it is either a basic particle of matter (proton, electron, quark, or whatever) or an aggregate structure composed exclusively of such particles. Ontological physicalism, therefore, denies the existence of things like Cartesian souls, supernatural divinities, "entelechies," "vital forces," and the like. Physicalists, however, differ widely when it comes to the question of *properties* of physical objects—whether complex physical systems can have properties that are in some sense nonphysical. But what is a *physical property*?

It is difficult to give a clear-cut answer to this question. In a narrow sense, physical properties are those properties, relations, quantities, and magnitudes that figure in physics, such as mass, energy, shape, volume, entropy, temperature, spatiotemporal position and distance, and the like. Most will also include chemical properties like valence, inflammability, and acidity, although these are not among the basic physical properties—properties that figure in basic physical laws (in this sense entropy and temperature are not basic

either). In discussions of the status of cognitive/psychological properties, physical properties are usually also taken to include such *higher-level* properties as biological properties and computational properties. This broad sense of physical property seems appropriate to the discussion of the question how psychological properties are related to physical properties—that is, the MIND-BODY PROBLEM. In its broad sense, therefore, "physical" essentially amounts to *"nonpsychological."* This leaves our previous question unanswered: what is a physical property? Mass, charge, energy, and the like are of course important properties in current physics, but the physics of the future may invoke properties quite different from those in today's physics. How would we recognize them as physical properties rather than properties of another sort? That is, how would we know that future physics is *physics*?

As noted, physicalists differ on the status of higher-level properties in relation to lower-level, basic physical properties. *Reductive physicalism* claims that higher-level properties, including psychological properties, are reducible to, and hence turn out to be, physical properties. Opposed to reductive physicalism is *nonreductive physicalism,* also called *property dualism,* which takes at least some higher-level properties, in particular cognitive/psychological properties, to form an irreducible autonomous domain. This would mean that psychology is a special science whose object is to investigate the causal/nomological connections involving these irreducible psychological properties and generate distinctively psychological explanations in terms of them. In this view, these laws and explanations cannot be formulated in purely physical terms—not even in an ideally complete physical theory—and a purely physical description of the world, however physically complete it may be, would leave out something important about the world. Nonreductive physicalism, therefore, leads to the doctrine of the AUTONOMY OF PSYCHOLOGY and, more generally, the autonomy of all special sciences in relation to basic physics (Davidson 1970; Fodor 1974).

The mind-brain identity theory (Feigl 1958; Smart 1959; Armstrong 1968) is a form of reductive physicalism. This approach proposes to identify psychological properties with their neural correlates; for example, pain is to be identified with its neural substrate ("C-fiber stimulation," according to armchair philosophical neurophysiology). These mental-neural identities are claimed to be just like the familiar identities discovered by science, for example, "Water = H_2O," "Light = electromagnetic radiation," and "Genes = DNA molecules." Just as the "true nature" of water is being composed of H_2O molecules, advances in neurophysiology will reveal to us the true nature of each type of mental state by identifying it with a specific kind of brain state.

EMERGENTISM, a doctrine popular in the first half of the twentieth century, is a form of nonreductive physicalism (Morgan 1923; Sperry 1969; McLaughlin 1992). Its central tenet is the claim that certain higher-level properties, in particular consciousness and intentionality, are *emergent* in the sense that, although they appear only when a propitious set of physical conditions are present, they are genuinely novel properties that are neither explainable nor predictable in terms of their underlying physical conditions. Moreover,

these emergent properties bring into the world their own distinctive causal powers, thereby enriching the causal structure of the world. FUNCTIONALISM is also often thought to be a form of nonreductive physicalism. According to this position, psychological properties are not physical or neural properties, but rather *functional kinds,* where a functional kind is a property defined in terms of causal inputs and outputs. To give a familiar example, pain is said to be a functional kind in that being in pain is to be in some physical/biological state that is typically caused by certain types of physical inputs (e.g., tissue damage) and that causes certain behavioral outputs (e.g., groaning, wincing, escape behavior). It is then noted that a psychological kind when given a functional interpretation of this kind has *multiple physical realizers* (Putnam 1967; Block and Fodor 1972; Fodor 1974); that is, the neural mechanism that realizes or implements pain in humans is probably vastly different from the pain mechanisms in reptiles, mollusks, and perhaps certain complex electromechanical systems. This is "the multiple realization argument" against reductionism: because pain is multiply realized in diverse physical/biological mechanisms, it cannot be identified with any single physical or biological property. This has led to the view that cognitive/psychological properties are at a higher level of abstraction and formality than the physical/biological properties that implement them (Kim 1992).

However, nonreductive physicalists, insofar as they are physicalists, will acknowledge that psychological properties, although physically irreducible, are in some sense dependent on, or determined by, physical properties—unless, that is, one is prepared to take their physical irreducibility as proof of their unreality and adopt eliminativism/irrealism (or ELIMINATIVE MATERIALISM) about the mental (Churchland 1981). That is, physicalists who accept the reality of the mental will accept the mind-body SUPERVENIENCE thesis (Hellman and Thompson 1975; Horgan 1982; Kim 1984): the psychological character of an organism or system is entirely fixed by its total physical nature. From this it follows that any two systems with a relevantly similar physical structure will exhibit an identical or similar psychological character. Even emergentists will grant that when identical physical conditions are replicated, the same mental phenomenon will emerge, or fail to emerge. Supervenience is also a commitment of functionalism: systems in identical physical conditions presumably have the same causal powers and so will instantiate the same functional properties. It is a basic commitment of all forms of physicalism that the world is the way it is because the physical facts of the world are the way they are. That is, physical facts fix all the facts.

Among the facts of this world are causal facts, including those involving mental and other higher properties. The supervenience thesis implies then that these higher-level causal facts are fixed by lower-level physical facts, presumably facts about physical causal relations. The same goes for higher-level laws: under supervenience, these laws are fixed once basic physical facts, in particular basic laws of physics, are fixed. According to the supervenience thesis, therefore, physical laws and causal relations are fundamental; they, and they alone, are ultimately responsible for the causal/nomic structure of the world. But this conclusion does not comport comfortably with the claim that the special sciences are autonomous vis-à-vis basic physics. For if the laws and causal relations obtaining at the basic physical level determine all higher-level causal relations and laws, it should be possible in principle, or at least so it seems, to formulate explanations of higher-level laws and phenomena within the physical domain. If the world works the way it does because the physical world works the way it does, why is it not possible to explain everything in terms of how the physical world works?

Some will challenge this reasoning. They will argue that for *X* to *determine Y* is one thing, but that for *X* to *explain* or *make intelligible* why *Y* occurs is quite another. Pain emerges whenever C-fibers are firing, and this may well be a lawlike correlation. But the correlation is "brute": it is not possible to explain why pain, rather than tickle or itch, emerges when C-fibers fire, or why pain emerges from C-fiber excitation but not from other kinds of neural activity. Nor do we seem able to explain why any conscious states should emerge from neural processes. For the emergentists, then, although all higher-level facts are determined by lower-level physical facts, the latter are powerless to explain the former. The world may be a fundamentally physical world, but it may well include physically inexplicable facts.

Whether and how the functionalist can resist the reductionist pressure is less clear. Suppose, as functionalism has it, that being in mental state *M* is to be in some physical state or other meeting a certain causal specification *D*. It would seem then that we could easily explain why something is in *M* by pointing out that it is in *P* and that *P* meets causal specification *D*—namely that *P* is a realizer of *M*. And given the functional characterization of *M,* it seems to follow that the causal powers of a given instance of *M* are just the causal powers of its realizer *P* on this occasion. Thus, if it is a special-science law that *M*-events cause *M**-events, that must be so because each of *M*'s physical realizers causes a physical realizer of *M**. In this way, special-science laws would seem reductively explainable in terms of laws governing the realizers of the special-science properties involved.

"Materialism" is often used interchangeably with "physicalism." However, there are some subtle differences between these terms, the most salient of which is that physicalism indicates acknowledgment that something like current physics is the ultimate explanatory theory of all the facts, whereas materialism is not necessarily allied with the success of physics as a basic explanatory theory of the world.

Piaget, Jean

Jean Piaget's (1896–1930) research program about human knowledge counts as one of the major contributions to psychology and epistemology because it has translated philosophical questions into empirical ones, setting a standard against which any new paradigm about the nature and growth of knowledge is still measured today. Hence its pertinence for cognitive sciences because, like them, Piaget departed from the limited aims of psychology to discover the most general principles of cognition.

Piaget's basic idea is that knowledge continues biological ADAPTATION by different means. This means that intelligence is considered as a sort of organ and, as such, has both a functional side and a structural one. But, whereas other organs have fixed structures and fixed functions, cognitive organs present a functional continuity within structural discontinuities. The functional continuity is the emergence and growth of knowledge during evolution. Structural discontinuities are the different forms knowledge takes during the course of the growth of a species, a culture, or an individual. These discontinuities are marked by a stage like construction of successive invariants ensuring a certain stability to the world in which the organism lives (homeostasis).

Such a position is called constructivism in epistemology, because it is a sort of midway between two opposites: realism and nominalism. REALISM pretends that things exist independently of their instances in the actual world by necessity. Such a view secures the objectivity and universality of knowledge. Nominalism considers that what we call things are mere conveniences that vary according to one's needs and conventions. This relativistic approach accounts for the variability of things according to cultural changes. As one can see, constructivism being both fixed in its functional dimension and ever changing in its structural one solves the opposition gracefully without reducing one perspective to the other or excluding one in favor of the other.

The rest of Piaget's program characterizes the sequences and mechanisms by which rational knowledge develops.

Sequences of development are marked by a constant abstraction of conservation from the mere permanence of objects to the laws of conservation in physics and chemistry. In order for the world to acquire the minimum stability requested to retrieve an object once it has disappeared from perception, space must be conceived as a container within which all the moves of an observer form a mathematical group of displacements. Then time, matter, weight, and volume need to be conserved first in action, symbols, and concepts, as well as logical classes, relations, and numbers, on the logico-mathematical side.

Conservation accounts for the preservation of knowledge at each level of development but not for the acquisition of new knowledge. This is made possible by *novelty* or the attainment of better knowledge and by *necessity* or the interconnection of all available knowledge into logically necessary systems.

Novelty plays an important role in Piaget's theorizing. First, the emergence of novelty in knowledge is considered by him as evidence in favor of his constructivistic view and against the two extreme positions in the nature-nurture dilemma. NATIVISM and environmentalism both exclude novelty because it is mere unfolding in nativism and a matter of learning in environmentalism. Second, the sudden emergence of novelty proves the stage like nature of the growth of knowledge. But, third and above all, novelty changes the face of knowledge both in the child and in science. Once a child has discovered that, when one gets the concept of number, all the numerical operations will yield a number and nothing else but a number ad infinitum, this

novel knowledge changes the child's outlook of the world in the very same way that the discovery of object permanence makes the baby search for objects that have disappeared and abandon the "out of sight out of mind" attitude so typical of newborns. In science, the double movement of geometrization of physics and physicalization of space accomplished by Albert Einstein when he applied Georg Riemann's geometry to gravity modified completely the way physicists looked at the world. Thus progress in cognition both generates and is generated by novelty.

But novelty is not enough. Knowledge needs to be true knowledge (novelty) and knowledge of the truth (necessity). This could not be explained only in terms of an interaction between nature and nurture because how could mere contingencies generate necessity? Piaget offers a more general factor: *equilibration,* subsuming nature and nurture, under one explanatory system transcending them in levels of generality, necessity, and abstraction. To understand the abstract nature of equilibration, let us suppose that living organisms are governed by the second law of thermodynamics. If this is so, then the resulting increase in entropy of the system cannot be considered as either innate or acquired but as depending on a law of probability. In the very same way, equilibration is the law of development, an abstract necessary principle independent of any contingencies and resulting in an endless optimization of living systems (homeorhesis) in a stage like sequence considered as the ideal course of evolution or chreode.

A number of criticisms have been raised against Piaget's psychological points: age of attainment, neuropsychological mechanisms of concept acquisition, etc. These criticisms have unfortunately confused Piaget's epistemological points that are essential to his theory with psychological ones that are contingent and thus open to change for him too, because they were just algorithms.

Pictorial Art and Vision

Pictorial art attempts to capture the three-dimensional structure of a scene—some chosen view of particular objects, people, or a landscape. The artist's goal is to convey a message about the world around us, but we can also find in art a message about the workings of the brain. Many look to art for examples of pictorial depth cues—perspective, occlusion, TEXTURE gradients, and so on—as these are the only cues available for depth in pictures. DEPTH PERCEPTION based on binocular disparity, vergence, and accommodation is inappropriate for the depths depicted, and head movements no longer provide new views of the scene. However, pictorial cues are abundant in real scenes—that is why they work in pictures—and there is no obvious benefit in studying their effectiveness in art as opposed to their effectiveness in natural scenes.

And yet pictorial art can tell us a great deal about vision and the brain if we pay attention to the ways in which paintings differ from the scenes they depict. First of all, we learn that artists get away with a great deal—impossible colors, inconsistent shading and shadows, inaccurate perspective, the use of lines to stand for sharp discontinuities in depth or brightness. These representational "errors" do not prevent human observers from perceiving robust three-dimensional forms. Art that captures the three-dimensional structure of the world without merely recreating or copying it offers a

(b)

13083 - MILANO - La Flagellazione di N. S. - Signorelli - Brera   Anderson - Rome

(c)

Figure 1. (a) An early example of outline drawing from France. (b) As you view this image from different angles, the changes in the distance from face to hand and in the shape of the head are subtle. A 3-D computer model of this scene would require large-scale relative motions and 3-D shape changes to maintain the 2-D view seen with changing viewpoints. (c) Impossible lighting, highlights, or shadows (note the overlapping cast shadows at the bottom) are difficult to spot in paintings, implying that human observers use a simplistic local model of light and shade.

revealing glimpse of the short cuts and economies of the inner codes of vision. The nonveridicality of representation in art is so commonplace that we seldom question the reason why it works.

A line drawing of a building or an elephant can convey its 3-D structure very convincingly, but remember that there are no lines in the real world corresponding to the lines used in the drawings. The surface occlusions, folds, or

creases that are represented by lines in drawings are revealed by changes in, say, brightness or texture in the real world, and these changes have one value extending on one side and a different value on the other. This is not a line. It is not obvious why lines should work at all. The effectiveness of line drawings is not based simply on learned convention, passed on through our culture. This point has been controversial (Kennedy 1975; see Deregowski 1989, and its following comments), but most recent evidence suggests that line drawings are universally interpreted in the same way—infants (Yonas and Arterberry 1994), stone-age tribesmen (Kennedy and Ross 1975), and even monkeys (Itakura 1994) appear to be capable of interpreting line drawings as we do. Nor is it the case that the lines in line drawings just trace the brightness discontinuities in the image, because this type of representation is rendered meaningless by the inclusion of cast shadow and pigment contours. By a quirk of design or an economy of encoding, lines may be directly activating the internal code for object structure, but only object contours can be present in the drawing for this shortcut to work. The shortcut, discovered and exploited by artists, hints at the simplicity of the internal code that underlies the vision of 3-D structures. This code is both simpler than the 2 ½-D sketch of David MARR and sparser than the compact, reversible codes (Olshausen and Field 1996) that may reflect the workings of early areas of VISUAL CORTEX. Both artists and brains have found out which are the key contours necessary to represent the essential structure of an object. By studying the nature of lines used in line drawings, scientists too may eventually join this group.

Another aspect as commonplace and as informative as the effectiveness of lines is that pictures are flat and yet they provide consistent, apparently 3-D interpretations from a wide range of viewpoints. This is not only convenient for the artist, but also prime evidence that our impressions of a 3-D world are not supported by true, 3-D internal representations. If we had real 3-D vision, the scene depicted in a flat picture would have to distort grotesquely in 3-D space as we moved about the picture. To the contrary, however, objects in pictures seem reassuringly the same as we change our vantage point (with some interesting exceptions; see Gregory 1994). We don't experience the distortions probably because the visual system does not generate a true 3-D representation of the object. It has some qualities of three dimensions but it is far from Euclidean. It may follow some other geometry, affine or nonmetric in nature (Todd and Reichel 1989; Busey, Brady, and Cutting 1990). The effectiveness of flat images is of course a boon to artists who do not have to worry about special vantage points and to film makers who can have theaters with more than one seat in them. It is also of great importance for understanding the internal representations of objects and space.

Finally, consider the enormous range of discrepancies between light and shade in the world and their renditions in art. When light and shade were introduced into art about 2,200 years ago, it was through the use of local techniques such as lightening a surface fold to make it come forward (a Greek technique described by Pliny the Elder; see Gombrich 1976 for a beautiful reinterpretation of this ancient presentation of painting techniques). These local techniques of shading, shadows, and highlights were applied with little thought to making them all consistent with a given light source—and yet they all work very well. Even 500 years ago, when the geometry of perspective was well understood, the geometry of light was still ignored. The resulting errors in light and shadow would be caught immediately by any analysis based on physical optics, but pass unnoticed to human observers. Modern artists with a full understanding of the physics of light and shade available to them often still choose inconsistencies in lighting either because it never matters much, or perhaps because it looks better.

Evidently, we as observers do not reconstruct a light source in order to recover the depth from shading and shadow, we do not act as optical geometers in the way that computer graphics programs can. We do not notice inconsistencies across different portions of a painting but recover depth cues locally. The message here is that in the real world, the information is rich and redundant, so we do not have to analyze the image much beyond a local region to resolve any ambiguities. When faced with the sparser cues of pictorial art, we do not adopt a larger region of analysis—the local cues are meaningful, albeit inconsistent with cues in other areas of the painting. To the advantage of the artist, the inconsistencies go unnoticed. And again, like many aspects of art, this discrepancy between the art and the scene it depicts informs us about the brain within us as much as about the world around us.

Pitts, Walter

Walter Pitts was born in 1923, vanished from the scene in the late 1950s, and died at the end of the 1960s, having destroyed, as much as he could, any traces of his past existence. He is a peculiarly difficult subject for a biography because, although he remains a vividly haunting memory to those who knew him, he seems only a group delusion to others. At least that was the opinion of the neurologist Norman GESCHWIND.

Pitts appeared as a penniless 14-year-old at the University of Chicago in 1937, attended various classes, though unregistered, and was accepted by Rashevsky's coterie as a very talented but mysterious junior. All that was known of him was that he came from Detroit, and that would be all that was known thereafter.

An autodidact, he read Latin, Greek, Sanskrit, and German (though did not speak them) and apparently was advanced well beyond his years in LOGIC. The last can be illustrated by a confirmable anecdote. In 1938 he appeared at the office of Rudolf Carnap, whose most recent book on logic had appeared the previous year. Without introducing himself, Pitts laid out his copy opened to a section annotated marginally, and proceeded to make critical comments on the material. Carnap, after initial shock, defended his work and engaged with Pitts in an hour or so of talk. Pitts then left with his copy. For several weeks, Carnap hunted through the university for "that newsboy who understood logic," finally located him, and found a job for him, for Pitts had no funds and lived only on what he could earn from ghosting papers for other students.

In 1938, Pitts, Jerry Lettvin, and Hy Minsky (the future economist) formed a friendship that would endure over the years. When Lettvin went to medical school in 1939 at the University of Chicago, they would still meet often. In 1941, Warren MCCULLOCH came to the University of Illinois from Yale and Gerhardt von Bonin introduced Pitts and Lettvin to him. Thereafter Pitts joined the laboratory unofficially.

Pitts was homeless, Lettvin wanted to escape his family, and so McCulloch, together with his remarkable wife Rook, in spite of having four children already, brought the pair into their household. In late 1942, after weeks of reviewing the material in neurophysiology, Pitts told McCulloch of Leibniz's dictum that any task which can be described completely and unambiguously by a finite set of terms can be performed by a logical machine. Six years earlier TURING had published his marvelous essay on the universal computing engine. The analogy of neurons (as pulsatile rather than two-state devices) to the elements of a logical machine was inescapable. By 1943 McCulloch and Pitts published their famous paper, "A Logical Calculus of the Ideas Immanent in Nervous Activity." In 1947 they added the work "How We Know Universals." It was an attempt to interpret the structure of cortex as providing the sort of net that could abstract form independent of scale.

In 1943 Pitts, visiting Lettvin (who was interning in Boston), met Norbert WIENER and was invited to come to MIT as a research assistant. By the beginning of 1944, Pitts had been taken by the Kellex Corporation (a branch of the atomic bomb project). In the late 1940s he returned to MIT and began a project extending the work of Caianiello (on two-dimensionally connected nets) to three-dimensionally connected arrays—an extremely difficult problem.

In 1951, Jerry Wiesner, at the behest of Wiener, invited McCulloch, Patrick Wall, and Lettvin to join the Research Laboratory of Electronics (RLE) as research associates. Despite the loss of status and income, the three accepted with the full enthusiasm of their wives. They and Pitts formed a new laboratory at RLE.

But in late 1952, Wiesner received a letter from Mexico City where Wiener and his wife were visiting Arthur Rosenblueth. Viciously phrased, it severed all relations with McCulloch's group, which included Pitts. Only after a decade did Rosenblueth reveal what had set off this explosion. It had nothing to do with any substantive cause but was the result of a deliberate and cynical manipulation designed to sever Wiener's connection with McCulloch and his group. The details are not edifying; Wiener was victimized as much as the group.

The effect on Pitts was devastating; he was the most vulnerable. Wiener had become the father he had never had. From that point on, Pitts went into a steep decline. He abandoned interest in the work, and though willing enough to help, lost all initiative. Nothing could be done to arrest his decline. Pitts would have nothing to do with any psychiatrist, even those whom he met at the Macy symposia and other such roundtables. He destroyed all of his past work that he could find and became a ghost long before he died.

On a personal level, Pitts was a wonderful friend, and an inexhaustible fount of knowledge about everything, the arts as much as the sciences. One asked him a serious question only if there was enough time to hear the full answer, which was sometimes several hours long, but never didactic, rather, extremely witty and tailored to the understanding of the inquirer.

All that vanished before the end of the 1950s. He died alone in a boarding house in Cambridge after doing his best for close to a decade to avoid being found by his friends. Nothing of his work was left. But beyond question his influence shaped much of the thought of the laboratory and the approach to physiology from a philosophical view.

Planning

Planning is the process of generating (possibly partial) representations of future behavior prior to the use of such plans to constrain or control that behavior. The outcome is usually a set of actions, with temporal and other constraints on them, for execution by some agent or agents. As a core aspect of human intelligence, planning has been studied since the earliest days of AI and cognitive science. Planning research has led to many useful tools for real-world applications, and has yielded significant insights into the organization of behavior and the nature of reasoning about actions.

Early work in cognitive science sought to create general domain-independent problem solvers that exhibited some of the characteristics observed in human problem solving. The most influential early example was the General Problem Solver (GPS) proposed in 1959 (Newell and Simon 1963). It introduced techniques still in regular use today: means-ends analysis or goal directed problem solving, and finding "differences" between goal and current states.

This work was combined with search methods being studied in operations research (e.g., branch-and-bound methods), and with research on representation and reasoning from predicate logic in various theorem proving methods (e.g., Green 1969), so that by the end of the 1960s some long-lasting methods were emerging (*see* HEURISTIC SEARCH and SITUATION CALCULUS).

In 1969, the Stanford Research Institute Problem Solver, or STRIPS, (Fikes, Hart, and Nilsson 1971) represented application domain states in first-order logic, introduced a way to represent the actions of the domain in terms of changes to the world state, used means-end analysis to identify goals and subgoals that needed to be solved as stepping stones to a solution, searched through a space of possible solutions, and employed a simple but effective representation of the actions possible in the domain—as STRIPS operators. Many of these techniques form the basis for later work in planning.

Many planning techniques are formulated as search problems. Early planning approaches, including STRIPS, used a search technique in which the nodes of the search represented application domain states directly and the search arcs were the domain actions that could transform those states. This is termed "application state space" or "situation space." For example, the node state might represent the position of a robot waiter and the items on various tables:

At(Robot,Counter) and On(Cup-a,Table-1) and On(Plate-a,Table-1),

and the action arcs might represent the movement of a robot waiter, or a pickup action of the robot:

Operator Pickup(x)
Preconditions: On(x,y) and At(Robot,y)
Delete list: On(x,y)
Add list: Held(x)

STRIPS operators represent an action as having preconditions that have to be satisfied in the state in which the action is performed, and a delete list and add list of effects that represent changes made to the state following the performance of the action.

Later approaches have concentrated on searching through a different space—that of partially defined plans. A search space node is a partial plan and an arc is a partial plan modification operator (PMO). For example, a PMO might ensure the satisfaction of a condition on some activity in the partial plan. Each node of the search space defines an entire set of possible plan elaborations that fit within the constraints in the partial-plan. This method therefore can support "constraint posting" or "least commitment planning" in which decisions are postponed rather than a selection being made arbitrarily.

The integration of powerful constraint management techniques alongside planning methods is possible within this framework (e.g., as in MOLGEN (Stefik 1981) for plan object constraints, Deviser (Vere 1981) and FORBIN (Dean, Firby, and Miller 1990) for temporal constraints, and SIPE (Wilkins 1988) for resource constraints). This means that planning and scheduling techniques can be intermixed (*see* TEMPORAL REASONING).

Partial-plan search spaces lend themselves very well to "refinement planning" approaches (Kambhampati, Knoblock, and Yang 1996), where an outline plan is refined to address outstanding flaws or issues. However, it also lends itself to refining existing partial descriptions of a solution to a problem, to instantiating previously created generic plans, or to adapting plans drawn from case libraries (*see* CASE-BASED REASONING AND ANALOGY).

In the mid-1970s, NOAH (for Net of Action Hierarchies) (Sacerdoti 1977), and then "Nonlin" (the nonlinear planner built by Austin Tate) (Tate 1977), began to allow plans to be represented as partial orders on the actions contained within them, rather than insisting on the activities within plans being fully ordered. (Unfortunately, the terminology of the time led to partially ordered plans also being called "nonlinear" plans, which caused confusion with the "linear" and "nonlinear" planning approaches to the order in which goals and sub goals were solved in planners.) Some problems that had caused difficulty for earlier planners such as STRIPS were more easily addressed when a partially ordered plan representation was used, but it became more difficult to ensure that conditions on actions in the plan were satisfied from the effects of earlier actions. Potential interactions with parallel actions had to be resolved in a valid plan. Means to "protect" the condition establishment had to be added to planners (as introduced in HACKER; Sussman 1975). The "Nonlin" planner's question answering procedure (Tate 1977) included means to decide whether a specified condition was already satisfied at a given point in a partially ordered network of actions and, if necessary, could propose orderings to be added to the plan to satisfy such a condition. This provides information that can support the protection of the plan's causal structure (also called "goal structure" or "teleology"). This work was later used as the basis for the formalization of the "modal truth criterion" (Chapman 1991) used at the heart of later planners for condition establishment and protection.

Partially ordered planning (POP) algorithms are the basis for a number of modern planners such as SIPE (Wilkins 1988), O-Plan (Currie and Tate 1991), and UCPOP (Penberthy and Weld 1992).

The hierarchical organization of action descriptions is an important technique that may reduce complexity and significantly increase the scale of plans that can be generated in some domains. Most practical planners employ "hierarchical planning" methods. A library of action descriptions is maintained, some of which have a decomposition into a number of subactions at a more detailed level, and some of which are considered "primitive." For example, in the robot waiter domain, a high-level "Cleartable" action may be decomposed into primitive subactions to move to a table, pick up an item on the table, move to the counter, and put down the item held in the robot hand. A higher-level action in the plan can then be replaced with some suitable decomposition into more detailed actions. This is sometimes referred to as "hierarchical task network" (HTN) planning.

HTN planning lends itself to the refinement planning model. An initial plan can incorporate the task specification, assumptions about the situation in which the plan is to be executed, and perhaps a partial solution. This can then be refined through the hierarchy into greater levels of detail while also addressing outstanding issues and flaws in the plan.

Researchers and technologists in the planning field have added many extra features to the basic STRIPS action representation over the years. These have included:

1. Abstraction of the levels of conditions and effects (as in ABSTRIPS (for ABstract STRIPS); Sacerdoti 1974) where a skeleton plan is first developed that addresses important preconditions before refining that to deal with other detailed preconditions; for example, in the robot waiter domain, we may first develop a plan that ignores details of the robot's movements between tables.
2. The addition of resource, time, and spatial constraints to reflect the scheduling requirements on actions.
3. The use of universally quantified preconditions or effects; for example, a "Clearall" action to move all items on a given table to the counter.

The expressiveness of a planner's action representation is a major contributor to the effectiveness of a planning system, but can also lead to very large search spaces if used in uncontrolled ways (see COMPUTATIONAL COMPLEXITY).

Techniques from knowledge engineering and knowledge acquisition are beginning to be used to improve the modeling and capture of information about planning domains. In common with experience in KNOWLEDGE-BASED SYSTEMS, the use of richer models of the application domain have been found to be beneficial, such as in search space pruning and guidance.

Planning as a field has branched out in recent years to include a wide range of research topics related to reasoning about activities. One important area of investigation involves planning for activities that take place in environments where the outcome of actions is uncertain. For example, the robot waiter "Pickup" action may fail if an object is too heavy. Some of the techniques used in "classical" AI planning assume "perfect" information about the outcomes of actions. However, there is also a great deal of work on coping with uncertainty during the planning process or during the execution of plans.

Conditional or "contingency" branches may be included in a plan to allow for the most likely scenarios. "Reactive planning" techniques can be used to select activities at execution time on the basis of the situation that a system finds itself in. Uncertainty has also been addressed by general-purpose algorithms for solving planning problems cast as Markov decision processes (Dean et. al. 1995; see also MULTIAGENT SYSTEMS).

The volume *Readings in Planning* (Allen, Hendler, and Tate 1990) collects together many seminal papers that have documented the main advances in the field of planning. It presents a historical perspective to the work undertaken in this field. Several overviews in the *Readings* volume from different perspectives serve as an introduction to research on planning.

Polysynthetic Languages

Polysynthetic languages are languages that allow the formation of extremely long and complex words that are built up spontaneously out of many smaller parts. One such word can typically be the functional equivalent of an entire sentence in a language like English. For example, a speaker of the Mohawk language might make up the word *wahonwatia'tawitsherahetkenhten',* and this would immediately be understood by other Mohawk speakers as meaning "She made the thing that one puts on one's body ugly for him." The term *polysynthesis* was coined in the late 1800s, when linguists began to develop typologies of natural languages based on knowledge of languages from outside Europe and the Middle East. For these early typologists, a *synthetic* language was one like Latin and Greek, which use affixes to express the structural and meaning relationships among the words in a sentence. A polysynthetic language, then, is one that carries this method of expression to an extreme (Boas 1911; Sapir 1921; the first important discussion of the concept is Humboldt 1836, although he doesn't use this term). Polysynthesis is particularly associated with the languages of North America, Inuit and Aztec being two paradigm-defining cases. Nevertheless, it refers to a structural type of language, not a linguistic area: there are polysynthetic languages spoken in Australia, New Guinea, Siberia, and India, whereas many native American languages are not polysynthetic. The polysynthetic languages probably do not constitute a discrete type; rather there seems to be a continuum of languages determined by how much they rely on complex words to express various linguistic relationships.

The study of polysynthetic languages has been important for several reasons. First, they present an excellent way of

exploring the relationships between the different branches of linguistics. In particular, ideas about the connections between SYNTAX and MORPHOLOGY are well studied by looking at these languages, because they seem to use a different division of labor from languages like English, with more burden on morphology and less on syntax. Thus, the study of such languages has led to new proposals about the relationship between these components (e.g., Sadock 1980, 1985; Baker 1988). These languages also raise interesting questions about the LEXICON and its relationship to both syntax and morphology, because it is clear that speakers of a polysynthetic language cannot possibly learn more than a tiny fraction of the expressions that count as words in their language.

However, the first and most important reason for studying polysynthetic languages is that they constitute one of the most extreme and "exotic" classes of language in a linguistic TYPOLOGY. As such, they provide one of the strongest testing grounds for the validity of proposed LINGUISTIC UNIVERSALS. In this way, they become indirectly relevant to questions about the INNATENESS OF LANGUAGE, because that idea implies that there must be many substantive features of natural language that are attested across the whole human species (see also RATIONALISM VS. EMPIRICISM). Finally, polysynthetic languages raise questions about the EVOLUTION OF LANGUAGE: their existence forces one to ask how it is that human linguistic capacities are articulated enough to account for the ease of language acquisition and yet flexible enough to generate languages that are superficially so different.

What linguists think they have learned about such matters from studying polysynthetic languages has varied over time. These languages contributed greatly to the impression of Boas and Sapir that "language is a human activity that varies without assignable limit" (Sapir 1921), leading away from linguistic universals, innateness, and rationalism. However, more recent research has uncovered facts that point toward the opposite conclusion. For example, one common aspect of polysynthesis is noun incorporation, whereby the noun referring to the thing affected by an action is expressed inside the verb, rather than as a separate direct object (see THEMATIC ROLES and GRAMMATICAL RELATIONS). Thus, in Mohawk one can say *wa'kana'tarakwetare'* 'It cut the bread,' a single word that contains both *na'tar* 'bread' and *kwetar* 'cut'. This is unlike English, where one cannot naturally say *It bread-cut*. However, there is a point of similarity as well. English does allow affected objects and verbs to be compounded in other environments: one can refer to a long, serrated knife as a *bread-cutter,* for example. Significantly, neither language allows a noun that refers to the cause of the event to be inside the verb. Thus, in Mohawk one cannot say *wawasharakwetare'* (containing *ashar* 'knife') for 'The knife cut it'; neither in English could one call a sliced-up loaf a *knife-cuttee*. Moreover, there is evidence that the verb and the affected object form a relatively tight unit in the syntax of English (the verb phrase) to the exclusion of the causer of the event (see X-BAR THEORY). Collating facts like these, one finds a true universal: affected objects form tighter constructions with verbs than causers do. This universal property then manifests itself in

different ways in English syntax, English morphology, and Mohawk syntax, because of differences in whether HEAD MOVEMENT takes place (Baker 1988).

Another property of polysynthetic languages is that their verbs contain elements that indicate the person, number, and gender of both the subject and object. As a result, the verb, subject, and object can appear in any imaginable word order, in addition to the subject-verb-object order that is required in English. The subject and the object can also be left out entirely. (Languages with these properties are called *nonconfigurational*; Hale 1983.) All this contributes to the impression that these languages have no syntactic structure to speak of—in contrast to English. The view changes, however, once one realizes that the elements in the verb are really the equivalent of English pronouns (Jelinek 1984; Van Valin 1985; Bresnan and Mchombo 1987; Mithun 1987). Thus, the Mohawk sentence *Sak wahahninu' atyatawi* is not best compared to English "Sak bought a dress," but rather to a colloquial dislocated structure "Sak, he finally bought it, the dress." Such structures allow some freedom of word order ("That dress, he finally bought it, Sak") and the omission of noun phrases ("He bought it") even in English. Baker (1996) argues that there are in fact many such abstract similarities between polysynthetic languages and more familiar ones. If this is correct, then polysynthetic languages could actually give some of the most striking evidence in favor of linguistic universals, the innateness of language, and a rationalist view.

Population-Level Cognitive Phenomena

See INTRODUCTION: CULTURE, COGNITION, AND EVOLUTION

Positron Emission Tomography

Emission tomography is a visualization technique in nuclear medicine that yields an image of the distribution of a previously administered radionuclide in any desired transverse section of the body. Positron emission tomography (PET) utilizes the unique properties of the annihilation radiation generated when positrons are absorbed in matter. It is characterized by the fact that an image reconstructed from the radioactive counting data is an accurate and quantitative representation of the spatial distribution of a radionuclide in the chosen section. This approach is analogous to quantitative antoradiography performed in laboratory animals but has the added advantage of allowing in vivo studies and, hence, studies to be performed safely in human subjects.

PET, now along with MAGNETIC RESONANCE IMAGING (MRI), is at the forefront of cognitive neuroscience research in normal humans. The signal used by PET and MRI in this research is based on the fact that changes in the cellular activity of the brain of normal, awake humans and unanesthetized laboratory animals are invariably accompanied by changes in local blood flow (for reviews, see Raichle 1987, 1998). While PET measures blood flow directly, functional MRI or fMRI as it is now called, relies on the local changes in magnetic field properties occurring in the brain that result from changes in the blood flow that exceed changes in oxygen consumption (Raichle 1998). This is known as the blood oxygen level–dependent or BOLD signal.

This robust, empirical relationship between blood flow and brain function has fascinated scientists for well over a hundred years. One has only to consult William JAMES's monumental two-volume text *Principles of Psychology* (James 1890) on page 97 of the first volume to find reference to changes in brain blood flow during mental activities. He references primarily the work of the Italian physiologist Angelo Mosso (1881) who recorded the pulsation of the human cortex in patients with skull defects following neurosurgical procedures. Mosso showed that these pulsations increased regionally during mental activity and concluded, correctly we now know, that brain circulation changes selectively with neuronal activity.

At the close of World War II, Seymour Kety and his colleagues opened the modern era of studies of brain circulation and metabolism, introducing the first quantitative methods for measuring whole-brain blood flow and metabolism in humans. The introduction by Kety's group of an in vivo tissue autoradiographic measurement of regional blood flow applicable only in laboratory animals (Kety 1960; Landau et al. 1955) provided the first glimpse of quantitative changes in blood flow in the brain related directly to brain function. This work clearly foretold what was to come in the modern era of functional brain imaging with PET and MRI.

Soon after Kety and his colleagues introduced their quantitative methods for measuring whole-brain blood flow and metabolism in humans, David Ingvar, Neils Lassen, and their Scandinavian colleagues introduced methods applicable to humans that permitted regional blood flow measurements to be made using scintillation detectors arrayed like a helmet over the head (Lassen et al. 1963). They demonstrated directly in normal human subjects that blood flow changed regionally during changes in brain functional activity.

In 1973 Godfrey Hounsfield (Hounsfield 1973) introduced x-ray computed tomography (CT), a technique based upon principles presented in 1963 by Alan Cormack (Cormack 1963, 1973). Overnight the way in which we looked at the human brain changed. Immediately, researchers envisioned another type of tomography, positron emission tomography, or PET (Hoffman et al. 1976; Ter-Pogossian et al. 1975).

With the introduction of PET (Hoffman et al. 1976; Ter-Pogossian et al. 1975) a new era of functional brain mapping began. The autoradiographic techniques for the measurement of blood flow (Kety 1960; Landau et al. 1955) and glucose metabolism (Sokoloff et al. 1977) in laboratory animals could now be performed safely in humans (Raichle et al. 1983; Reivich et al. 1979).

Soon it was realized that highly accurate measurements of brain functional anatomy in humans could be performed with PET (Posner and Raichle 1994). While such functional brain imaging could be accomplished with either measurements of blood flow or metabolism (Raichle 1987), blood flow became the favored technique with PET because it could be measured quickly (in less than one minute) using an easily produced radiopharmaceutical ($H_2^{15}O$) with a short half-life (123 sec) which allowed many repeat measurements in the same subject (Raichle 1998).

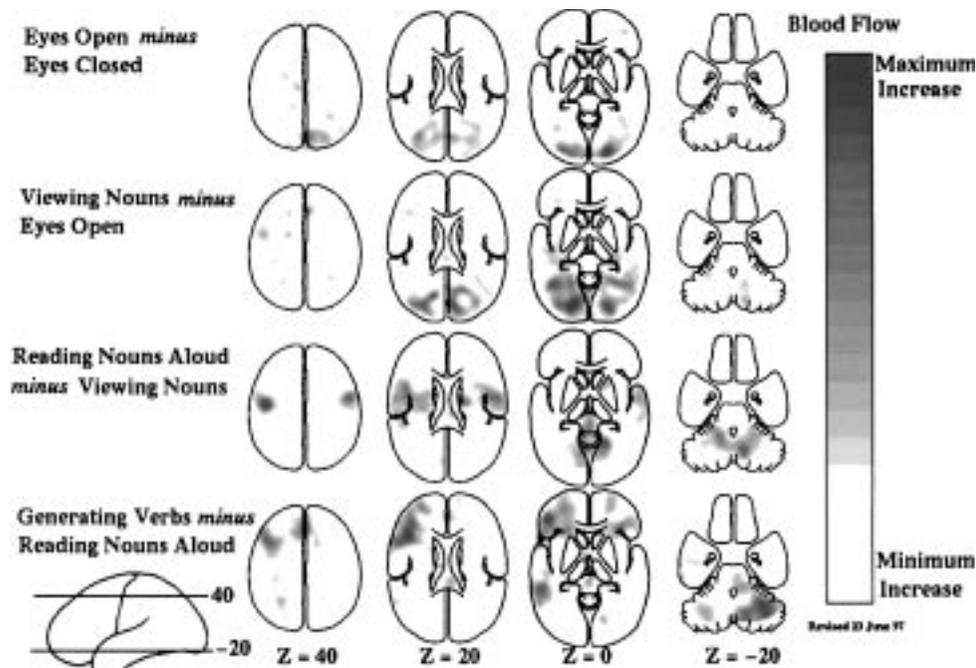
The study of human cognition with PET was aided greatly by the involvement of cognitive psychologists in the 1980s whose experimental designs for dissecting human behaviors using information processing theory fit extremely well with the emerging functional brain imaging strategies (Posner and Raichle 1994). As a result of collaboration among neuroscientists, imaging scientists, and cognitive psychologists, a distinct behavioral strategy for the functional mapping of neuronal activity emerged. This strategy was based on a concept introduced by the Dutch physiologist Franciscus C. Donders in 1868 (reprinted in Donders 1969).


Figure 1. Four different hierarchically organized conditions are represented in these mean blood flow difference images obtained with PET. All of the changes shown in these images represent increases over the control state for each task. A group of normal subjects performed these tasks involving common English nouns (Petersen et al. 1988; Petersen et al. 1989) to demonstrate the spatially distributed nature of the processing by task elements going on in the normal human brain during a simple language task. Task complexity was increased from simply opening the eyes (row 1) through passive viewing of nouns on the television monitor (row 2); reading aloud the nouns as they appear on the screen (row 3); and saying aloud an appropriate verb for each noun as it appeared on the screen (row 4). These horizontal images are oriented with the front of the brain on top and the left side to the reader's left. The marking "Z = 40" indicates milimeters above and below a horizontal plane through the brain marked "Z = 40".

Donders proposed a general method of measuring thought processes based on a simple logic. He subtracted the time needed to respond to a light (say, by pressing a key) from the time needed to respond to a particular color of light. He found that discriminating color required about 50 msec. In this way, Donders isolated and measured a mental process for the first time by subtracting a control state (i.e., responding to a light) from a task state (i.e., discriminating the color of the light). This strategy (figure 1) was first introduced to functional brain imaging with PET in the study of single-word processing (Petersen et al. 1988, 1989, 1990) but quickly became the dominant approach to the study of all aspects of human cognition with functional brain imaging.

One criticism of this subtractive approach has been that the time necessary to press a key after a decision to do so has been made, for instance, is affected by the nature of the decision process itself. By implication, the nature of the processes underlying key press, in this example, may have been altered. Although this issue (known in cognitive science jargon as the assumption of pure insertion) has been the subject of continuing discussion in cognitive psychology, it finds its resolution in functional brain imaging, where changes in any process are directly signaled by changes in observable brain states. Events occurring in the brain are not hidden from the investigator as in the purely cognitive experiments. Careful analysis of the changes in the functional images reveals whether processes (e.g., spe-

cific cognitive decisions) can be added or removed without affecting ongoing processes (e.g., motor processes). Processing areas of the brain whose activity is differentially altered at various stages of a hierarchically organized cognitive paradigm can be readily seen with imaging (figure 2). Clearly, extant data now provide many examples of areas of the brain active at one stage in a hierarchically designed paradigm which become inactive as task complexity is increased (for a recent review, see Raichle 1998). While changes of this sort are hidden from the view of the cognitive scientist they become obvious when brain imaging is employed.

A final caveat with regard to imaging certain cognitive paradigms is that the brain systems involved do not necessarily remain constant through many repetitions of the task (e.g., see Raichle et al. 1994; Raichle 1998). While simple habituation might be suspected when a task is tedious, this is not the issue referred to here. Rather, when a task is novel and, more importantly, conflicts with a more habitual response to the presented stimulus, major changes can occur in the systems allocated to the task. Such changes have both practical and theoretical implications when it comes to the design and interpretation of cognitive activation experiments.

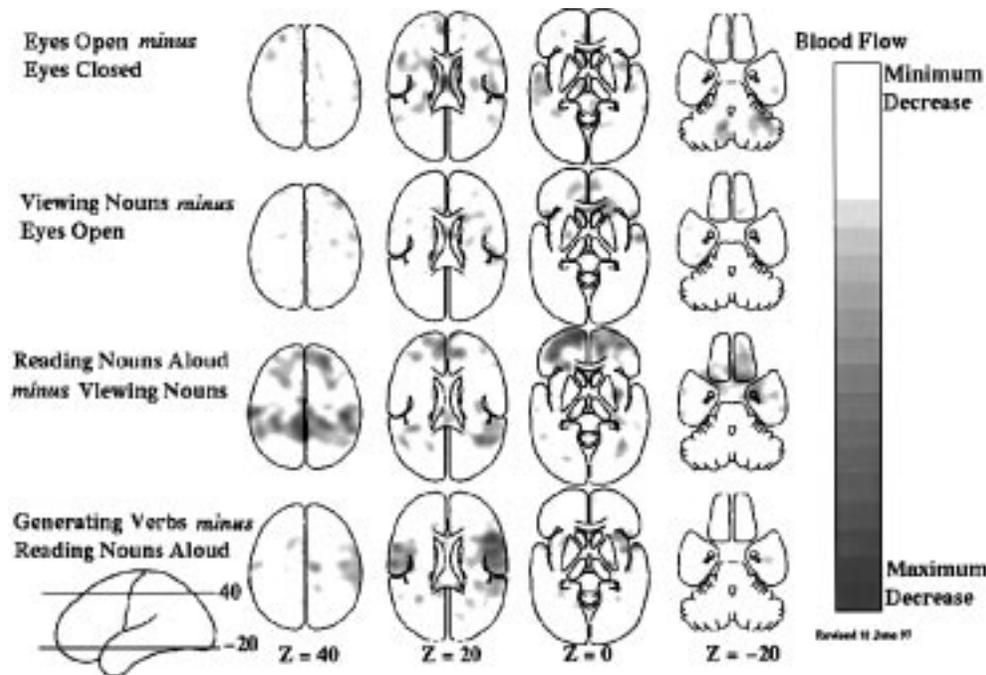
Functional brain imaging provides a unique perspective on the relationship between brain function and behavior in humans that is unavailable in the purely cognitive experiments and, in many instances, unattainable in experiments


Figure 2. Hierarchically organized subtraction involving the same task conditions as shown in Figure 1 with the difference being that these images represent areas of decreased activity in the condition as compared with the control condition. Combining the information available in Figures 1 and 2 provides a fairly complete picture of the interactions between tasks and brain systems in hierarchically organized cognitive tasks when studied with functional brain imaging.

restricted to laboratory animals. fMRI has greatly expanded the work initiated with PET owing to its better spatial and temporal resolution. Using fMRI it is now possible, for example, to image the brain changes associated with single cognitive events in individual subjects (Buckner et al. 1996).

One of the great challenges remaining in the use of functional imaging with either PET or MRI is to understand more fully the relationship between brain blood flow and brain function (Raichle 1998).

Possible Worlds Semantics

The use of possible worlds as a part of a semantic theory of natural language is based on the truth-conditional theory of meaning, that is, that the meaning of a sentence in a language is constituted by the conditions under which that sentence is true. On this view, to know the meaning of a sentence is to know what the world would have to be like if that sentence were true. If the way the world is construed as the actual world, then other ways the world could be may be thought of as alternative possible but nonactual worlds. Knowing how the world would be if a particular sentence were true does not require knowledge of whether it *is* true, because in a given world *w*, a person need not know in *w* that *w* is the actual world. Thus, if I know the meaning of "Wellington is the capital of New Zealand," I do not have to know whether in fact it is the capital, but I do have to know what it would be like for it to be the capital. In possible worlds terms I have to know of any given world *w*, whether *w* is a world in which the sentence is true or whether *w* is a world in which it is false, but I do not have to know whether *w* is the actual world. To know which world is actual would be to be omniscient.

Our language has to be able to talk about things that may not exist. In a sentence that has become rather famous in the semantical literature, "Someone seeks a unicorn," there need be no particular unicorn that is being sought, and so in some way the idea of a unicorn, a creature that does not actually exist, has to be involved in the content of that sentence—a sentence, moreover, that all of us understand.

Possible worlds semantics is used in compositional theories of meaning, where the meaning of a complex sentence is to be obtained from the meaning of its parts (*see* COMPOSITIONALITY). It developed from the languages of MODAL LOGIC where the meaning of "*p* is true by necessity" (written *Lp* or □*p*) is obtained from the meaning of *p* by specifying the worlds in which *Lp* is true given the worlds in which *p* is. To be specific, *Lp* is true in *w* provided *p* is true in every *w'* possible relative to *w*. Dual to necessity is possibility. "It is possible that *p*" (written *Mp* or ◊*p*) is true at a world *w* if *p* itself is true in at least one *w'* possible relative to *w*. A more elaborate example is found in the semantics of counterfactual sentences. Where *p* □→ *q* means that if *p* were the case, then *q* would be too, then (on one account) *p* □→ *q* is true in a world *w* iff there is a world *w'* in which *p* and *q* are both true that is more similar to *w* than any world in which *p* is true but *q* is not. In studying these as logics it is customary (depending on which logic is being studied) to set up first a structure in which relations are given to specify that one world is or is not possible relative to another, or that a world *w$_1$* is further from a world *w$_2$* than a world *w$_3$* is. But for studying natural language we cannot assume that any particular words like "possibly" are in any way special.

Typically, an implementation of possible worlds semantics for a language will require the language to be specified by a system of rules that give the LOGICAL FORM of every sentence. Then values are assigned to the simple symbols of a sentence in logical form in such a way that a set of indices (worlds, times, speaker, and whatever else is involved in the meaning of the sentence) emerges as the meaning of the final sentence. Thus in the sentence "Possibly Felix lives," the name "Felix" will have a person Felix as value, the verb "lives" will have as its value an operation that associates with an individual (in this case Felix) the set of worlds (and times) at which that individual lives; the adverb "possibly" will have as its value an operation that associates with a set of worlds (in this case the set of worlds in which it is the case that Felix lives) another set of worlds, in fact all the worlds from which the worlds in the first set are possible. The final sentence will then be true in a world *w* if there is a world *w'* possible relative to *w*, such that *w'* is in the set assigned to "Felix lives," that is, in the set of worlds in which Felix lives.

To deal with tensed languages worlds can be thought of as worlds at times. More neutrally these are called "semantical indices." Possible worlds semantics requires supplementation by generalizing such indices in various ways. Thus, to interpret "I" in a sentence like "I'd like an apple," one needs an index to supply a speaker (or someone regarded as the speaker). To interpret a sentence like "Everyone is present" one requires an index to supply a domain of people, because the sentence is presumably not intended to claim that everyone in the world is present, but only everyone in some contextually provided universe.

Possible worlds semantics abstracts from many features of linguistic behavior that have sometimes been thought important, though the extent to which this should be done can be controversial. Thus, for some possible worlds theorists the ascription of truth conditions to a sentence is intended to be completely neutral on the question of what an utterance of that sentence is being used to do. It might

be being used to report a fact or issue an order or ask a question. Other theorists may be more hesitant to speak of nondeclaratives as having truth conditions. But perhaps more importantly for cognitive science, the ascription of truth conditions to a sentence is neutral on the question of just how those truth conditions are represented in the mind of a speaker. It is concerned with the question of how to categorize what constitutes a representation's having a certain content, not on the nature of the representation itself.

Possible worlds semantics as such can be neutral on the metaphysical status of possible worlds. At one extreme is the view that other possible worlds are just as real as the actual world. At another extreme is the view that possible worlds are no more than linguistic descriptions of how the world might be. For certain limited purposes, as for example in describing the language of a computer where the possibilities that can be represented are fixed and limited, it may be plausible to consider worlds to be descriptions. But it is plausible to claim that a general theory of MEANING should not presuppose any particular way of representing worlds.

Poverty of the Stimulus Arguments

The "poverty of the stimulus argument" is a form of the problem of the under-determination of theory by data, applied to the problem of language learning. Two other well-known problems of under-determination include Willard Van Orman Quine's (1960) Gavagai example (a visitor to a foreign country sees a rabbit pass just as his informant utters the word "gavagai;" given only this evidence, "gavagai" might mean anything from *rabbit, furry* or *nice day, isn't it?* to *undetached part of rabbit*) and Nelson Goodman's Grue paradox (why is it that we take our experience in which all emeralds that we have thus far observed have been green to suggest that emeralds are green rather than the (equally confirmed so far) possibility that emeralds are grue, namely "green when examined before the year 2000, and blue when examined thereafter"?).

Learning a language involves going beyond the data: a child hears only a finite number of sentences, yet learns to speak and comprehend sentences drawn from a grammar that can represent an infinite number of sentences. The trouble that the child faces is thus a problem of under-determination: any finite set of example sentences is compatible with an infinite number of grammars. The child's task is to pick among those grammars.

The term "poverty of the stimulus" itself is relatively recent, perhaps first used by Noam Chomsky (1980: 34); but the argument as applied to language learning goes at least as far back as Chomsky's (1959) review of B. F. Skinner's *Verbal Behavior.* The exact formulation of the argument varies (Chomsky 1980; Crain 1991; Garfield 1994; Wexler 1991), but a typical version states that (1) children rapidly and, to first approximation, uniformly acquire language; (2) children are only exposed to a finite amount of data; yet (3) children appear to converge on a grammar capable of interpreting unfamiliar sentences; the conclusion is often argued to be that some aspect of grammar is innate.

Although the poverty of the stimulus argument is sometimes described in conjunction with the claim that children do not receive correction for their grammatical errors (for a recent review of the role of parental correction in the acquisition of grammar, see Marcus 1993), it is important to reject the notion that nativist explanations of language acquisition depend on the lack of parental correction. Even if parents did provide reliable correction to their children, innate constraints on the generalizations that children make would be necessary, because many plausible errors simply never occur. For instance, children never go through a period where they erroneously form yes-no questions by moving the first *is* to the front of the sentence. Although one can turn *The man is hungry* into *Is the man hungry?,* children never, by a false analogy, turn *The man who is hungry is ordering dinner* into *Is the man who hungry is ordering dinner?* (e.g., Chomsky 1965; Crain and Nakayama 1987). More generally, at every stage of LANGUAGE ACQUISITION—inferring the meaning of a new word or morpheme, creating a morphological or syntactic rule, or determining the subcategorization frame of a new verb—the child can make an infinity of logically possible generalizations,

regardless of whether negative evidence exists. But children do not simply cycle through all logical possibilities and check to see what their parents say about each one; their choice of hypotheses instead must, in part, be dictated by innately given learning mechanisms. The open question is not whether there are innately given constraints, but rather whether those constraints are specific to language.

An excellent example of the poverty of the stimulus argument comes from Peter Gordon's (1985) work on the relation between plural formation and compounding. Paul Kiparsky (1983) had noted that while irregular plurals can appear in compounds (*mice-infested*), regular plurals sound awkward inside of compounds (*rats-infested*), perhaps because the design of the grammar is such that the process of compounding can only use stored (irregular) plurals as input, whereas the process of compounding serves as input to the process of regular plural formation. If irregular plurals inside compounds were common, it would be easy to see how a general purpose learning device might learn the contrast between regulars and irregulars, but in fact, as Gordon noted, plurals inside compounds are rare. Given this, one might expect that children would not be able to systematically distinguish between regulars and irregulars appearing in compounds. But Gordon found that although children allow irregular plurals inside of compounds, they systematically exclude regulars from compounds; children say things like *mice-eater*, but not *rats-eater*. As Gordon put it, "it would seem that of all the hypotheses available, there would be little to persuade an open-minded learner to choose this, rather than some other path." Instead, Gordon suggests, the child's mind is structured such that it is predisposed to learn one kind of grammar rather than another.

Recently, some scholars have tried to use CONNECTIONIST APPROACHES TO LANGUAGE learning to challenge the poverty of the stimulus argument, but connectionist models cannot obviate the need for innate constraints; instead they would simply provide a different theory of what those constraints are. Different connectionist models differ from one another in their architecture, representational schemes, learning algorithms, and so forth; each model thus differs from every other model in its innate design (Marcus 1998a, 1998b). Advocates of radical connectionism often overlook the importance of these innate design features, but such models cannot refute the poverty of stimulus argument; instead they can only show that (at most) the innate constraints are different in character than those suggested by other researchers. Moreover, such researchers have yet to provide any concrete example of a putatively unlearnable aspect of language that has been later shown to be learnable; hence their critique of the poverty of the stimulus argument is for now without much force.

Pragmatics

Pragmatics is the study of the context-dependent aspects of MEANING that are systematically abstracted away from in the construction of LOGICAL FORM. In the semiotic trichotomy developed by Charles Morris, Rudolph Carnap, and C. S. Peirce in the 1930s, SYNTAX addresses the formal relations of signs to one another, SEMANTICS the relation of signs to what they denote, and pragmatics the relation of signs to their users and interpreters. Although some have argued for a pragmatics module within the general theory of speaker/hearer competence (or even a pragmatic component in the grammar), Sperber and Wilson (1986) argue that, like scientific reasoning—the paradigm case of a nonmodular, horizontal system—pragmatics cannot be a module, given the indeterminacy of the predictions it offers and the global knowledge it invokes (see MODULARITY AND LANGUAGE). In any case, a regimented account of language use facilitates a simpler, more elegant description of language structure. Those areas of context-dependent yet rule-governed aspects of meaning reviewed here include deixis, speech acts, presupposition, reference, and information structure; see also IMPLICATURE.

Pragmatics seeks to "characterize the features of the speech context which help determine which proposition is expressed by a given sentence" (Stalnaker 1972: 383). The meaning of a sentence can be regarded as a function from a context (including time, place, and possible world) into a proposition, where a proposition is a function from a possible world into a truth value. Pragmatic aspects of meaning involve the interaction between an expression's context of utterance and the interpretation of elements within that expression. The pragmatic subdomain of deixis or indexicality seeks to characterize the properties of shifters, indexicals,

or token-reflexives (expressions like *I, you, here, there, now, then, hereby,* tense/aspect markers, etc.) whose meanings are constant but whose referents vary with the speaker, hearer, time and place of utterance, style or register, or purpose of speech act (see Levinson 1983, chap. 2).

If pragmatics is "the study of linguistic acts and the contexts in which they are performed" (Stalnaker 1972: 383), speech-act theory constitutes a central subdomain. It has long been recognized that the propositional content of utterance U can be distinguished from its illocutionary force, the speaker's intention in uttering U. The identification and classification of speech acts was initiated by Wittgenstein, Austin, and Searle. In an explicit performative utterance (e.g., *I hereby promise to marry you*), the speaker does something—that is—performs an act whose character is determined by her intention, rather than merely saying something. Austin (1962) regards performatives as problematic for truth-conditional theories of meaning, because they appear to be devoid of ordinary truth value; an alternate view is that a performative is automatically self-verifying when felicitous, constituting a contingent a priori truth like *I am here now*. Of particular linguistic significance are indirect speech acts, where the form of a given sentence (e.g., the yes/no question in *Can you pass the salt?*) belies the actual force (here, a request for action) characteristically conveyed by the use of that sentence. (See Levinson 1983; chap. 4, and Searle and Vanderveken 1985 for more on speech-act theory and its formalization.)

Although a semantic or logical presupposition is a necessary condition on the truth or falsity of statements (Frege 1892, Strawson 1950), a pragmatic presupposition is a restriction on the common ground, the set of propositions constituting the current context. Its failure or nonsatisfaction results not in truth-value gaps or nonbivalence but in the inappropriateness of a given utterance in a given context (Stalnaker 1974; Karttunen 1974). In presupposing Φ, I treat Φ as an uncontroversial element in the context of utterance; in asserting Ψ, I propose adding the propositional content of Ψ to the common ground or, equivalently, discarding $\sim\Psi$ from the set of live options, winnowing down the context set (possible worlds consistent with the shared beliefs of S[peaker] and H[earer]) by jettisoning worlds in which Ψ does not hold.

In stating *Even Kim left* I assert that Kim left while presupposing that others left and that Kim was unlikely to have left. Such presuppositions can be communicated as new information by a speaker who "tells his auditor something . . . by pretending that his auditor already knows it" (Stalnaker 1974: 202). S's disposition to treat a proposition as part of the common ground, thereby getting H to adjust his model of the common ground to encompass it, is codified in Lewis's rule of accommodation for presupposition (1979: 340): "If at time *t* something is said that requires presupposition *P* to be acceptable, and if *P* is not presupposed just before *t,* then—*ceteris paribus* and within certain limits—presupposition *P* comes into existence at *t'.*" Accommodation, a special case of Gricean exploitation, is generalized by Lewis to descriptions, modalities, vagueness, and performatives.

How are the presuppositions of a larger expression determined compositionally as a function from those of its subexpressions? Karttunen's (1974) solution to this "projection problem" partitions operators into plugs, holes, and filters, according to their effect on presupposition inheritance, whereas Karttunen and Peters (1979) propose a formalization of inheritance of pragmatic presuppositions qua "conventional implicatures." Gazdar (1979) offers an alternative mechanism in which the potential presuppositions induced by subexpressions are inherited as a default but are canceled if they clash with propositions already entailed or implicated by the utterance or prior discourse context.

Subsequent work identifies empirical and conceptual problems for these models. Heim (1983) identifies an operator's projection properties with its context-change potential. Presuppositions are invariant pragmatic inferences: A sentence Σ presupposes ϕ if every context admitting entails ϕ. If a context *c* (a conjunction of propositions) is true and *c* admits Σ, then Σ is true with respect to *c* if the context incremented by Σ is true. But if Σ is uttered in a context *c* not admitting it, the addressee will adjust *c* to *c'*, a context close to *c* but consistent with Σ. Heim's projection theory thus incorporates Stalnaker-Lewis accommodation, which appeals in turn to the Gricean model of a cooperative conversational strategy dynamically exploited to generate pragmatic inferences (see DYNAMIC SEMANTICS).

Soames (1989) provides a conspectus of formal approaches to presupposition, and see also van der Sandt (1992) for an anaphoric account of PRESUPPOSITION, projection, and accommodation formulated within discourse representation theory. On van der Sandt's theory, the very presupposition that presuppositions are determined compositionally is challenged, leading to a reassessment of the entire projection-problem enterprise.

Although speech acts and presuppositions operate primarily on the propositional level, reference operates on the phrasal level. Reference is the use of a linguistic expression (typically a noun phrase) to induce a hearer to access or create some entity in his mental model of the discourse. A discourse entity represents the referent of a linguistic expression—that is, the actual individual (or event, property, relation, situation, etc.) that the speaker has in mind and is saying something about.

Within philosophy, the traditional view has been that reference is a direct *semantic* relationship between linguistic expressions and the real world objects they denote (see SENSE AND REFERENCE and REFERENCE, THEORIES OF). Researchers in computer science and linguistics, however, have taken a different approach, viewing this relation as mediated through the (assumed) mutual beliefs of speakers and hearers, and therefore as quintessentially pragmatic. Under this view, the form of a referring expression depends on the assumed information status of the referent, which in turn depends on the assumptions that a speaker makes regarding the hearer's knowledge store as well as what the hearer is attending to in a given discourse context.

Given that every natural language provides its speakers with various ways of referring to discourse entities, there are two related issues in the pragmatic study of reference: (1) What are the referential options available to a speaker of a

given language? (2) What are the factors that guide a speaker on a given occasion to use one of these forms over another? The speaker's choice among referring expressions (e.g., zero forms, pronominals, indefinites, demonstratives, definite descriptions, proper names) is constrained by the information status of discourse entities. Unidimensional accounts (e.g,. Gundel, Hedberg, and Zacharski 1993) provide a single, exhaustively ordered dimension ("assumed familiarity," "accessibility," "givenness") along which the various types of referring expressions are arranged. More recently, Prince (1992) offers a two-dimensional account in which entities are classified as, on the one hand, either discourse-old or discourse-new (based on whether or not they have been evoked in the prior discourse) and, on the other hand, either hearer-old or hearer-new (based on whether they are assumed to be present within the hearer's knowledge-store).

Related to information status is the notion of definiteness, which has been defined both as a formal marking of NPs and as an information status. Research into the meaning of the English definite article has generally been approached from one of two perspectives (Birner and Ward 1994); its felicitous use has been argued to require that the referent of the NP be either familiar within the discourse or uniquely identifiable to the hearer. In the absence of prior linguistic evocation, the referent must be accommodated (Lewis 1979) into the discourse model by the hearer.

Research into the discourse functions of syntax is based on the observation that every language provides its speakers with various ways to structure the same proposition. That is, a given proposition may be variously realized by a number of different sentence-types, or constructions, each of which is associated with a particular function in discourse. Consider the sentences in (1).

(1) a. John did most of the work on that project.
    b. Most of the work on that project was done by John.
    c. Most of the work on that project John did.
    d. It's John who did most of the work on that project.

The same proposition expressed by the canonical word-order sentence in (1a) can also be expressed by the (truth-conditionally equivalent) passive sentence in (1b), by the topicalization in (1c), and by the cleft sentence in (1d), among others, each of which reflects the speaker's view on how it is to be integrated by the hearer into the current discourse. For example, the topicalization (1c) allows the speaker to situate familiar, or discourse-old (Prince 1992) information in preposed position, thus marking the preposed constituent as related—or "linked"—to the prior discourse, whereas use of the cleft in (1d) reflects the speaker's belief that her hearer has in mind the fact that somebody did most of the work in question. Finally, with the passive in (1b), in which the canonical order of arguments is reversed, the speaker may present information that is relatively familiar within the discourse before information that is relatively unfamiliar within the discourse.

Such constructions serve an information-packaging function in that they allow speakers to structure their discourse in a maximally accessible way, thereby facilitating the incorporation of new information into the hearer's knowledge-store.

Like referring expressions, propositions contain information that can be either discourse-new/old and hearer-new/old.

Vallduví (1992) proposes a hierarchical articulation of information within his theory of informatics. Sentences are divided into the focus, which represents that portion of information that is hearer-new, and the ground, which specifies how that information is situated within the hearer's knowledge-store. The ground is further divided into the link, which denotes an address in the hearer's knowledge-store under which he is instructed to enter the information, and the tail, which provides further directions on how the information must be entered under a given address (see also Rooth 1992). Lambrecht (1994) identifies three categories of information structure: presupposition and assertion (the structure of propositional information into given and new); identifiability and activation (the information status of discourse referents); and topic and focus (the relative predictability of relations among propositions). (See also the Functional Sentence Perspective frameworks of Firbas 1966 and Kuno 1972 and the overview in Birner and Ward, 1998.)

Presupposition

There are two principal aspects of the MEANING conventionally conveyed by a linguistic expression, its *presupposed content* and its *proffered content* (Stalnaker 1979; Karttunen and Peters 1979; Heim 1982; Roberts 1996b). The proffered content is what we usually think of as the literal content of the expression: what is asserted by using a declarative sentence, the question raised by an interrogative, the command (or wish, or suggestion, etc.) posed by an imperative. It is the information that is treated as new by the speaker (or writer, etc.). The presupposed content is ostensibly old information: it is information that the speaker (behaves as if she) assumes is already known in the context of the discourse in progress. Hence, a presupposition imposes a requirement on the context of use, the requirement that it already contain the presupposed information. An older view of presuppositions treats them as *semantic*—that is, as entailments of both a sentence and its negation (Van Fraassen 1971). By contrast, the present notion is called *pragmatic presupposition,* because a presupposition so analyzed is an entailment not of the utterance itself, but of any context which satisfies the imposed requirement.

Consider (1), where the capital letters indicate emphasis on the subject.

(1) MARCIA has a bicycle, too.

(1) cannot be used without presuming that someone other than Marcia has a bicycle, demonstrating that this proposition is in some way conventionally associated with the utterance. This contrasts with conversational implicatures, which in general only arise when context interacts with the conventional content of an utterance in a certain way. That the presupposed proposition in (1) isn't part of what's directly asserted is suggested by the fact that if the addressee directly denies the speaker's assertion of (1), for example replying *No,* he is not taken thereby to deny that someone

other than Marcia has a bicycle but rather to deny that Marcia has a bicycle. In fact, such a reply implicitly acknowledges the truth of the presupposition, as reflected in the dilemma of the man under oath who must reply to the question *Have you stopped stealing bicycles?* The indirectness of presuppositions and their conventional (i.e., noncancellable) nature is also reflected in the behavior of examples like (1) under negation, interrogation, and conditional assumption, as in the following:

(2) It's not as if MARCIA has a bicycle, too.

(3) Does MARCIA have a bicycle, too?

(4) If MARCIA has a bicycle, too, we can go for a ride by the river.

The retention in such variants of the presupposition that someone other than Marcia has a bicycle demonstrates that presuppositions are logically stronger than mere entailments, which are lost under negation, interrogation, or conditional assumption: Here, what is directly entailed by (1), that Marcia has a bicycle, is not entailed by (2), (3), or (4).

There are many kinds of expressions that conventionally trigger presuppositions, including inflectional affixes, lexical items, and syntactic constructions. Among others in English, besides *too,* we find presuppositions conventionally associated with the possessive case, as in *Marcia's bicycle* (which presupposes that Marcia has a bicycle), with the adverbials *only* and *even,* with factive predicates like *regret,* and with constructions like the pseudo-cleft construction, as illustrated by the following. (The reader may use the negated, interrogative, and conditional forms of these examples to test that the presuppositions noted are implicated.)

(5) Marcia even sold her BICYCLE.
       Presupposed: Her bicycle was one of the least likely things for Marcia to have sold, and there are other things that she sold.
       Asserted: Marcia sold her bicycle.

(6) Marcia regrets that she sold her bicycle.
       Presupposed: Marcia sold her bicycle.
       Asserted: Marcia regrets having done so.

(7) What Marcia sold is her bicycle.
       Presupposed: Marcia sold something.
       Asserted: Marcia sold her bicycle.

If the interlocutors in a conversation do not already agree on the truth of a presupposition associated with an utterance, then we say that the presupposition has failed to be *satisfied* in the context of utterance. Presupposition failure often leads to infelicity. Following the seminal work of Karttunen (1973) and Stalnaker (1974), an utterance with presupposition *p* is *felicitous* in context *c* iff *c* entails *p*. If one utters (1) in a conversation whose interlocutors don't have in their common ground the information that someone besides Marcia has a bicycle, then it will sound distinctly odd. If the interlocutors haven't been discussing what Marcia (perhaps among others) sold, then (7) will seem infelicitous. That the presupposition *p* itself needn't have been directly asserted is demonstrated by the following type of

example:

(8) a. All Dutch people own bicycles.
       b. Marcia is Dutch.
       c. She rides her bicycle to work.

(8c) contains the noun phrase *her bicycle,* with *her* anaphoric to *Marcia,* and hence presupposes that Marcia has a bicycle. This presupposition is satisfied in the context suggested, where (8a) and (8b) together (though neither alone) entail that Marcia owns a bicycle.

But presupposition failure doesn't always lead to infelicity. Sometimes a cooperative addressee will be willing to accommodate the speaker by assuming the truth of the presupposed proposition after the fact, as if it had been true all along (Lewis 1979; Heim 1983; Thomason 1990). In such a case, we say that the addressee has *accommodated* the failed presupposition, saving the conversation from infelicity. This is not uncommon with factive verbs, such as *regret* in (6), and in fact gossips often use factives as a way of reporting juicy news while pretending it was already common knowledge.

The linguistic and philosophical literature on presupposition since the early 1970s has largely focused on the so-called *projection problem:* how to predict the presuppositions that a possibly complex sentence will inherit from the words and phrases that constitute it. Uttered out of the blue, (9) seems to presuppose that Marcia has a bicycle. However, this is only apparent, as we can see when we put (9) in the appropriate sort of context, illustrated by (9').

(9) Marcia believes that she sold her bicycle.

(9') Marcia is quite mad. Last week, she imagined that she had acquired a bicycle and a motorscooter. Now, she believes that she sold her bicycle.

Hence, the effect of the main verb *believe* in (9) is quite different from that of *regret* in the otherwise identical (6): *regret* always passes along the presuppositions of its sentential complement *she sold her bicycle,* (that is, the proposition that Marcia had a bicycle), to the matrix sentence; we say that the complement sentence's presuppositions are *projected.* But *believe* doesn't necessarily do so—whether it does depends on the context of utterance.

Karttunen (1973) classifies so-called *factive* predicates like *regret* as *holes to presupposition,* because they pass along the presuppositions of their complements to become presuppositions of the clause of which they are the main verb. Other holes include negation (in (2)), the interrogative construction (in (3)), and the antecedent of a conditional (in (4)). Predicates like *say* are said to be presupposition *plugs,* not passing along any of the presuppositions of a complement; replacing *regrets* with *says* in (6) gets rid of the presupposition that Marcia sold her bicycle. Predicates like *believe* are said to be presupposition *filters,* since they only pass along their complement's presuppositions under certain conditions. Filters include a number of syntactic constructions, as well as embedding predicates and other operators. The filtering behavior of the conditional construction is illustrated in (10):

(10) If Marcia sold her bicycle, then by now she regrets selling it.

The consequent of (10) carries the presupposition that Marcia regrets selling her bicycle; but (10) as a whole does not presuppose this. Although one can utter (10) in a context in which it's known that Marcia sold the bicycle, it would also be felicitous in a context in which we only know that she was contemplating doing so.

The merits of three principal types of theories of presupposition and of presupposition projection are currently being debated: satisfaction theories (Karttunen 1973; Stalnaker 1974, 1979; Heim 1983, 1992), cancellation theories (Gazdar 1979; Soames 1989), and anaphoric theories (Van der Sandt 1989, 1992). See Beaver 1998 for an excellent technical overview of current theory with extensive comparison. For historical overviews of the linguistic and philosophical literature on presupposition (including the important debate on the purported presuppositions of definite Noun Phrases in Frege 1892; Russell 1905, and Strawson 1950), the reader is referred to Levinson (1983) and Soames (1989). Evans (1977), Heim (1982), Kadmon (1990), and Neale (1990), among others, continue the Russell/Strawson debate. And Roberts (1996a) discusses a phenomenon dubbed *modal subordination,* which poses *prima facie* problems for most theories of presupposition

Primate Cognition

Ludwig Wittgenstein remarked that if lions could speak we would not understand them. David Premack (1986), following this conceptual thread, commented that if chickens had syntax they would have nothing much to say. The first comment raises a methodological challenge, the second a conceptual one. Studies of primate cognition have faced both.

For some, monkeys and apes appear much smarter than nonprimates. If so, why might this be the case? One dominant perspective suggests that social life has exerted extraordinary pressure on brain structure and function, and has led to a mind that is capable of tracking dynamically changing social relationships and political struggles (Byrne and Whiten 1988; Cheney and Seyfarth 1990; Humphrey 1976; Povinelli 1993). In primates—but few other species—individuals form coalitions to outcompete others, and following aggressive attack, subordinates often reconcile their differences with a dominant, engaging in exceptional acts of kindness and trust such as kissing and testicle holding (de Waal 1996; Harcourt and de Waal 1992). Such behavior, along with apparent acts of deception (Hauser 1996), has provided the foundation for experimental investigations of underlying

cognitive mechanisms. Here, I tackle three problems so as to shed light on the architecture of the primate mind: (1) IMITATION, (2) abstract CONCEPTS, and (3) mental state attribution.

Imitation

In some monkey species, all chimpanzee populations, and one orangutan population—but in no gorilla populations—individuals use tools to gain access to food (Matsuzawa and Yamakoshi 1996; McGrew 1992; Visalberghi and Fragaszy 1991). The observation that individuals within a population ultimately acquire the same tool-using technique has been taken as evidence that primates are capable of imitation. There are, however, several paradoxical findings and controversies over the interpretation of these observations (Heyes and Galef 1996; Tomasello and Call 1997; Byrne and Russon forthcoming). First, in some study populations, young require 5–10 years before they master tool technology. Although some of this can be accounted for by maturational issues associated with motor control, one would expect faster acquisition if imitation, or a more effective teaching system, was in place (Caro and Hauser 1992). Second, most experiments conducted in the lab have failed to provide evidence that naturally reared monkeys and apes can imitate (Whiten and Ham 1992), although a recent set of studies on chimpanzees and marmosets suggest that some of the previous failures may be due to methodological problems rather than conceptual ones (Heyes and Galef 1996). Third, and perhaps most paradoxical of all, apes reared by humans can imitate human actions (reviewed in Tomasello and Call 1997). This suggests that the ape mind has been designed for imitation, but requires a special environment for its emancipation—a conceptual puzzle that has yet to be resolved (see SOCIAL COGNITION IN ANIMALS).

Abstract Concept

In several primates, the number of food calls produced is positively correlated with the amount of food discovered (reviewed in Hauser 1996). In chimpanzees, a group from one community will kill a lone individual from another community, but will avoid others if there are two or more individuals. Are such assessments based on an abstract conceptual system, akin to our number system? Recent experiments, using different experimental procedures, reveal that both apes and monkeys have quite exceptional numerical skills (reviewed in Gallistel 1990; Hauser and Carey forthcoming). Thus, chimpanzees who have learned arabic numbers understand the primary principles of a count system (e.g., one-one mapping, item indifference, cardinality) and can count up to and label nine items (Boysen 1996; Matsuzawa 1996). Using the violation of expectancy procedure designed for human infants, studies of rhesus monkeys and cotton-top tamarins have revealed that they can spontaneously carry out simple arithmetical calculations, such as addition and subtraction (Hauser and Carey forthcoming; Hauser, MacNeilage, and Ware 1996). Although nonhuman primates will never join the intellectual ranks of our mathematical elite, they clearly have access to an abstract number concept, in addition to other abstract concepts (e.g., transitivity, color names, sameness, cause-effect, identity, kinship) that contribute to the intricacies of their social life. And primates are probably not even unique within the animal kingdom in terms of such conceptual capacities, as other species have demonstrated comparable cognitive prowess (see review in Thompson 1995).

Mental State Attribution

Are primates intuitive psychologists in that they can reflect upon their own beliefs and desires and understand that others may or may not share such mental states? Consider the following observation: a low-ranking male chimpanzee who is about to mate sees a more dominant male approaching. The low-ranking male covers his erect penis as the dominant walks by. This kind of interaction—and there are thousands of observations like this in the literature—suggests a capacity for intentional deception (see MACHIAVELLIAN INTELLIGENCE HYPOTHESIS). If true, the following capacities must be in place: the ability to represent one's own beliefs and desires, the ability to understand perspective, and the ability to attribute intentions to others. The evidence for each of these capacities is weak, at best, but the experimental research program is only in its infancy. Studies using mirrors suggest that all of the apes, and at least one monkey (cotton-top tamarins), respond to their reflection as if they see themselves, rather than a conspecific (Gallup 1970; Hauser et al. 1995; Povinelli et al. 1993). Self-recognition can be computed by perceptual mechanisms alone, whereas self-awareness implies some access to one's own beliefs and desires, how they can change, and how they might differ from those of another individual. The mirror test is blind to issues of awareness.

Many animals, primates included, follow the direction of eye gaze. However, current evidence suggests that neither monkeys nor apes understand that seeing provides a window into knowledge. A suite of experiments now show that monkeys and apes do not use eye gaze to infer what other individuals know, and thus do not alter their behavior as a function of differences in knowledge (Cheney and Seyfarth 1990; Povinelli and Eddy 1996). Given that this capacity emerges in the developing child well before the capacity to attribute intentional states to others and that perspective taking plays such a critical role in mental state attribution, it seems unlikely that primates have access to a theory of mind. But we should withhold final judgment until additional experiments have been conducted.

The human primate once held hands with a nonhuman primate ancestor. But this phylogenetic coupling happened 5–6 million years ago, ample time for fundamental differences to have emerged in the human branch of the tree. Nonetheless, many features of the primate mind have been left unchanged, including some capacity for imitation and some capacity to represent abstract concepts. The future lies in uncovering the kinds of selective pressures that led to changes in and conservation of the general architecture of the primate mind.

Primate Language

Curiosity regarding apes' capacity for language has a long history. From DARWIN's nineteenth century postulations of both biological and psychological continuities between animals and humans, to the more recent discovery (Sibley and Ahlquist 1987) that chimpanzee *(Pan)* DNA is more similar to human than to gorilla *(Gorilla)* DNA, scientific findings have encouraged research into the language potential of apes. A recent report (Gannon et al. 1998) that the chimpanzee planum temporale is enlarged in the left hemisphere, with a humanlike pattern of Wernicke's brain language-area homolog, will provide additional impetus. That area is held basic to human language. Does, in fact, elaboration in the chimpanzee's planum temporale provide for language-relevant processes or potential? Is its elaboration an instance of homoplasy (convergent evolution)? Or is its function not necessarily related to language?

Language research with apes was revitalized in the 1960s as Beatrix and Allen Gardner (Gardner, Gardner, and Cantfort 1989) used a variation of American Sign Language to establish two-way communication with their chimpanzee, Washoe, and as David Premack (Premack and Premack 1983) used an artificial language system of plastic tokens with his chimpanzee, Sarah. In the 1970s, Sue Savage-Rumbaugh's group (1977) developed a computer-monitored keyboard of distinctive geometric patterns, called *lexigrams,* to foster studies of language capacity with Lana, a chimpanzee. Herbert Terrace's (1979) chimpanzee Project Nim, Lynn Miles's (1990) orangutan Project Chantek, and Roger and Deborah Fouts's (1989) project with Washoe and other chimpanzees obtained from the Gardners also started during the '70s.

These projects initially emphasized language production. It was assumed that if an ape appropriately produced a sign then it must also understand its meaning. That assumption proved unwarranted. Apes were proved capable of selecting seemingly appropriate symbols without understanding their meanings, even at a level grasped by 2- and 3-year-old children as they use words. Studies of comprehension ensued.

But how can one assess whether symbol meaningfulness and comprehension are present, given that apes can't speak? There are several ways. First, the meaningfulness of symbols with Sherman and Austin chimpanzees (Savage-Rumbaugh 1986) was documented by their symbol-based, cross-modal matching. Without specific training, they could look at a lexigram and select the appropriate object, by touch, from others in a box into which they could not see. They also could label, by use of word-lexigrams, single objects that they could feel but not see. Second, and more importantly, they learned word-lexigrams for the *categories* of "food" and "tool" to which they appropriately sorted 17 individual lexigrams, each representing a specific food and implement. (Each lexigram represented either a food or a tool, such as a banana, magnet, cheese, lever, etc.) Thus, their lexigrams represented things not necessarily present—the essence of SEMANTICS or *word meaning.*

Comprehension became of special interest with the discovery that Kanzi, a bonobo (a rare species of chimpanzee, *Pan paniscus*), *spontaneously* learned the meanings of word-lexigrams and later came to understand human speech—both single words and novel sentences of request (Savage-Rumbaugh et al. 1993). The discovery was made in the course of research with Matata, his adoptive mother. Matata's essential failure in learning lexigrams was likely a reflection of her feral birth and development.

Though always present during Matata's language training, Kanzi was not taught; but later, when separated from her, it became clear that he had learned a great deal! Spontaneously, he began to request and go get specific foods and drinks, to label objects, and to announce what he was about to do with the appropriate lexigrams.

From that time forward, Kanzi was reared in an even richer language-structured milieu. Caregivers commented on events (present, future, and past) and particularly on things of special interest to him. Where possible, caregivers used word-lexigrams as they spoke specific words. Kanzi was not required to use a keyboard to receive objects or to participate in activities and was given no formal lessons.

Kanzi quickly learned by observation how to ask to travel to specific sites in the forest, to play a number of games, to visit other chimps, to get and even cook specific foods, and to watch television. He also commented on things and events and continued to announce eminent actions. In sharp contrast with our other apes, Kanzi also began to comprehend human speech—not just single words but also sentences.

Consequently, Kanzi's (8 yrs.) speech comprehension was compared with that of a human child, Alia (2½ yrs.). In controlled tests, they were given 415 novel requests—to take a specific object to a stated location or person ("Take the gorilla (doll) to the bedroom"), to do something to an object ("Hammer the snake!"), to do something with a specific object relative to another object ("Put a rubber band on your ball"), to go somewhere and retrieve a specific object ("Get the telephone that's outdoors"), and so on. An ever-changing variety of objects was present on each trial, and the ape and child were asked to fulfil various requests with them. Each request was novel and had not been modeled by others.

Both Kanzi and Alia were about 70 percent correct in carrying out the requests on their first presentation. As with the human child, Kanzi's comprehension skills outpaced those of production. Kanzi understood much more than he "could say." Though his comprehension skills compared favorably with those of a 2½-year-old child, his productive skills were more limited and approximate those of the average 1 to 1½-year-old child (Greenfield and Savage-Rumbaugh 1993). These major findings were replicated in subsequent research with two other apes (Savage-Rumbaugh and Lewin 1994).

Thus, speech comprehension can be acquired spontaneously (e.g., without formal training) by apes if from birth they are reared much as one would rear human children—with language used by caregivers throughout the day to describe, to announce, and to coordinate social activities (i.e., feeding, traveling, and playing).

These findings indicate that language acquisition (1) is based in the social-communicative experiences of early infancy; (2) is based, first, in comprehension, not production or speech; and (3) is based in the evolutionary processes that have selected for primate taxa that have large and complex brains (Rumbaugh, Savage-Rumbaugh, and Washburn 1996).

Thus, the question should not be, "Do apes have language?" Given a brain only about one third the size of ours, it would be unreasonable to expect the ape to have full competence for language and its several dimensions. Rather, the question should be, "Which aspects of language can they acquire, and under what conditions do they do so?"

Just as the discovery of even elementary forms of life on another planet will not be trivialized, the documentation of elementary language competence in species other than humans has significant implications for the understanding of evolution and brain. Although the capacity for acquiring even elementary language skills is surely limited among animal species, at least some ape, marine mammal, and avian species have capacities that include the abilities to name, to request, to comprehend, and both to use and to comprehend symbols as representations of things and events not necessarily present in space and time. These capacities are inherently in the domain of language.

Probabilistic Reasoning

Probabilistic reasoning is the formation of probability judgments and of subjective beliefs about the likelihoods of outcomes and the frequencies of events. The judgments that people make are often about things that are only indirectly observable and only partly predictable. Whether it is the weather, a game of sports, a project at work, or a new marriage, our willingness to engage in an endeavor and the actions that we take depend on our estimated likelihood of the relevant outcomes. How likely is our team to win? How frequently have projects like this failed before? And what is likely to ameliorate those chances?

Like other areas of reasoning and decision making, the study of probabilistic reasoning lends itself to normative, descriptive, and prescriptive approaches. The normative approach to probabilistic reasoning is constrained by the same mathematical rules that govern the classical, set-theoretic conception of probability. In particular, probability judgments are said to be "coherent" if and only if they satisfy conditions commonly known as Kolmogorov's axioms: (1) No probabilities are negative. (2) The probability of a tautology is 1. (3) The probability of a disjunction of two logically exclusive statements equals the sum of their respective probabilities. And (4), the probability of a conjunction of two statements equals the probability of the first, assuming that the second is satisfied, times the probability of the second. Whereas the first three axioms involve unconditional probabilities, the fourth introduces conditional probabilities. When applied to hypotheses and data in inferential contexts, simple arithmatic manipulation of rule (4) leads to the result that the (posterior) probability of a hypothesis conditional on the data is equal to the probability of the data conditional on the hypothesis times the (prior) probability of the hypothesis, all divided by the probability of the data. Although mathematically trivial, this is of central importance in the context of so-called Bayesian inference, which underlies theories of belief updating and is considered by many to be a normative requirement of probabilistic reasoning (see BAYESIAN NETWORKS and INDUCTION).

There are at least two distinct philosophical conceptions of probability. According to one, probabilities refer to the relative frequencies of objective physical events in repeated trials; according to the other, probabilities are epistemic in nature, expressing degrees of belief in specific hypotheses. While these distinctions are beyond the scope of the current entry, they are related to ongoing debate concerning the status and interpretation of some experimental findings (see, e.g., Cosmides and Tooby 1996; Gigerenzer 1994, 1996; Kahneman and Tversky 1996). What is notable, however, is the fact that these different conceptions are arguably constrained by the same mathematical axioms above. Adherence to these axioms suffices to insure that probability judgment is coherent. Conversely, incoherent judgment entails the holding of contradictory beliefs and leaves the person open to possible "Dutch books." These consist of a set of probability judgments that, when translated into bets that the person deems fair, create a set of gambles that the person is bound to lose no matter how things turn out (Osherson 1995; Resnik 1987; see also DECISION MAKING).

Note that coherent judgment satisfies a number of logical, set-theoretic requirements. It does not insure that judgment is correct or even "well calibrated." Thus, a person whose judgment is coherent may nonetheless be quite foolish, believing, for example, that there is a great likelihood that he or she will soon be the king of France. Normative probabilistic judgment needs to be not only coherent but also well calibrated. Consider a set of propositions each of which a person judges to be true with a probability of .90. If she is right about 90 percent of these, then she is said to be well calibrated. If she is right about less or more than 90 percent, then she is said to be overconfident or underconfident, respectively.

A great deal of empirical work has documented systematic discrepancies between the normative requirements of probabilistic reasoning and the ways in which people reason about chance. In settings where the relevance of simple probabilistic rules is made transparent, subjects often reveal appropriate statistical intuitions. Thus, for example, when a sealed description is pulled at random out of an urn that is known to contain the descriptions of thirty lawyers and seventy engineers, people estimate the probability that the description belongs to a lawyer at .30. In richer contexts, however, people often rely on less formal considerations emanating from intuitive JUDGMENT HEURISTICS, and these can generate judgments that conflict with normative requirements. For example, when a randomly sampled description from the urn sounds like that of a lawyer, subjects' probability estimates typically rely too heavily on how representative the description is of a lawyer and too little on the (low) prior probability that it in fact belongs to a lawyer.

According to the representativeness heuristic, the likelihood that observation A belongs to class B is evaluated by the degree to which A resembles B. Sample sizes and prior odds, both of which are highly relevant to likelihood, do not impinge on how representative an observation appears and thus tend to be relatively neglected. In general, the notion that people focus on the strength of the evidence (e.g., the warmth of a letter of reference) with insufficient regard for its weight (e.g., how well the writer knows the candidate) can explain various systematic biases in probabilistic judgment (Griffin and Tversky 1992), including the failure to appreciate regression phenomena, and the fact that people are generally overconfident (when evidence is remarkable but its weight is low), and occasionally underconfident (when the evidence is unremarkable but its reliability high). Probability judgments based on the support, or strength of evidence, of focal relative to alternative hypotheses form part of a theory of subjective probability, called support theory. According to support theory, which has received substantial empirical validation, unpacking a description of an event into disjoint components generally increases its support and, hence, its perceived likelihood.

As a result, different descriptions of the same event can give rise to different judgments (Rottenstreich and Tversky 1997; Tversky and Koehler 1994).

Probability judgments often rely on sets of attributes—for example, a prospective applicant's exams scores, relevant experience, and letters of recommendation—which need to be combined into a single rating, say, likelihood of success at a job. Because people have poor insight into how much weight to assign to each attribute, they are typically quite poor at combining attributes to yield a final judgment. Much research has been devoted to the tension between intuitive ("clinical") judgment and the greater predictive success obtained by linear models of the human judge (Meehl 1954; Dawes 1979; Dawes and Corrigan 1974; Hammond 1955). In fact, it has been repeatedly shown that a linear combination of attributes, based, for example, on a judge's past probability ratings, does better in predicting future (as well as previous) instances than the judge on whom these ratings are based. This bootstrapping method takes advantage of the person's insights captured across numerous ratings, and improves on any single rating where less than ideal weightings of attributes may intrude. Moreover, because attributes are often highly correlated and systematically misperceived, a unit assignment of weights, not properly devised for the person, can often still outperform the human judge (Dawes 1988).

While human intuition can be a useful guide to the likelihoods of events, it often exhibits instances of incoherence, in the sense defined above. Methods have been explored that extract from a person's judgments a coherent core that is maximally consistent with those judgments, and at the same time come closer to the observed likelihoods than do the original (incoherent) judgments (Osherson, Shafir, and Smith 1994; Pearl 1988). Probabilistic reasoning occurs in complex situations, with numerous variables and interactions influencing the likelihood of events. In these situations, people's judgments often violate basic normative rules. At the same time, people can exhibit sensitivity to and appreciation for the normative principles. The coexistence of fallible intuitions along with an underlying appreciation for normative judgment yield a subtle picture of probabilistic reasoning, and interesting possibilities for a prescriptive approach. In this vein, a large literature on expert systems has provided analyses and applications.

Probability, Foundations of

According to one widely held interpretation of probability, the numerical probability assigned to a proposition given particular evidence is a measure of belief in that proposition given the evidence. For example, the statement "The probability that the next nerve impulse will occur within .1 seconds of the previous impulse is .7, given that 70 of the last 100 impulses occured within .1 seconds" is an assertion of degree of belief about a future event given evidence of previous similar events. In symbols this would be written:

P(impulse-within-.1-seconds | 70 out of 100 previous within .1 sec.) = .7,

where the "|" symbol (called the "givens") separates the target proposition (on the left) from the evidence used to support it (on the right), the *conditioning evidence*. It is now widely accepted that unconditioned probability statements are either meaningless or a shorthand for cases where the conditioning information is understood.

Probability can be viewed as a generalization of classical propositional LOGIC that is useful when the truth of particular propositions is uncertain. This generalization has two important components: one is the association of a numerical degree of belief with the proposition; the other is the explicit dependence of that degree of belief on the evidence used to assess it. Writers such as E. T. Cox (1989) and E. T. Jaynes (1998) have derived standard probability theory from this generalization and the requirement that probability should agree with standard propositional logic when the degree of belief is 1 (true beyond doubt) or 0 (false beyond doubt). This means that any entity that assigns degrees of belief to uncertain propositions, given evidence, must use probability to do so, or be subject to inconsistencies, such as assigning different degrees of belief to the same proposition given the same evidence depending on the order that the evidence is evaluated. The resulting laws of probability are:

1. $0 \leq P(A|I) \leq 1$
2. $P(A|I) + P(\text{not } A|I) = 1$ (Probabilistic Law of excluded middle)
3. $P(A \text{ or } B|I) = P(A|I) + P(B|I) - P(A \& B|I)$
4. $P(A \& B|I) = P(A|I)*P(B|A \& I)$ (Product Law)

All other probability laws, such as Bayes's theorem, can be constructed from the above laws.

This derivation of probability provides a neat resolution to the old philosophical problem of justifying INDUCTION. In the eighteenth century, the philosopher David HUME disproved the assumption that all "truth" could be established deductively, as in mathematics, by showing that propositions such as "The sun will rise tomorrow" can never be known with certainty, no matter how may times the sun has risen in the past. That is, generalizations induced from particular evidence are always subject to possible refutation by further evidence. However, an entity using probability will assign such a high probability to the sun rising tomorrow, given the evidence, that it is rational for it to make decisions based on this belief, even in the absence of complete certainty.

Several important consequences follow from this "conditioned degree of belief" interpretation of probability. One consequence is that two different probability assertions, such as the one above, and

P(impulse-within-.1-seconds | 70 out of 100 previous within .1 sec. & dead(cell)) = 0

are not contradictory because the probabilities involve different conditioning evidence, although the latter assertion is a better predictor if its conditioning evidence is correct. Different entities can condition on different evidence, and so can assign different probability values to the same proposition. This means that there is a degree of subjectivity in evaluating probabilities, because different subjects generally have different experience. However, when different subjects agree on the evidence, they typically give the same probabilities. That is, a degree of objectivity with probabilities can be achieved through intersubjective agreement. Another consequence of the degree of belief interpretation of probability is that the conditioning propositions do not have to be true—a probability assertion gives the numeric probability *assuming* the conditioning information is true. This means that probability theory can be used for hypothetical reasoning, such as "If I drop this glass, it will probably break."

Another consequence of the degree of belief interpretation of probability is that there is no such thing as *the* probability of a proposition; the numerical degree is always dependent on the conditioning evidence. This means that a statement such as "the probability of a coin landing tails is 1/2," is meaningless—some experts are able to flip coins on request so that they land heads or tails. The existence of such experts refutes the view that the probability of 1/2 for tails is a physical property of the coin, just like its mass, as has been asserted by some writers. The reason many users of probability talk about "the" probability of tails for a coin or any other event is that the event occurence is assumed to be under "typical" or "normal" conditions. In a "normal" coin toss, we expect tails with a probability of 1/2, but this probability is conditioned on the normality of the toss and the coin, and has no absolute status relative to any other conditional probability about coins. Probabilities that are implicitly conditioned by "normal" operation are called by some "propensities," and assumed to be an intrinsic property of a proposition. For example, an angry patient has a propensity to throw things, even if that patient is physically restrained. However, this statement is just a shorthand for the probability of the patient to behave in a particular way, conditioned on being angry and unconstrained—"normal" behavior for an angry person.

Although there is universal agreement on the fundamental laws of probability, there is much disagreement on interpretation. The two main interpretations are the "degree of belief" (subjective) interpretation and the "long run frequency" (frequentist or objective) interpretation. In the frequentist interpretation, it is meaningless to assign a probability to a particular proposition, such as "This new type of rocket will launch successfully on the first try," because there are no previous examples on which to base a relative frequency. The degree of belief interpretation can assign a probability in this case by using evidence such as the previous history of other rocket launches, the complexity

of the new rocket, the failure rate of machinery of comparable complexity, knowing who built it, and so on. When sufficient frequency evidence is available, and this is the best evidence, then the frequentist and the subjectivist will give essentially the same probability. In other words, when the observed frequency of similar events is used as the conditioning information, both interpretations agree, but the degree of belief interpretation gives reasonable answers even when there is insufficient frequency information.

The main form of probabilistic inference in the degree of belief interpretation is to use Bayes's theorem to go from a prior probability (or just "prior") on a proposition to a posterior probability conditioned on the new evidence. For this reason, the degree of belief interpretation is referred to as *Bayesian inference.* It dates back to its publication in 1763 in a posthumous paper by the Rev. Thomas Bayes. However, before any specific evidence has been incorporated in Bayesian inference, a prior probability distribution must be given over the propositions of interest. In 1812, Pierre Simon Laplace proposed using the "principle of indifference" to assign these initial (prior) probabilities. This principle gives equal probability to each possibility. When there are constraints on this set of possibilities, the "principle of maximum entropy" (Jaynes 1989) must be used as the appropriate generalization of the principle of indifference. Even here, subjectivity is apparent, as different observers may perceive different sets of possibilities, and so assign different prior probabilities using the principle of indifference. For example, a colorblind observer may see only small and large flowers in a field, and so assign a prior probability of 1/2 to the small size possibility; but another observer sees that the large flowers have two distinct colors, and so assigns a prior probability of 1/3 to the small size possibility because this is now one of three possibilities. There is no inconsistency here, as the different observers have different information. As specific flower data is collected, a better estimate of the small flower probability can be obtained by calculating the posterior probability conditioned on the flower data. If there is a large flower sample, the posterior probabilities for both observers converges to the same value. In other words, data will quickly "swamp" weak prior probabilities such as those based on the principle of indifference, which is why different priors are typically not important in practice.

The main reason for the vehement disagreement between the frequentist (or classical statistics) interpretation and the degree of belief (or Bayesian) interpretation is the perjorative label "subjective" associated with the Bayesian approach, particularly in the assignment of prior probabilities. This dispute is largely academic, as in practice, domain knowledge usually suggests appropriate priors. Because priors are inherently subjective does not mean that they are arbitrary, as they are based on the subject's experience. Recently, writers such as J. O. Berger (1985) have shown that the "objective" frequentist interpretation is just as subjective as the Bayesian. In other words, the attempt to circumscribe the definition of probability to "objective" long-run frequencies not only greatly reduced its applicability but did not succeed in eliminating the inherent subjectivity in reasoning under UNCERTAINTY.

Problem Solving

Solving a problem is transforming a given situation into a desired situation or goal (Hayes 1989). Problem solving may occur inside a mind, inside a computer, in some combination of both, or in interaction with an external environment. An example of the first would be generating an English sentence; of the last, driving to the airport. If a detailed strategy is already known for reaching the goal, no problem solving is required. A strategy may be generated in advance of any action (planning) or while seeking the goal.

Studying how humans solve problems belongs to *cognitive psychology.* How computers solve problems belongs to *artificial intelligence.* ROBOTICS studies how computers solve problems requiring interaction with the environment. As similar processes are often used, there is frequent exchange of ideas among these three subdisciplines.

To solve a problem, a *representation* must be generated, or a preexisting representation accessed. A representation includes (1) a *description* of the given situation, (2) *operators* or actions for changing the situation, and (3) *tests* to determine whether the goal has been achieved. Applying operators creates new situations, and potential applications of all permissible operators define a branching tree of achievable situations, the *problem space.* Problem solving amounts to searching through the problem space for a situation that satisfies the tests for a solution (VanLehn 1989).

In computer programs and (as cumulating evidence indicates) in people, operators usually take the form of condition-action rules (*productions*). When the system notices that the conditions of a production are satisfied, it takes the corresponding action of accessing information in memory, modifying information, or acting on the environment (Newell and Simon 1972).

In most problems of interest, the problem space is very large (in CHESS, it contains perhaps 10^{20} states; in real life, many more). Even the fastest computers cannot search such

spaces exhaustively, and humans require several seconds to examine each new state. Hence, search must be highly selective, using *heuristic rules* to select a few promising states for consideration. Chess grandmasters seldom search more than 100 states before making a move; the most powerful chessplaying computer programs search tens of billions, still a minuscule fraction of the total. In such tasks, expert computer programs trade off computer speed for some human selectivity (De Groot 1965).

The *heuristics* that guide search derive from properties of the task (e.g., in chess, "Ignore moves that lose pieces without compensation"). If a domain has strong mathematical structure (e.g., is describable as a linear programming problem), strategies may exist that always find an optimal solution in acceptable computation time. In less well structured domains (including most real-life situations) the heuristics follow plausible paths that often find satisfactory (not necessarily optimal) solutions with modest computation but without guarantees of success. In puzzles, the problem space may be small, but misleadingly constructed so that plausible heuristics avoid the solution path. For example, essential intermediate moves may increase the distance from the goal, whereas heuristics usually favor moves that decrease the distance.

An important heuristic is *means-ends* analysis (Newell and Simon 1972). Differences between the current situation and the goal situation are detected, and an operator selected that usually removes one of these differences. After application of the operator eliminates or decreases the difference, the process is repeated. If the selected operator is not applicable to the current situation, a subgoal is established of applying the operator. Means-ends analysis is powerful and general, but is not useful in all problems: for example, it cannot solve the Rubik's Cube puzzle in any obvious way.

Problems are called *well structured* if the situations, operators, and goal tests are all sharply defined; *ill structured,* to the extent that they are vaguely defined. Blending petroleum in a refinery, using linear programming, is a well-structured problem. Playing chess is less well structured, as it requires fallible heuristics to seek and evaluate moves.

Designing buildings and writing novels are highly ill-structured tasks. The tests of success are complex and ill defined, and are often elaborated during the solution process (Akin 1986). The alternative operations for synthesizing a design are innumerable, and may be discovered only by inspecting a partially completed product. As optimization is impossible and several satisfactory solutions may be encountered, the order in which alternatives are synthesized strongly affects the final product. Starting with the floor plan produces a different house than starting with the facade.

The study of problem solving has led to considerable understanding of the nature of EXPERTISE (human and automated). The expert depends on two main processes: HEURISTIC SEARCH of problem spaces, and *recognition* of cues in the situation that access relevant knowledge and suggest heuristics for the next step. In domains that have been studied, experts store tens of thousands or hundreds of thousands of "chunks" of information in memory, accessible when relevant cues are recognized (Chi, Glaser, and Farr 1988). Medical diagnosis (by physicians or computers) pro-

ceeds largely by recognition of symptoms, reinforced by inference processes. Most of what is usually called "intuition," and even "inspiration," can be accounted for by recognition processes.

Testing theories of problem solving, usually expressed as computer programs that simulate the processes, requires observing both outcomes and the steps along the way. At present, the most fine-grained techniques for observation of the processes are verbal (*thinking aloud*) or video protocols, and eye movement records (Ericsson and Simon 1993). Studies of brain damage and MAGNETIC RESONANCE IMAGING (MRI) of the brain are beginning to provide some sequential information, but most current understanding of problem solving is at the level of symbolic processes, not neural events.

Research has progressed from well-structured problems calling for little specific domain knowledge to ill-structured problems requiring extensive knowledge. As basic understanding of problem solving in one domain is achieved, research moves to domains of more complex structure. There has also been considerable movement "downward" from theories, mainly serial, of symbolic structures that model processes over intervals of a fraction of a second or longer, to theories, mainly parallel, that use *connectionist networks* to represent events at the level of neural circuits. Finally, there has been movement toward linking problem solving with other cognitive activities through *unified models of cognition* (Newell 1990).

Recent explorations extend to such ill-structured domains as *scientific discovery* (e.g., Langley et al. 1987) and architectural design (Akin 1986). In modeling scientific discovery and similarly complex phenomena, multiple problem spaces are required (spaces of alternative hypotheses, alternative empirical findings, etc.). We are learning how experimental findings induce changes in representation, and how such changes suggest new experiments. Allen Newell's (1990) Soar system operates in such multiple problem spaces. Kim, Lerch, and Simon (1995) have explored the generation of problem representations, and there is increasing attention to nonpropositional inference (e.g., using mental IMAGERY in search; Glasgow, Narayanan, and Chandrasekaran 1995). Several models now can represent information in both propositional (verbal or mathematical) and diagrammatic forms, and can use words and mental images conjointly to reason about problems.

Another important area of recent research activity explains intuition and insight in terms of the recognition processes of the large memory structures found in knowledge-rich domains (Kaplan and Simon 1990; Simon 1995). Yet another area, robotics, shows, by studying problem solving in real-world environments (Shen 1994), how the problem-solver's incomplete and inaccurate models of changing situations are revised and updated by sensory feedback from the environment.

Finally, interest in knowledge-rich domains has called attention to the essential ties between problem solving and LEARNING (Kieras and Bovair 1986). Both connectionist learning systems and serial symbolic systems have shown considerable success in accounting for concept learning (CATEGORIZATION), a key to the recognition capabilities of

knowledge-rich systems. Self-modifying systems of condition-action rules (*adaptive production systems*) have been shown capable, under classroom conditions, of accounting for students' success in learning such subjects as algebra and physics from *worked-out examples* (Zhu et al. 1996).

Production Systems

Production systems are computer languages that are widely employed for representing the processes that operate in models of cognitive systems (NEWELL and Simon 1972).

In a production system, all of the instructions (called productions) take the form:

IF<<conditions>, THEN<<actions>,

That is to say, "if certain conditions are satisfied, then take the specified actions" (abbreviated $C \rightarrow A$). Production system languages have great generality: they can possess the full power and generality of a Turing machine (see TURING). They have an obvious affinity to the classical stimulus-response $(S \rightarrow R)$ connections in psychology, but greater complexity and flexibility, for, in production systems, both the conditions and the actions may, and generally do, contain variables that are instantiated to the appropriate values in each separate application.

The conditions of a production are propositions that state properties of, or relations among, the components of the system being modeled, in its current state. In implementing production systems the conditions are usually stored in a WORKING MEMORY, which may represent short-term memory or current sensory information, or an activated portion of semantic memory (Anderson 1993). To activate a production, all of the conditions specified in its "IF" clause must be satisfied by one or more elements in working memory. The actions that are then initiated may include actions on the system's environment (e.g., motor actions) or actions that alter its memories, including erasing and creating working memory elements.

The operation of a production system can be illustrated by a simple algebraic example that solves linear equations in one unknown:

1. IF the expression has the form $X = N$, where N is a number, THEN halt and check by substituting N in the original equation.
2. IF there is a term in X on the right-hand side, THEN subtract it from both sides, and collect terms.
3. IF there is a numerical term on the left-hand side, THEN subtract it from both sides, and collect terms.
4. IF the equation has the form $NX = M$, $N \neq 1$, THEN divide both sides by N.

If, for instance, the equation were $7X + 6 = 4X + 12$, the condition of the second production would be satisfied, and $4X$ would be subtracted from both sides, yielding $3X + 6 = 12$. Now the condition of the third production is satisfied, and 6 is subtracted from both sides, yielding $3X = 6$. Next, the condition of the fourth production is satisfied and both sides are divided by 3, yielding $X = 2$. Finally, the condition of the first production is satisfied, and substituting 2 for X in the original equation and simplifying gives $14 + 6 = 8 + 12$, or $20 = 20$.

Notice that at the outset, the conditions of both productions 2 and 3 were satisfied. A production system must contain precedence rules that select which production will be executed when the conditions of more than one are satisfied (Brownston et al. 1985). One way in which the set of productions that are executable at any time can be limited is by including goals among their conditions. A goal is simply a symbol that must be present in working memory in order for a production containing that goal among its conditions to execute. Goals are set (i.e., goal symbols are placed in working memory) as part of the actions of other productions. Goals establish contexts so that only productions relevant to the current context will be executed. For example, we could add to the condition side of each production in the system for algebra described above "IF the goal is to solve an equation &." Then, even if the other conditions of these productions were satisfied, if that goal symbol were not in working memory, the productions would not execute.

Production systems were first invented by the logician Emil Post (1943) to provide a simple, clean language for the investigation of questions in the foundations of LOGIC and mathematics. They were borrowed, sometimes under the label of "Markov productions," for use in computer systems programming (languages for compiling compilers). In about the mid-1960s, they were introduced into cognitive science at Carnegie Mellon University, some of their early uses being in the General Problem Solver (GPS; Newell, Shaw, and Simon 1960), and in Tom Williams' thesis (Williams 1972) on a general game-playing program (*see* GAME-PLAYING SYSTEMS). They also found early use as languages for FORMAL GRAMMARS of natural language. Among production systems widely used in cognitive simulation are OPS5 (Brownston et al. 1985; Cooper and Wogrin 1988), Prolog (Clocksin and Mellish 1994), and Act-R (Anderson et al. 1993).

Adaptive production systems are production systems that contain a learning component that is capable of modifying productions already in the system and of creating new productions that can be added to the system (Neves 1978; see LEARNING SYSTEMS). Neves showed how this could be done for algebra by the method of learning from worked-out examples. Consider our earlier example:

$$7X + 6 = 4X + 12$$
$$3X + 6 = 12$$
$$3X = 6$$
$$X = 2$$

Assume that the adaptive production system had learned previously that the allowable actions include adding or subtracting the same numbers from both sides of an equation, or multiplying or dividing both sides by the same number, and simplifying by combining similar terms, but did not know when these actions should be applied to solve a problem. It would now examine the first two lines above, discovering that the unwanted $4X$ ("unwanted" because there is no such term in the last line) had been removed from the right-hand side, and that the action was to subtract this term. In the same way it would find that the condition "unwanted numerical term on left-hand side" characterized the second change, and "unwanted numerical coefficient of X," the third. It would create three new productions (the ones we

have already seen above) and add them to its production system. Thenceforth, it would be capable of solving equations of this general kind.

This method, widely applied in adaptive production systems, of noting and eliminating from an equation expressions that are absent from the final result, is essentially the method of means-ends analysis incorporated in the General Problem Solver (Newell and Simon 1972; see also HEURISTIC SEARCH and PROBLEM SOLVING). The key steps in means-ends analysis are (1) to detect differences between the current and goal situations and (2) to find actions capable of removing these differences. The set of productions shown earlier is simply the "Table of Connections" between differences and operations in the GPS system.

Adaptive production systems, using the method of worked-out examples, today provide the theoretical foundation for a number of computer tutoring systems and mathematics textbooks and workbooks employed successfully in the United States and China (Anderson et al. 1995; Zhu et al. 1996)

Propositional Attitudes

Propositional attitudes are mental states with representa-
tional content. Belief is the most prominent example of a
propositional attitude. Others include intention, wishing and
wanting, hope and fear, seeming and appearing, and tacit
presupposition. Verbs of propositional attitude express a
relation between an agent and some kind of abstract
object—the content of the attitude, the object that is denoted
by a nominalized sentence. So a statement such as "Fred
believes that fleas have wings" says that Fred stands in the
believes relation to *that fleas have wings.* The predicate
"*believes that fleas have wings*" expresses a property that is
ascribed to Fred. A philosophical account of propositional
attitudes must answer two interrelated kinds of questions:
first, what kind of thing is the content of an attitude (what is
the object denoted by the *that*-clause)? Second, how can the
states of mind of agents relate them to such objects? The
problem of explaining how mental states can have represen-
tational content is the problem of INTENTIONALITY.

A propositional attitude—more generally, any state or act
that can be said to be representational—represents the world
as being a certain way, and the content of the attitude is what
determines the way the world is represented (see MENTAL
REPRESENTATION). So propositions must be objects that
have truth conditions that must be satisfied for a representa-
tional state with that content to correctly represent the world.

Many different accounts of the contents of propositional
attitudes have been proposed. Often, propositions are
assumed to be complex objects, ordered sequences with
ordered sequences as parts that reflect the recursive seman-
tic structure of the sentences that express the proposition. In
one kind of account of structured propositions, the primitive
constituents are taken to be Fregean senses, modes of pre-
sentation (see SENSE AND REFERENCE), or CONCEPTS. In an
alternative account of structured propositions, the constitu-
ents are individuals, properties, and relations. So, for exam-
ple, the proposition that Booth killed Lincoln might contain,
as constituents, the senses of the names "Booth" and "Lin-
coln" and of the verb "kill," or alternatively, the men Booth
and Lincoln and the killing relation.

Both of these kinds of account treat the content of propo-
sitional attitudes as a recipe for determining the truth condi-

tions of the representation. A third alternative is to take
propositional contents—the referents of that-clauses—to be
the truth conditions themselves. In this account, the proposi-
tion that Booth killed Lincoln can be identified with the set
of possible circumstances in which Booth killed Lincoln.
This conception of a proposition—call it an *informational
content*—is the most coarse-grained conception of represen-
tational content. Any structured proposition will determine
a unique informational content, but different structured
propositions may have the same informational content.

The choice between different accounts of content
depends on the role of content in determining the proposi-
tional attitudes—the way in which the properties such as
believing that Booth killed Lincoln are determined as a func-
tion of the content *that Booth killed Lincoln.* The more fine-
grained conceptions of content will be justifiable only if the
distinctions between different fine-grained contents with the
same informational content play a role in distinguishing dif-
ferent states. We also need a conception of content that can
account for intuitive judgments about attitudes. If it is intu-
itively obvious that believing that P is different from believ-
ing that Q, then we need a notion of content according to
which "that P" and "that Q" denote different propositions.
The defender of the coarse-grained conception of content
needs to reconcile this account with apparently conflicting
intuitions (see LOGICAL OMNISCIENCE).

The problem of propositional attitudes is often discussed
in the context of a problem of semantics: the problem of
giving the compositional semantics for propositional atti-
tude *reports.* The focus of attention in such discussions has
been on the role of pronouns and other context dependent
expressions, and of quantification in belief contexts. The
problems are closely connected: obviously, the question,
"what kind of object is the content of a belief?" cannot be
answered independently of the question, "what kind of
object is the referent of a that-clause?" But the question
about the semantics of attitude reports needs to be distin-
guished from the philosophical problem of explaining what
propositional attitude properties are, and what it is that
gives them their content. There are a number of alternative
strategies that have been developed for giving such expla-
nations.

First, in one familiar kind of account of propositional
attitudes, belief and desire are correlative dispositions that
are displayed in rational action (see RATIONAL AGENCY and
INTENTIONAL STANCE). Roughly, to believe that P is to be
disposed to act in ways that would satisfy one's desires if P
(along with one's other beliefs) were true, and to desire that
P is to be disposed to act in ways that would tend to bring it
about in situations in which one's beliefs were true. This is
only a very rough sketch of a strategy of locating belief and
desire in a general theory of action. Because belief and
desire are explained in terms of each other, the strategy does
not offer the promise of a reductive analysis of propositional
attitudes, and must be supplemented with additional con-
straints if the contents of attitudes are not to be wholly inde-
terminate.

A second strategy that may supplement the first—the in-
formation theoretic strategy—is to explain representational
states in terms of causal and counterfactual dependencies

between the agent and the world (see INFORMATIONAL SE-MANTICS). One may explain the content of the representational states of an agent in terms of the way those states tend to vary systematically in response to states of the environment. A state of a person or thing *carries the information that P* if the person or thing is in the state because of the fact that P, and would not be in the state if it were not the case that P. The strategy is to explain the content of representational states in terms of the information that the states tend to carry, or the information that the states would carry if they were functioning properly, or if conditions were normal. The information theoretic strategy will give determinate content to representational states only relative to some specification of the relevant normal conditions. A central task of the development and defense of the information-theoretic strategy is to give an account of these conditions.

A third strategy—the *linguistic strategy*—is to begin with linguistic representation, and to explain the content of mental states in terms of the content of sentences that realize the mental states, or of sentences to which the agent is disposed to assent. One version of this strategy, defended by Jerry Fodor (1987) among others, assumes that propositional attitudes are realized by the storage (in the "belief box," to use the popular metaphor) of sentences of a LANGUAGE OF THOUGHT. Another version takes a social practice of speech as primary, accounting for the contents of beliefs in terms of the contents of the sentences of the public language that the agent "holds true," or to which the agent is disposed to assent. Donald Davidson (1984) has defended this kind of strategy (see RADICAL INTERPRETATION). The first version of the linguistic strategy needs a distinction between explicit or "core" beliefs and implicit beliefs, because it would not be plausible to say that everything believed is explicitly stored. The second version has a problem explaining attitudes with content that is not easily expressed in linguistic form (for example, perceptual states), and it seems to conflict with the intuition that thought without the capacity for speech is at least a possibility. Both accounts need to be supplemented with some account of what it is in virtue of which the relevant kind of linguistic representations have content.

Prosody and Intonation

The term *prosody* refers to the grouping and relative prominence of the elements making up the speech signal. One reflex of prosody is the perceived rhythm of the speech. Prosodic structure may be described formally by a hierarchical structure in which the smallest units are the internal components of the syllable and the largest is the intonation phrase. Units of intermediate scale include the syllable, the metrical foot, and the prosodic word (Selkirk 1984; Hayes 1995).

Intonation refers to phrase-level characteristics of the melody of the voice. Intonation is used by speakers to mark the pragmatic force of the information in an utterance. The alignment of the intonation contour with the words is constrained by the prosody, with intonational events falling on the most prominent elements of the prosodic structure and at the edges. As a result, intonational events can often provide information to the listener about the prosodic structure, in addition to carrying a pragmatic message. The term intonation is often used, by extension, to refer to systematic characteristics of the voice melody at larger scales, such as the discourse segment or the paragraph (Beckman and Pierrehumbert 1986; Pierrehumbert and Hirschberg 1990; Ladd 1996).

The primary phonetic correlate of intonation is the fundamental frequency of the voice (F0), which is perceived as pitch and which arises from the rate of vibration of the vocal folds. The F0 is determined by the configuration of the larynx, the subglottal pressure, and the degree of oral closure (Clark and Yallop 1990; Titze 1994). Articulatory maneuvers that change the rate of vibration of the vocal folds also affect the exact shape of the glottal waveform and hence the voice timbre (or voice quality). Perceived voice quality is probably used in perception to assist in the identification of intonation patterns (Pierrehumbert 1997). Intonation is not the only source of F0 variation. Speech segments also have systematic effects on F0. However, the largest segmental effects are on the time-frequency scale of the smaller intonational effects. Thus, F0 contours can be roughly viewed as a superposition of segmental factors on the intonationally determined contour.

Many experimental studies show that prosody affects all aspects of the speech signal (see *Papers in Laboratory*

Phonology and references cited there). In general, elements found in prosodically prominent positions are more forcefully and fully articulated than elements in prosodically weak positions. The space of acoustic contrasts is therefore expanded in strong positions compared to that in weak positions. Edges of prosodic units also affect phonetic outcomes. Consonantal articulations tend to be strengthened at initial edges of prosodic words and intonation phrases. Final syllables of words and intonation phrases are regularly lengthened. An extensive literature on isochrony addresses the possibility that speech has a steady beat with a constant interval between the stresses. This literature has established that interstress intervals in fact vary widely as a function of the material comprising the interval. However, when the principle determinants of duration are controlled for, evidence of a tendency towards isochrony is reported in some studies.

Contextual effects related to prosody are substantial and rank with speech style and speaker characteristics as sources of variation in the realization of phonemes and DISTINCTIVE FEATURES. The variation is great enough that a token of one phoneme in one prosodic position can be identical to a token of a different phoneme in some other prosodic position. For example, in American English, a phrase-final /z/ is virtually identical to a medial /s/. Similarly, a 20-story building in Evanston, Illinois, provides an example of a "tall building," but it would be an example of a "short building" if it were in downtown Chicago. That is, the context-dependence of the phonetic realizations of phonemes is similar in character to context-dependence found in other domains, and it provides an example of the abstractness and adaptability of human cognition.

Because of intense research activity over the last two decades, the phonological theory of prosody and intonation is now well developed. It characterizes the cognitive structures that must be viewed as implicitly present in the minds of speakers in order to explain their use of prosody and intonation in both speech production and SPEECH PERCEPTION.

The central concepts of prosodic theory are the prosodic units (the syllable, the foot, the intonation phrase, etc.) and the relations defined among these units. The units are temporally ordered. Bigger units dominate smaller ones. Within each unit, a relationship of strength is available that singles out one element as more prominent than the other elements of the same type in the group. Strength is inherited through the hierarchy; the head syllable of an intonation phrase can be defined as the strongest syllable in the strongest foot in the strongest word in that phrase. Although it is generally agreed that prosodic structures are hierarchical, they contrast with syntactic structures in making much less use of recursion. In SYNTAX, we find clauses embedded within other clauses, but in PHONOLOGY, we do not find syllables embedded within other syllables. The only serious candidate for a recursive node in prosody is the prosodic word, and scholars do not agree about whether this node is recursive or not. As a consequence of the relative flatness of the prosodic structure, syntactic structures are flattened when the prosodic phrasing is computed. For example, in sentence (1), a recursive syntactic structure corresponds to a prosodic structure in which three intonation phrases are on a par with each other.

(1) This is the cat % that ate the rat % that stole the cheese.

The intonation system of English has been extensively studied. Points of agreement among many researchers in the English-speaking countries have recently been codified in the ToBI transcription standard, for which on-line training materials are available (Pitrelli, Beckman, and Hirschberg 1994; Beckman and Ayers Elam 1994/97). According to this standard, intonation contours may be "spelled" using three basic tonal elements: low tone (L), high tone (H), and downstepped high tone (!H). !H represents the combination of high tone with a compression and lowering of the pitch range; a sequence of !Hs generates an F0 contour with a descending staircase. Pitch accents, which mark prominently stressed syllables in the phrase, are made up of these elements. The nuclear accent is defined as the accent on the main stress of the entire phrase. The prenuclear accents fall on prominent syllables earlier in the phrase. Every complete utterance must have (at least one) nuclear accent, but some utterances lack prenuclear accents. In addition to the pitch accents, each contour has boundary tones which mark the edges of the intonation phrase.

All languages have prosody and intonation, but there are many important differences among the systems found in various languages. They differ in the total inventory of intonational patterns and in the pragmatic meanings assigned to particular patterns. Languages with lexical tone (whether tone languages such as Mandarin or classic pitch accent languages such as Japanese) tend to have somewhat simpler intonational systems than English, presumably because much of the F0 contour is taken up with providing phonetic expression of the tones in the words (see Pierrehumbert and Beckman 1988; Hayes and Lahiri 1991; Hayes 1995; Myers 1996).

In the prosodic domain, languages differ in the constraints they impose on the composition of the various units. At the phrasal level, they differ in how they set up the correspondance between intonational phrases and syntactic and semantic structures. Some languages tend to locate prosodic breaks after a syntactic head, whereas others tend to locate breaks before. Some languages (such as English) permit the main prominence to be located anywhere in the phrase (for the purpose of highlighting or foregrounding particular words). Other languages make little or no use of variable placement of prominence within the phrase, instead moving new information to fixed prosodically prominent positions. Turning to smaller prosodic units, some languages permit syllables with complicated consonant clusters and others do not (Goldsmith 1990). Languages also differ in foot structure (Hayes 1995) and in the salience or importance of the different prosodic units (Beckman 1995). For example, in English the foot structure conspicuously shapes the lexical inventory and greatly affects how phonemes are pronounced. Foot structure exists in Japanese but smaller units (the syllable and the mora) vary much less with position in the foot and, as a result, exhibit a robustness that they lack in English.

In considering the contribution of prosody to interpretation, it is useful to separate prosodic structure within the

word from prosodic structure above the word level. Prosodic structure within the word (i.e., syllable and foot structure) is an important factor in lexical access, shaping the segmentation strategy in each language and the set of active competitors for any given word at any given time (Cutler 1995). Prosodic structure above the word level (phrasing and phrasal prominence) reflects syntax, SEMANTICS, and DISCOURSE structure. As a result, it has repercussions for syntactic parsing, for the scope of operators such as "only," "even," and "not," for the understood reference of pronouns, and for the topic/comment structure of the discourse (Jackendoff 1972; Terken and Nooteboom 1987; Hirschberg and Ward 1991).

Intonation contours function as independent pragmatic morphemes. According to Pierrehumbert and Hirschberg (1990), the contour indicates the relationship of each utterance to the mutual beliefs that are developed and modified in the course of a conversation. For example, an H accent marks an intended addition to the mutual beliefs, whereas L accents mark information that is marked as salient but not to be added. The tremendous variety of understood meanings of patterns in context arises from the interplay of these factors with the goals and assumptions of the interlocutors. (For other treatments of the pragmatic meaning of intonational morphemes, see Gussenhoven 1983, Ward and Hirschberg 1985, and Morel 1995.)

Intonation and prosody are obligatory. Every single utterance has a prosodic analysis and represents some choice of intonation pattern, just as it represents some choice of phonemes and syllables. In experimental studies with aural stimuli, it is not possible to avoid or omit the contribution of intonation by using a monotone F0 contour. Similarly, experiments on words "in isolation" are in fact using words which are phrase-initial, phrase-final, and under main stress in the phrase (if the stimuli are well formed), because linguistic structure requires that every utterance no matter how short be a full intonation phrase. As a result, words produced "in isolation" also carry a complete phrasal melody. Results of experiments on words in isolation often show artifacts of this prosodic positioning and fail to generalize to words in running speech, which most often constitute only a part of a full intonation phrase.

The outcomes of experiments on syntactic processing, scope, and reference resolution in running speech are likely to be affected by the phrasal prosody of the stimuli. It is therefore desirable to control for this factor and to use an established transcriptional standard to report the prosody of the stimuli actually used. Orthogonal variation of the word string and the prosodic pattern may be used to factor out the prosodic and nonprosodic factors in the domain under investigation.

Experimental work on intonational meaning is challenging because the meanings by their very nature are highly variable with context. Judgments of intonational meaning obtained for materials out of context are variable and difficult to interpret because they are affected by the subjects' uncontrolled imaginings of what the context might be. However, very good results have been achieved with experimental studies in which subjects evaluate the felicity of particular patterns for specified discourse contexts or the understood force of patterns as they are presented in context. With a careful eye to the discourse context, experimental work on intonational meaning is one of the more feasible and promising areas for experimental work in PRAGMATICS.

Prosody and Intonation, Processing Issues

PROSODY AND INTONATION determine much of the form of spoken language. An account of the processing of language—the production and comprehension of words and sentences—must therefore pay attention to prosodic (rhythmic, grouping) and intonational (melodic) structure. The fact that more research in PSYCHOLINGUISTICS has involved written language than spoken language, however, means that the role of prosody and intonation in processing is not yet fully described.

In studies of language comprehension, prosody and intonation have figured in research on SPOKEN WORD RECOGNITION, on SENTENCE PROCESSING (the computation of syntactic structure) and on DISCOURSE processing. One role of prosody and intonation in word recognition is to aid in the operation of segmenting a continuous input into its component words. Studies in many languages (see, for example, the summaries in Otake and Cutler 1996) have shown that listeners can use the rhythmic structure of utterances to determine where word boundaries are most likely to fall. Because rhythmic structure differs across languages, this means that the processes involved in segmenting utterances into words can also be language-specific—stress-based in English (Cutler and Norris 1988), syllable-based in French (Mehler et al. 1981), and mora-based in Japanese (Otake et al. 1993). This language specificity can result in inappropriate application of native-language segmentation procedures to foreign languages with a different rhythmic structure (Otake and Cutler 1996). Young infants can discriminate between rhythmically dissimilar but not rhythmically similar languages (Nazzi, Bertoncini, and Mehler 1998).

Whether prosodic and intonational information play a role in the processing of word forms per se—for instance, in the activation of lexical entries—is as yet unresolved. The structure of spoken words again differs across languages in ways that affect this issue. Explicit suprasegmental distinctions between words—for example, TONE in languages such as Thai, pitch accent in languages such as Japanese—constrain word activation and thus show that suprasegmental information can play a role at this level. Suprasegmental cues to LINGUISTIC STRESS in English nevertheless appear to play no part in word activation (Cutler 1986): two words that differ solely in suprasegmental structure, such as *foregoing* (primary stress on the first syllable) and *forgoing* (primary stress on the second syllable), are both activated when listeners hear either one, just as is the case with two words pronounced in every respect identically (such as *sale* and *sail*). However, stress in English is, except in rare pairs such as *foregoing/forgoing*, expressed segmentally (in vowel quality) as well as suprasegmentally, so that segmental information alone may in practice suffice for lexical activation in this language. This is not necessarily the case in other stress languages (Cutler, Dahan, and van Donselaar 1997).

In syntactic processing, the relevant questions have been: do prosody and intonation serve to divide the input into major syntactically motivated chunks? Does such information help to resolve ambiguity, such that sentences which allow more than one interpretation when they are written—for example, *I read about the repayment with interest*—are effectively unambiguous when spoken? And does prosodic and intonational information determine selection between alternative syntactic analyses that present themselves, albeit temporarily, during the processing even of an unambiguous sentence—for example, between possible continuations of *The horse raced by the*—(*—gate*;—*Queen won*)? The evidence is mixed (see special issues of *Language and Cognitive Processes* and *Journal of Psycholinguistic Research* in 1996 for overviews) but in general offers little support for direct availability of syntactic information in prosodic and intonational structure. Prosodic hierarchies, after all, encode specifically prosodic, not syntactic relationships (Shattuck-Hufnagel and Turk 1996; Beckman 1996). Prosody may signal syntactic cohesion (Tyler and Warren 1987), and the presence of a sentence accent or of prosodic correlates of a syntactic boundary can have an effect on syntactic analysis in that it can, for example, lead the listener to prefer analyses that are consistent with the prosody (Nespor and Vogel 1983). But no evidence suggests that syntactic analysis is directly derived from prosodic or intonational cues.

In the comprehension of discourse structure, prosodic salience appears most important; speakers highlight via accent the words that are semantically more central to a message (Bolinger 1978; Ladd 1996), and listeners actively search for accented words because of their central semantic role (Cutler 1982; Sedivy et al. 1995). Furthermore, processing is facilitated by the placement of accent on new information, and the deaccenting of old information (Bock and Mazzella 1983). Experimental evidence suggests that the processing of deaccented words involves integration with an existing discourse model (Fowler and Housum 1987), but it is unclear whether the facilitation observed

with deaccentuation reflects direct exploitation of accent information in discourse-structure decisions or arises indirectly via reference to an existing discourse model in the course of decoding the poorer acoustic information available from deaccented speech. Finally, listeners can interpret prosodic information to derive cues to topic and turn-taking structure in discourse (Hirschberg and Pierrehumbert 1986). Intonational structure is also important for the interpretation of discourse (Pierrehumbert and Hirschberg 1990); the derivation of meaning from intonation involves simultaneous consideration of contours and of the sentential and discourse context in which they appear (Grabe et al. 1997).

The computation of both prosodic and intonational form must of course likewise play a role in speakers' utterance production (Levelt 1989), with prosodic generation referring both to the lexical items and the syntactic structure selected (Ferreira 1993; Meyer 1994), and intonational generation referring to both the sentence to be spoken and its context (Ladd 1996). Production of phonologically alternative forms of words (e.g., via deletion or addition of sounds, as when the middle vowel of *family* is deleted, or a vowel is inserted between the last two sounds of *film*) can be prompted by the prosodic pattern in which the word is uttered (Kuijpers and van Donselaar 1998).

Because, as noted above, there has been less psycholinguistic research on issues specific to spoken language than on the processing of written language, and because it is in addition true that LANGUAGE PRODUCTION has so far attracted far less experimental research than language comprehension, it will be obvious that the production of prosody and intonation is a research area very much in need of wider empirical attention.

Psychoanalysis, Contemporary Views

Though a number of key issues have been clarified, there is no more agreement now than there was half a century ago concerning the status and objectivity of psychoanalysis.

Controversy in the understanding and evaluation of psycho-analysis has its origin in the multifaceted character of Sigmund FREUD's theorizing—the plurality of other disciplines with which Freud allied it, and the mix of methodologies that he employed—but it is also a function of several other variables, including the diversity of schools (Kleinian, Jungian, ego-psychological, etc.) within the psychoanalytic movement itself, the uncertainty as to whether psychoanalysis is fundamentally a theory or a practice, and the variety of philosophical outlooks that have had an interest in either assimilating or repudiating psychoanalytic ideas.

It is helpful to distinguish in the diversity of schools two modes of approach to psychoanalysis: those that locate discussion of psychoanalysis firmly in the context of scientific methodology, and those that give priority to issues in the philosophy of mind. There is a tendency for this distinction to be correlated with contrasting estimates—respectively negative and positive—of the objectivity of psychoanalysis.

In the first group, the two landmark writings are Karl Popper 1963 (ch. 1) and Adolf Grünbaum 1984. Popper's enormously influential attack on psychoanalysis, in the context of a general rejection of inductivism in the philosophy of science, consists of the claim that psychoanalysis fails to open itself to refutation and so does not satisfy the condition of falsifiability that (in his account) supplies the only alternative to inductive support. On account of its alleged immunity to counter-evidence, psychoanalysis is classified as a "pseudoscience." Popper's criticisms (which in part stand independently of his own philosophy of science) had the effect of making untenable the naive view of psychoanalysis as a set of hypotheses unproblematically grounded in experience, and of provoking attempts—the results of which have been markedly inconclusive—to test psychoanalytic hypotheses experimentally in controlled, extra-clinical contexts (see Eysenck and Wilson 1973).

In direct opposition to Popper, Grünbaum maintains that psychoanalysis can be evaluated scientifically, and has elaborated a highly detailed critique of psychoanalysis centered on Freud's avowed aspiration to provide a theory of the mind that is successful by the canons of natural science, these being inductive, in Grünbaum's view. Grünbaum argues that Freudian theory reposes on claims that only psychoanalysis can give correct insight into the cause of neurosis, and that such insight is causally necessary for a durable cure. Grünbaum then proceeds to underline the empirical weakness of psychoanalysis' claim to causal efficacy, and presses the familiar objection that the therapeutic effects of psychoanalysis may be due to suggestion. Furthermore, Grünbaum argues that even if the clinical data is taken at face value, the inferences that Freud draws are unwarranted. (For further discussion of psychoanalysis' scientificity, see Hook 1964 and Sachs 1991.)

Discussion of psychoanalysis was initiated by philosophers sensitized by Wittgenstein's work in the philosophy of psychology to a set of issues independent from scientific methodology. They addressed the more basic conceptual question of whether psychoanalytic explanations are causal or rationalizing in form—the common assumption being that these are exclusive modes of explanation—and on this basis formulated different views of psychoanalysis' cogency, some

of them positive (see MacDonald 1954: pt. VI). In response to the perceived problem of mechanism in Freudian metapsychology, Schafer (1976) undertook to translate its terms into those of "action language," an approach found attractive by many psychoanalytic theorists.

Contemporary developments in this vein bear witness to the subsequent explosion of work in the philosophy of mind, particularly to the influence of Donald Davidson's compatibilism of reasons and causes, and his ANOMALOUS MONISM. The significance of Davidson's work is to allow a reading of psychoanalysis that is consistent with physicalism and does justice simultaneously to psychoanalysis' commitment to search for meaningful connections among mental phenomena and its claim to provide causal explanation, while freeing it from the obligation to come up with strict causal laws. Against this background it becomes possible to argue that psychoanalysis is an extension of commonsense FOLK PSYCHOLOGY, arrived at by modifying the familiar "belief-desire" schema of practical reason explanation, for which it substitutes the concepts of wish and fantasy. (Melanie Klein's development of Freud's theories assumes, in this approach, special importance.) In such a view, psychoanalysis does not, contra Grünbaum, repose logically on therapeutic claims, and the specific inductive canons of the natural sciences are inappropriate to its evaluation; the grounds for psychoanalysis lie instead in its offering a unified explanation for phenomena (DREAMING, psychopathology, mental conflict, sexuality, and so on) that commonsense psychology is unable, or poorly equipped, to explain. (Defending this broadly circumscribed approach, see above all Wollheim 1984, 1991, and 1993, Hopkins 1988, 1991, and 1992; and also Davidson 1982; Lear 1990; Cavell 1993; and Gardner 1993.) This approach can be vindicated only if there is a determinate interpretative path from the attributions of commonsense psychology to those of psychoanalysis, a matter that can be decided only by examining clinical material. The central philosophical difficulty facing this approach is to show that psychoanalysis can extend commonsense psychology at the same time as revising it, that is, that the modifications psychoanalysis makes to commonsense psychology are not so radical as to effectively cut it loose from the latter. Thus two important questions for this approach, which continue to generate controversy, concern the intelligibility of postulating mental states that are unconscious (see Searle 1992: ch. 7) and mental content that is prelinguistic, unconceptualized, or nonpropositional (see Cavell 1993).

The ascent of cognitive science has encouraged the formulation of a further set of positions on psychoanalysis, which stand midway between the two groups just described. Freud's very early "Project for a scientific psychology" (1950/1895), an attempt at a general neurological theory of mental functioning, allows itself to be recast in more contemporary, computational terms (see Gill and Pribram 1976), and subpersonal reconstructions of Freud's properly psychoanalytic theories, implying their fundamental continuity with the "Project," have been offered (see Erdelyi 1985). Kitcher (1992) has made a detailed case for the stronger thesis that Freud should be interpreted as seeking to establish an interdisciplinary science of the mind of the

sort that cognitive science now aims at. Cummins (1983: ch. 4) offers an understanding of psychoanalysis as striving to coordinate an interpretive level of description of the mind with an underlying functional story. Assuming psychoanalysis and cognitive science to be both empirically well grounded, some degree of fit between their functional delineations of the mind is almost certain. Whether any substantial theoretical integration of psychoanalysis with cognitive science can reasonably be expected is moot, however, and arguably stands or falls with the success of cognitive science in analyzing higher-level, propositional attitude-involving cognitive capacities.

The positions indicated above are far from exhaustive, and a comprehensive survey would include also Continental developments. One particularly influential early contribution is Jürgen Habermas's (1971/1968) hermeneutic reading, which seeks to separate psychoanalysis wholly from the natural sciences—this association being attributed to a naturalistic and scientific misconception of psychoanalysis on Freud's part—and integrate it with communication theory. Later Continental writers, having Lacanian psychoanalysis as a model, have tended to develop theories of psychoanalysis strongly oriented toward purely philosophical themes of representation and subjectivity.

Collections discussing psychoanalysis from various philosophical angles include Wollheim and Hopkins 1982, Clark and Wright 1988, and Neu 1991.

Psychoanalysis, History of

One of Sigmund Freud's basic psychoanalytic claims was that dreams and symptoms were *wish fulfillments* (Freud 1900; for italicized terms see Laplanche and Pointalis 1973). A particularly simple example is that in which a thirsty person dreams of drinking, and thereby temporarily pacifies the underlying desire. Schematically, in the case of real satisfaction, a desire that P (that I get a drink) brings about a real situation that P (I get a drink), and this in turn brings about an experience or belief that P which pacifies the desire, that is, causes it to cease to operate. In Freudian wish fulfillment, by contrast, a desire operates to bring about an experience- or belief-like representation of satisfaction (I dream of drinking) and so pacifies the desire in the absence of the real thing. Freud hypothesized that this process was effected by the activation of neural prototypes of past desire-satisfaction sequences, and he took this to be the mind/brain's earliest and most basic way of coping with *desire* (1895).

FREUD found this pattern of representational pacification in more complex instances, and was thus able to see dreams, symptoms, and many other depictive phenomena as representing the satisfaction of unfulfilled wishes or desires, which could be traced back to childhood and bodily experience. Analysis indicated that little children attached great

and formative emotional significance to very early interactions with their parents in such basic proto-social activities as feeding and the expulsion and management of waste. These involved the first use of the mouth, genitals, and anus, and the early stimulus of these organs apparently roused feelings continuous with their later uses in normal and abnormal *sexuality* (1905). Little children's motives thus included desires to harm or displace each parent, envied and hated as a rival for the love of the other, as well as to preserve and protect that same parent, loved both sensually and as a caretaker, helper, and model. Because these desires were subject to particularly radical conflict they were characteristically *repressed,* and thus rendered *unconscious,* and kept from everyday planning and thought.

Repression entailed that such desires could enter consciousness only in a symbolic form, and so could be expressed in intentional action only via symbol-forming processes such as *sublimation* (1908). Symbolizing incestuous desires in terms of ploughing and planting mother earth, for example, could render such activities meaningful as expressions of wish fulfilling *phantasy.* Thus, according to Freud, the activities of everyday life acquired the kind of unconscious representational significance he had found in dreams and symptoms, and were accordingly subject to unconscious reinforcement, inhibition, etc. Infantile desires (or the contents of infantile neural prototypes) were not lost, but were continually rearticulated through symbolism so as to direct action toward their pacification throughout life. This was thus the *primary process* through which desire was regulated.

Particular phantasies also realize many of the mechanisms described in psychoanalytic theory. Thus phantasies of *projection* assign (usually undesirable) traits from the self to another, whereas those of *introjection* assign (usually desired) traits of the other to the self. The "good in/bad out" operation of these mechanisms, and the processes of *identification* that they effect, are significant for both individual development and social organization.

The young child achieves self-control partly by forming phantasy images derived from the parents as regulators of its early bodily activities. Because these "earliest parental *imagoes*" (1940) embody the child's infantile aggression in a projected form, they are introjected as a *super-ego* far more threatening and punitive than the actual parents. Later the child identifies with its parents in their role as agents, that is, as satisfiers and pacifiers of their own desires, and these identifications form the *ego.* The members of many groups identify with one another by introjecting a common idealized leader or cause (1921: 67ff), or by projecting their destructive motives into a common locus that thereby becomes a legitimated focus of collective hate. Those who find such a common good or bad object feel united, purified, and able to validate destructive motives by common ideals. The processes that establish the individual conscience thus also create a pattern of "good us/bad them" that enlists its ferocity in the service of group aggression.

After the Nazi occupation many analysts left Europe, and post-Freudian psychoanalysis evolved in distinct ways in different countries, often in response to analysts who settled there. In England, Anna Freud and Melanie Klein developed

techniques for analyzing the play of children. This made it possible for child analysts to confirm and revise Freud's descriptions of childhood, and to propose further hypotheses about infancy.

Klein (1975) noted that the uninhibited play of children in analysis showed that their conflicts were rooted in unconscious images that represented versions of their parents as both unrealistically good and extremely bad and malevolent. She explained these as resulting from a process of projection that represented the other as containing disowned aspects of the self, which in turn was fragmented and depleted by the projective loss. Klein called this *projective identification,* and hypothesized that it operated most forcefully before the child gained a working grasp of the concept of identity, and hence before it recognized that the parental figures it felt as bad were the same as those it felt as good. Klein called this preobjectual phase of development the *paranoid-schizoid position,* the term "paranoid" marking the extremity of the baby's potential for anxiety, and "schizoid" the fragmentary way it represents both itself and its objects. As the infant starts unifying its images, this phase yields to the *depressive position,* so named because unification entails liability to depression about harming or losing the object (principally the feeding, caring mother), now seen as complex (frustrating as well as gratifying) and liable to be misconceived, but also as unique and irreplaceable.

Klein's discussions of the child's relation to phantasied objects, characteristically different from those in the actual environment, inaugurated the *object-relations* approach to psychoanalysis, continued by Ronald Fairbairn (1954), Donald Winnicott (1958), and a number of others of the so-called British School. Accounts in these terms have now been elaborated by all schools (see Kernberg 1995). Klein's ideas were applied to groups by Wilfred Bion (1961), and by Bion (1989) and Hanna Segal (1990) to the infantile origins of symbolism and thought. They also influenced John Bowlby (1980), whose work fostered extensive study of child-parent attachment (Ainsworth 1985; Karen 1994).

Freud introduced the ego and super-ego both as functional systems mediating between the individual's innate *drives* and the external world, and as modelled on persons. In this he attempted to combine functional explanation with the empirical claim that the way persons function depends upon their internal representations of themselves and others. This mode of explanation, called *ego-psychology,* was elaborated by Anna Freud (1936), and by Heinz Hartmann (1958) and his colleagues in the United States. Hartmann focused particularly upon the attainment of autonomy in object-relations, which he took to be dependent upon object constancy, the ability to represent self and other consistently, despite absence and changes in emotion. This was carried into empirical research on children by Renee Spitz (1965), and developed further by Edith Jackobsen (1964) and Margaret Mahler (1968) and her associates, who sought to describe the process of individuation that issued in object constancy.

More recently, Heinz Kohut (1977) has argued that the pathology of the "fragmented" or "depleted" SELF requires a new "self-psychology" for its conceptualization. He introduces the notion of "self-object," that is, another who is

experienced as performing essential psychological functions for the self, and so felt part of it. When the parents fail in essential self-object functions the child—or the analytic patient in whom such needs have been re-activated—responds with narcissistic rage, and may become convinced that the environment is fundamentally hostile. Kohut compares this situation to Klein's paranoid-schizoid position, and the fragmentation and depletion with which he is concerned is evidently linked to that which Klein describes as consequent on infantile projective identification (for a recent synthesis see Kumin 1996).

Psychoanalysis in France has been particularly influenced by Jacques Lacan, whose resonant formulations (1977) link analytic ideas with themes in French philosophy, linguistics, and anthropology. A baby who joyfully identifies itself in a mirror, according to Lacan, thereby represents itself as having a wholeness, permanence, and unity that anticipates and facilitates its ability to move and relate to others. But this identification is also an alienation, for the infant now regards itself as something it does not actually feel itself to be, and which it may yet fail to become. Identifications with others are simultaneously enabling and alienating in the same way, so that the external images by which the self is constituted always threaten to confront it as reminders of its own lack of being.

Lacan assigns these images to an order of representations that he describes as the *imaginary,* and contrasts with the *symbolic order* of personal and social sign-systems whose elements are constrained by rules of combination and substitution comparable to those of natural language. The combinations/substitutions of (representations of) objects in dreams and symptoms, or again in the course of development, can be seen as constrained by such rules, and so as instances of metaphor, metonymy, and other linguistic forms. So, Lacan argues, the unconscious is structured like a language. Comparable structuring holds for social phenomena. Thus the resolution of the *Oedipus Complex* is a development in which the boy forgoes an imaginary relation with the mother to occupy a place in the social order that is symbolic, social, and constitutive of human culture. As in the prior instance of the mirror, the child secures a potentially fulfilling identity via the enabling but alienating assumption of an image, this time of the symbolic father, who embodies the social laws regulating sexual desire and providing for its procreative satisfaction.

Psycholinguistics

Psycholinguistics is the study of people's actions and mental processes as they use language. At its core are speaking and listening, which have been studied in domains as different as LANGUAGE ACQUISITION and language disorders. Yet the primary domain of psycholinguistics is everyday language use.

Speaking and listening have several levels. At the bottom are the perceptible sounds and gestures of language: how speakers produce them, and how listeners hear, see, and identify them (see PHONETICS, PHONOLOGY, SIGN LANGUAGES). One level up are the words, gestural signals, and syntactic arrangement of what is uttered: how speakers formulate utterances, and how listeners identify them (see SENTENCE PROCESSING). At the next level up are communicative acts: what speakers do with their utterances, and how listeners understand what they mean (see PRAGMATICS). At the highest level is DISCOURSE, the joint activities people engage in as they use language. At each level, speakers and listeners have to coordinate their actions.

Speakers plan what they say more than one word at a time. In conversation and spontaneous narratives, they tend to plan in *intonation units,* generally a single major clause or phrase delivered under a unifying intonation contour (Chafe 1980). Intonation units take time to plan, so they often begin with pauses and disfluencies (*uh* or *um,* elongated words, repeated words). For example, one speaker recounting a film said: "[1.0 sec pause] A--nd u--m [2.6 sec pause] you see him taking . . . picking the pears off the leaves."

Planning such units generally proceeds from the top level of language down—from intention to ARTICULATION (Levelt 1989). Speakers decide on a message, then choose constructions for expressing it, and finally program the phonetic segments for articulating it. They do this in overlapping stages.

Formulation starts at a *functional level.* Consider a woman planning "Take the steaks out of the freezer." First she chooses the subject, verb, direct object, and source she wants to express, roughly "the addressee is to get meat from a freezer." Then she chooses an appropriate syntactic frame, an imperative construction with a verb, object, and source location. She then finds the noun and verbs she needs, *take, steak,* and *freeze.* Finally, she fills in the necessary syntactic elements—the article *the,* the preposition *out of,* and the suffixes *-s* and *-er.* Formulation then proceeds to a *positional level.* She creates a phonetic plan for what she has formulated so far. She uses the plan to program her articulatory organs (tongue, lips, glottis) to produce the actual sounds, "Take the steaks out of the freezer." Processing at these levels overlaps as she plans later phrases while articulating earlier ones.

Much of the evidence for these stages comes from slips of the tongue collected over the past century (Fromkin 1973; Garrett 1980). Suppose that the speaker of the last example had, by mistake, transposed *steak* and *freeze* as she introduced them. She would then have added *-s* to *freeze* and *-er* to *steak* and produced "Take the freezes out of the steaker." Other slips occur at the positional level, as when the initial sounds in *left hemisphere* are switched to form *heft lemisphere.*

Listeners are often thought to work from the bottom up. They are assumed to start with the sounds they hear, infer the words and syntax of an utterance, and, finally, infer what the speakers meant. The actual picture is more complicated. In everyday conversation, listeners have a good idea of what speakers are trying to do, and working top down, they use this information to help them identify and understand what they hear (Tanenhaus and Trueswell 1995).

Spoken utterances are identified from left to right by an incremental process of elimination (Marslen-Wilson 1987). As listeners take in the sounds of "elephant," for example, they narrow down the words it might be. They start with an *initial cohort* of all words beginning with "e" (roughly 1000 words), narrow that to the cohort of all words beginning with "el" (roughly 100 words), and so on. By the sound "f" the cohort contains only one word, allowing them to identify the word as "elephant." This way listeners often identify a word before it is complete. Evidence also suggests that listeners access all of the meanings of the words in these cohorts (Swinney 1979). For example, the moment they identify "bugs" in "He found several bugs in the corner of his room" they activate the two meanings "insects" and "hidden microphones." Remarkably, they activate the same two meanings in "He found several spiders, roaches, and other bugs in the

corner of his room," even though the context rules out microphones. But after only .2 to .4 seconds "hidden microphones" gets suppressed in favor of "insects."

Still, listeners do use top-down information in identifying words and constructions (Tanenhaus et al. 1995). When people are placed at a table with many objects on it and are asked, "Pick up the candle," they move their gaze to the candle before they reach for it. Indeed, they start to move their eyes toward the candle about 50 msec *before* the end of "candle." But if there is candy on the table along with the candle, they do not start to move their eyes until 30 msec *after* the end of "candle." As a sentence, "Put the apple on the towel in the box" may mean either (1) an apple is to go on a towel that is in a box, or (2) an apple on a towel is to go into a box. Without context, listeners strongly prefer interpretation 1. But when people are placed at a table with two apples, one on a towel and another on a napkin, their eye movements show that they infer interpretation 2 from the beginning. In identifying utterances, then, listeners are flexible in the information they exploit—auditory information, knowledge of syntax, and the context.

Speaking and listening aren't autonomous processes. People talk in order to do things together, and to accomplish that they have to coordinate speaking with listening at many levels (Clark 1996).

One way people coordinate in conversation is with *adjacency pairs*. An adjacency pair consists of two turns, the first of which projects the second, as in questions and answers:

Sam: And what are you then?
Duncan: I'm on the academic council.

In his first turn Sam *proposes* a simple joint project, that he and Duncan exchange information about what Duncan is. In the next turn Duncan *takes up* his proposal, completing the joint project, by giving the information Sam wanted. People use adjacency pairs for establishing joint commitments throughout conversations. They use them for openings (as in the exchange "Hey, Barbara" "Yes?") and closings ("Bye" "Bye"). They use them for setting up narratives ("Tell you who I met yesterday—" "Who?"), elaborate questions ("Oh there's one thing I wanted to ask you" "Mhm"), and other extended joint projects.

Speakers use their utterances to perform *illocutionary acts*—assertions, questions, requests, offers, promises, apologies, and the like—acts that differ in the uptake they project. Most constructions (e.g., "Sit down") can be used for more than one illocutionary act (e.g., a command, a request, an advisory), so speakers and listeners have to coordinate on what is intended. One way they coordinate is by treating each utterance as a contribution to a larger joint project. For example, when restaurant managers were asked on the telephone, "Do you accept American Express cards?" they inferred that the caller had an American Express card and wanted a "yes" or "no" answer. But when they were asked "Do you accept any kinds of credit cards?" they inferred the caller had more than one credit card and wanted a list of the cards they accepted ("Visa and Mastercard"). Listeners draw such inferences more quickly when the construction is conventionally used for the intended action.

"Can you tell me the time?" is a conventional way to ask for the time, making it harder to construe as a question about ability (Gibbs 1994).

People work hard in conversation to establish that each utterance has been understood as intended (Clark 1996). To do that, speakers *monitor* their speech for problems and repair them as quickly as reasonable (Levelt 1983; Schegloff, Jefferson, and Sacks 1977). In "if she'd been—he'd been alive," the speaker discovers that "she" is wrong, replaces it with "he," and continues. Listeners also monitor and, on finding problems, often ask for repairs, as Barbara does here:

Alan: Now,—um do you and your husband have a j- car?
Barbara: Have a car?
Alan: Yeah.
Barbara: No.

People monitor at all levels of speaking and listening. Speakers, for example, monitor their addressees for lapses of attention, mishearings, and misunderstandings. They also monitor for positive evidence of attention, hearing, and understanding, evidence that addressees provide. Addressees, for example, systematically signal their attention with eye gaze and acknowledge hearing and understanding with "yeah" and "uh huh."

Speaking and listening are not the same in all circumstances. They vary with the language (English, Japanese, etc.), with the medium (print, telephones, video, etc.), with age (infants, adults, etc.), with the genre (fiction, parody, etc.), with the trope (irony, metaphor, etc.), and with the joint activity (gossip, court trials, etc.). Accounting for these variations remains a major challenge for psycholinguistics.

Psychological Laws

Psychology is a science. Sciences are supposed to feature laws, that is, laws of nature, generalizations that are strongly projectible past the actual data that confirm them. Yet in general, psychologists are reluctant to dub their generalizations "laws," even when they have great confidence in those generalizations; some are even uncomfortable in talking of psychological laws at all.

Over the decades, a few generalizations or regularities have explicitly been called laws, in GESTALT PSYCHOLOGY (the laws of organization), in the theory of conditioning (the law of effect, the law of exercise, Jost's law, the law of generalization), in neuropsychology (Bowditch's laws, Hebb's law), and of course in psychophysics (Weber, Fechner, Thurstone, Steven, Bloch, Ricco, Bunsen-Roscoe, Ferry-Porter, Grassmann, Yerkes-Dodson, Schachter). For the most part—the law of effect being arguably an exception— these are empirical generalizations.

Most such laws are equations relating one measurable magnitude to one or more other, independently measurable, magnitudes. Laws of this particular type are of course found throughout the natural and social sciences. But there are psychological generalizations of other kinds that are laws or lawlike as well, even if they are not commonly called by that name. For example, some of the empirical laws are thought to be explained by higher-level theoretical principles or hypotheses, which would themselves have to be considered lawlike in order to play that explanatory role. And surely there are qualitative rather than quantitative generalizations, truths of the form "Whenever organism S is in state A and X occurs, S goes into state B," that are lawlike.

Such qualitative laws would be derived from a standard explanatory pattern in psychology: the *function-analytical* explanation in the sense of Cummins (1983), as found in much of current cognitive theory, perceptual psychology, and PSYCHOLINGUISTICS. (The pattern is ubiquitous in biology, in computer science, and in electronics as well.) Some psychological questions take the form, "How does S Φ?," where "Φ" designates some accomplishment carried out by the organism S (e.g., "How do speakers of English understand novel sentences?" or "How does an experimental subject estimate the distance in miles from her present location to the place she was born?" or "How do dogs recognize individual human smells?"). In answer to such a question, the theorist appeals to a functional or componential analysis of S. S's performance is explained as being the joint product of several constituent operations, individually less demanding, by components or subagencies of the subject acting in concert. The components' individual functions are specified first, and then the explanation details the ways in which they cooperate in producing the more sophisticated corporate explanandum activity.

For example, to explain language understanding, a psycholinguist posits a phonological segmenter, a parser, a SYNTAX, a LEXICON, and (notoriously) a store of real-world knowledge, and starts to tell a story of how those components interact. Of any functionary figuring in that story, we might want to ask in turn how it performs its own particular job. This is another psychological question of just the same form as the first, only this time about the functional organization of one of the subagencies. It is important to see that we can go on asking our function-analytical questions at considerable length. (What neural structures ultimately realize the lexicon?)

Thus we can see human beings and other psychological subjects as *being* simply functionally organized systems, corporate entities that have myriad behavioral capacities by virtue of their internal bureaucratic organizations. An organism's complete psychological description would consist of a flow chart depicting the organism's immediate subagencies and their routes of cooperative access to each other, followed by a set of lower-level flow charts—"detail" maps or "blowups"—for each of the main components, and so on down. At any given level, the flow charts show how the components depicted at that level cooperate to realize the capacities of the single agency whose functional analysis they corporately constitute.

Function-analytical *laws* of two kinds could be read off such diagrams. First there would be qualitative laws of the sort mentioned above; a given flow chart would show what a creature would do, given that it is in such-and-such a state and that (say) it received a stimulus of a certain sort. These "horizontal" laws would be of direct use in the prediction and control of behavior. Second, there would be "vertical" laws, relating lower-level states to the higher-level states that they constitute at a time. Of course, all such laws would be qualified by normalcy or "ceteris paribus" clauses because exceptions to them can be created by hardware breakdown or by perturbation of the system by some external agent.

Philosophers have raised several deeper, skeptical questions about putative laws that are more distinctive to psychology than to the natural sciences, though none of these questions is directed at the acknowledged empirical laws with which we began. The questions stem from the widely shared assumption that many psychological states are representational (see MENTAL REPRESENTATION). One might suggest that what distinguishes psychological laws from those of other natural sciences is that they concern representational states of organisms, but that would seem to rule out laws of conditioning.

Contemporary cognitive and perceptual psychology do traffic in representations, information-carrying states produced and computationally manipulated by psychological mechanisms. By its nature, a representation represents *something.* That is, it has a content or, as the medieval philosophers called it, an "intentional object." And, remarkably, that content or object need not exist in reality; for instance, through deceptive environment or malfunction, a visual edge detector may signal an edge that is not really there (see INTENTIONALITY).

A first skeptical question is this: *Representation of a possibly inexistent object* is a property not found in physics or chemistry—and it is a relational property, ostensibly a relation that its subject bears to an external thing, determined in part by factors external to the organism. Yet natural laws are causal, and some philosophers (notably Fodor 1987 and Searle 1983) have argued that because an entity's causal powers are intrinsic to the entity itself, either representational properties cannot properly figure in psychological laws or there must be a kind of "narrow" representational content that is intrinsic to the subject and independent of environmental factors. (See INDIVIDUALISM. Against that view, see Burge 1986; McClamrock 1995; and Wilson 1995.)

A second set of questions concerns commonsense mental notions, such as those of believing, desiring, seeing, feeling pain, and the like (see PROPOSITIONAL ATTITUDES). Jerry Fodor (1975, 1981) argues that only slightly cleaned-up versions of those concepts have a home in scientific psychology and indeed will figure explicitly in laws; certainly some current psychological experiments make unabashed reference to subjects' beliefs, desires, memories, etc.

However, Donald Davidson (1970, 1974) and Daniel Dennett (1978, 1987) contend that such commonsense concepts correspond to no NATURAL KINDS, not even within psychology. This is in part because they are ascribed to subjects on grounds that are in large part normative rather than empirical, and in part because (Davidson alleges) the "ceteris paribus" clauses needed as qualifying such commonsense generalizations as "If a man wants to eat an acorn omelette, then he generally will if the opportunity exists and no other desire overrides" (1974: 45) are open-ended and unverifiable in a way that such clauses are not when they occur in biology or chemistry. For somewhat different reasons, Paul Churchland (1989) agrees that commonsense concepts correspond to nothing real in psychology or biology and that they will very probably be dropped from science altogether (see ELIMINATIVE MATERIALISM).

Psychology, History of

See INTRODUCTION: PSYCHOLOGY; EBBINGHAUS, HERMANN; HELMHOLTZ, HERMANN LUDWIG FERDINAND VON; WUNDT, WILHELM

Psychophysics

Psychophysics is the scientific study of relationships between physical stimuli and perceptual phenomena. For example, in the case of vision, one can quantify the influence of the physical intensity of a spot of light on its detectability, or the influence of its wavelength on its perceived hue. Examples could as well be selected from the study of AUDITION or other sensory systems.

In a typical psychophysical experiment, subjects are tested in an experimental environment intended to maximize the control of stimulus variations over variations in the subject's responses. Stimuli are carefully controlled, often varying along only a single physical dimension (e.g., intensity). The subject's responses are highly constrained (e.g., "Yes, I see the stimulus," or "No, I don't see it"). Small numbers of subjects are tested with extensive within-subject designs. Individual differences are small in the normal population. Experiments are routinely replicated and replicable across laboratories.

Theoretical treatments of the data consist of computational or physiological models, which attempt to provide an account of the transformation between stimulus and perception within the sensory neural system. The classic modeling approach is SIGNAL DETECTION THEORY. Many other experimental uses and theoretical treatments are illustrated in the related entries listed below.

A *detection threshold* is the smallest amount of physical energy required for the subject to detect a stimulus. The example of the intensity required to detect a spot of light will be used throughout the following paragraphs.

There are a variety of formalized methods for measuring detection thresholds (Gescheider 1997). In the *method of adjustment,* the subject is given control of the intensity of the stimulus and asked to vary it until her perception reaches some criterion value (e.g., the light is just barely visible). In the *method of constant stimuli,* a set of intensities of the

light is preselected and presented many times in a random series. The result is a *psychometric function,* describing the percent of a particular response (e.g., "Yes") as a function of light intensity. In *staircase* or *iterative* methods, the stimulus in each trial is chosen based on the accumulated data from previous trials, using a rule designed to optimize the efficiency of threshold estimation.

When a series of trials is used, there are two major options concerning the subject's task and responses. In *Yes/No techniques,* the subject reports whether she did or did not see the stimulus in each trial. In *forced-choice techniques,* the stimulus is presented in one of two spatial locations or temporal intervals, and the subject's task is to judge in which location or interval the stimulus occurred.

Briefly, the method of adjustment has the advantage of maximal efficiency if the effects of stimulus history and subject bias are small. The method of constant stimuli reduces the influence of stimulus history. Forced-choice techniques have the advantage of minimizing the influence of subject bias, and forced-choice iterative techniques often provide an optimal balance of efficiency and bias minimization.

A *discrimination threshold* is the smallest physical difference between two stimuli required for the subject to discriminate between them. Measurement techniques are analogous to those used for detection thresholds.

In *supra-threshold* experiments, the subject views readily visible stimuli and is asked to report the quantity or quality of her own SENSATIONS. For example, in a *scaling* experiment, a subject could be shown lights of different intensities. The task would be to describe the perceived brightness of each stimulus by assigning a number to it. The result is a description of how brightness grows with intensity. In a *color-naming* experiment, a subject could be shown lights of different wavelengths. The task would be to describe the perceived hues using a constrained set of color names (e.g., red, yellow, green, and blue), and partitioning the perceived hue among them (e.g., "10% Green, 90% Blue"). The result is a description of the variations in hue across the spectrum.

Psychophysics is also marked by a variety of experimental paradigms with established theoretical interpretations (Graham 1989; Wandell 1995). For example, in the *summation-at-threshold* paradigm, thresholds are measured for two component stimuli and for a compound made by superimposing the two. The goal is to quantify the energy required for detection of the compound stimulus with respect to the energy required for detection of each of the components. Outcomes vary widely, from facilitation to linear summation to independent detection to interference, and lead to different theoretical conclusions concerning the degree and form of interaction of the mechanisms detecting the two components.

Similarly, *selective adaptation* paradigms examine the extent to which adaptation to one stimulus affects the threshold for another, and are used to argue for independent or nonindependent processing of the two stimuli. *Identification/detection* paradigms examine whether or not two different stimuli can be identified (discriminated) at detection threshold, and are used to determine the extent to which the

mechanisms that detect the stimuli also code the properties required for identification.

Much psychophysical research is guided and united by sophisticated mathematical modeling. For example, spatiotemporal aspects of vision have been treated in extensive theories centered around the concept of multiple, more or less independent processing mechanisms (e.g., Graham 1989; see also SPATIAL PERCEPTION), and COLOR VISION has been similarly unified by models of the encoding and recoding of wavelength and intensity information (e.g., Wandell 1995).

Models of psychophysical data are often heavily influenced by the known anatomy and physiology of sensory systems, and advances in each field importantly influence the experiments done in the other. For example, the psychophysical trichromacy of color vision provided the first evidence for the presence of three and only three channels underlying color vision, and provided the impetus for a century of anatomical, physical, physiological, and genetic as well as psychophysical attempts to identify the three cone types. As a converse example, anatomically and physiologically based models of parallel processing of color and motion have importantly influenced the psychophysical investigation of losses of motion perception for purely chromatic (isoluminant) stimuli (see MOTION, PERCEPTION OF). Treatments are also available of the need for special bridge laws, or *linking propositions*, in arguments that attempt to explain perceptual events on the basis of physiological events (Teller 1984).

In sum, psychophysics underlies the accumulation of knowledge in many parts of perception. It has many tools to offer to cognitive scientists. Its empirical successes illustrate the value of tight experimental control of stimuli and responses. It provides experimental paradigms that can be generalized successfully to higher level perceptual and cognitive problems (e.g., Palmer 1995). The extensive modeling in the field provides successes that might be worth emulating, and perhaps blind alleys that might be worth avoiding. Finally, and most importantly, in combination with direct studies of the neural substrates of sensory processing, psychophysics provides an important example of interdisciplinary research efforts that illuminate the relationship between mind and brain.

Qualia

The terms *quale* and *qualia* (pl.) are most commonly used to characterize the qualitative, experiential, or felt properties of mental states. Some philosophers take qualia to be essential features of all conscious mental states; others only of SEN-SATIONS and perceptions. In either case, qualia provide a particularly vexing example of the MIND-BODY PROBLEM, because it has been argued that their existence is incompatible with a physicalistic theory of the mind (see PHYSICAL-ISM).

Three recent antiphysicalist arguments have been especially influential. The first claims that one can conceive of the qualitative features of one's pains or perceptions in the absence of any specific physical or functional properties (and vice versa), and that properties that can be so conceived must be distinct (Kripke 1980). The second argument claims that one cannot know, even in principle, WHAT-IT'S-LIKE to be in pain or see a color before actually having these (or similar) experiences, and that no physical or functional properties can afford this perspectival or subjective knowledge (Nagel 1974; Jackson 1982). The third states that no physical or functional characterization of mental states can explain what it's like to have them, and that such an EXPLANATORY GAP raises doubts about whether qualia can be identified with such properties (Levine 1983). They conclude that qualia cannot be (or, at least, cannot be easily believed to be) identical with physical or functional properties.

These arguments are linked in that each first premise assumes (a) that there is no conceptual connection between qualitative and physicalistic terms or concepts. Otherwise, it would be impossible to conceive (for example) of pain qualia existing apart from the relevant physical or functional properties, and it would be possible to know all there is to know about pain without ever having experienced pain oneself; it would also be easy to explain why it feels painful to have the associated physical or functional property. The second premise also depends upon a common thesis, (b) that given this lack of connection, the use of qualitative terms or concepts requires (or at least suggests) the existence of irreducibly qualitative properties. This thesis is supported, at least implicitly, by a theory of reference, deriving from Gottlob FREGE, that permits nonequivalent concepts to denote the same item only by picking out different properties (modes of presentation) of it; in this view, if pain is not equivalent to any physical or functional concept, then even if pain denotes the same property as some physicalistic concept, this can only be by introducing a mode of presentation that is distinct from anything physical or functional. In addition, anti-physicalists have cited inductive evidence for this premise, namely, that in all other cases of intertheoretic reduction, there have been successful analyses, using terms constructed from those of the reducing theory, of the concepts of the theory to be reduced (Jackson 1993; Chalmers 1996).

Physicalists, in turn, have attempted to deny both theses. Those denying (a) have argued that there is in fact a conceptual connection between qualitative and physicalistic con-cepts, the best candidates being causal or functional concepts that have claim to being part of our commonsense understanding of mental states (see FUNCTIONALISM). Many have doubted, however, that commonsense characterizations could be necessary or sufficient to capture qualitative concepts (Block 1978). In response, some physicalists argue that there are ways to broaden the scope of commonsense characterization (Levin 1991), others that any knowledge we gain uniquely from experience is merely a kind of *practical* knowledge—the acquisition of new imaginative or recognitional abilities, rather than concepts that one previously lacked (Nemirow 1990; Lewis 1990). Yet others suggest that, despite appearances to the contrary, there is no determinate, coherent content to our qualitative concepts over and above that which can be explicated by functional or causal characterizations (Dennett 1991).

Another physicalist strategy is to reject thesis (b) and argue that the irreducibility of qualitative to physicalistic *concepts* does not entail the irreducibility of qualitative to physicalistic *properties*. Some have argued that there can be plausible non-Fregean, direct accounts of how qualitative concepts denote physical states—on the model of INDEXI-CALS AND DEMONSTRATIVES—that do not require the introduction of further irreducible properties (Loar 1990; Tye 1995). Others have argued that the lack of conceptual connection between qualitative and physicalistic concepts is not unique, but occurs in many cases of successful intertheoretic reduction (Block and Stalnaker forthcoming).

It is also commonly thought that (sincere) beliefs about our own qualia have special authority (that is, necessarily are for the most part true), and are also self-intimating (that is, will necessarily produce, in individuals with adequate conceptual sophistication, accurate beliefs about their nature). Insofar as they have these special epistemic features, qualia are importantly different from physical properties such as shape, temperature, and length, about which beliefs may be both fallible and uncompelled. Can they nonetheless be physical or functional properties?

Functionalists can claim that qualia have these features as a matter of conceptual necessity, because according to (at least some versions of) this doctrine, states with qualitative properties and the beliefs they produce are interdefined (Shoemaker 1990). Physicalists who deny such definitional connections have argued instead that sufficient introspective accuracy is insured by the proper operation of our cognitive faculties; thus, as a matter of law, we cannot be mistaken about (or fail to notice certain properties of) our mental states (Hill 1991). In such a view, these epistemic features of our mental states will be nomologically necessary, but not necessary in any stronger sense (*see* INTROSPECTION and SELF-KNOWLEDGE).

There are many other interesting issues regarding qualia, among them whether qualia, if physical, are to be identified with neural or narrow functional properties of the individual who has them (Block 1990), or whether, to have qualia, one must also be related to properties of objects in the external world (Lycan 1996; Dretske 1995; cf. INTENTIONALITY). Yet another question is whether (and if so, how) the myriad qualia we seem to experience at any given time are bound

together at a given moment, and are continuous with our experiences at previous and subsequent times, or whether the commonsense view that we enjoy a unity of consciousness, and a stream of consciousness, is rather an illusion to be dispelled (Dennett 1991).

Quantifiers

Sentences (Ss) such as *All cats are grey* consist of a predicate *are grey* and a noun phrase (NP) *all cats,* itself consisting of a noun *cats* and a determiner (Det), of which the quantifiers *all, some,* and *no* are special cases. Semantically we treat both the noun and the predicate as denoting *proper-ties* of individuals, and we interpret the S as True in a situation *s* if the individuals with those properties (in *s*) stand in the relation expressed by the quantifier. Different quantifiers typically denote different relations. ALL (we write denotations in upper case) says that the individuals that have the noun property (CAT) are included in those with the predicate property (GREY). SOME says that the individuals with the CAT property overlap with those that are GREY; NO says there is no overlap. EXACTLY TEN says the overlap has exactly ten members. MOST, in the sense of MORE THAN HALF, expresses a *proportion:* The overlap between CAT and GREY is larger than that between CAT and NON-GREY; that is, the number of grey cats is larger than the number of non-grey ones. LESS THAN HALF makes the opposite claim.

The role of the noun is crucial. Syntactically it forms an NP constituent (*all cats*) with the quantifier. We interpret this NP as a function, called a *generalized quantifier,* that maps the predicate property to True or False (in a situation). So we interpret *All cats are grey* by (ALL CAT)(GREY), where ALL CAT is a function mapping a property *P* to True in a situation *s* if the cats in *s* are a subset of the objects with *P* in *s*. More generally, Ss of the form [[Det+N]+Predicate] denote the truth value given by $(D(N))(P)$, where *P* is the property denoted by the predicate, *N* that denoted by the noun, *D* the denotation of the Det, and $D(N)$ the denotation of Det+noun NP.

Semantically the noun property *N* serves to *restrict* the class of things we are quantifying over. The literature captures this intuition with two very general constraints on possible Det denotations. These constraints limit both the logical expressive power of natural languages and the hypotheses children need consider in learning the meanings of the Dets in their language (Clark 1996; see SEMANTICS, ACQUISITION OF).

One condition is *extensions* (Van Benthem 1984), which says in effect that the truth of *Det Ns are Ps* cannot depend on which individuals are non-Ns. For example, scouring Old English texts, you will never stumble upon a Det *blik* that guarantees that *Blik cats are grey* is true if and only if the number of non-cats that are grey is ten.

The second condition is *conservativity* (Keenan 1981; Barwise and Cooper 1981; Higginbotham and May 1981; Keenan and Stavi 1986), which says that the truth of *Det Ns are Ps* cannot depend on Ps that lack N. So *Det Ns are Ps* must have the same truth value as *Det Ns are Ns that are Ps.* For instance, *Most cats are grey* is equivalent to *Most cats are cats that are grey.* And *most* can be replaced by any Det, including syntactically complex ones: *most but not all, every child's,* or *more male than female.* Despite appearances this semantic equivalence is not trivial. Keenan and Stavi show that in a situation with only two individuals there are 65,536 logically possible Det denotations (functions from pairs of properties to truth values). Only 512 of them are conservative!

The restricting role of the noun property distinguishes natural languages from first-order LOGIC (FOL). FOL essentially limits its quantifiers to $(\forall x)$ *every object* and $(\exists x)$ *some object* and forces logical forms to vary considerably and nonuniformly from the English Ss they represent. *All*

cats are grey becomes "For all objects *x*, if *x* is a cat *then x is grey*"; *Some cats are grey* becomes "For some object *x*, *x* is a cat *and x is grey*." Now proportionality quantifiers (*most, less than half, a third of the, ten percent of the*) are *inherently* restricted (Keenan 1993): there is no Boolean compound S of *cat(x)* and *grey(x)* such that *(for most x)S* is True if and only if the grey cats outnumber the non-grey ones. Indeed the proper proportionality Dets are not even definable in FOL (see Barwise and Cooper (1981) for *most*), whence the logical expressive power of natural languages properly extends that of FOL.

English presents subclasses of Dets of both semantic and syntactic interest. We note two such: First, *simplex* (= single word) Dets satisfy stronger conditions than conservativity and extension. We say that an NP X is *increasing* (↑) if and only if *X is a P* (or *X are Ps*) and *all Ps are Qs* entails that X is a Q. Proper names are ↑: If all cats are grey and Felix is a cat, then Felix is grey. An NP of the form [Det+N] is ↑ when Det is *every, some, both, most, more than half, at least ten, infinitely many,* or a possessive Det like *some boy's* whose possessor NP *(some boy)* is itself increasing. X is *decreasing* (↓) if *all Ps are Qs and X is a Q* entails *X is a P.* [Det+N] is ↓ when Det is *no, neither, fewer than ten, less than half, not more than five, at most five* or *NP's,* for NP ↓. X is *monotonic* if it is either increasing or decreasing. [Det+N] is non-monotonic if Det equals *exactly five, between five and ten, all but ten, more male than female, at least two and not more than ten.* Simplex Dets build monotonic NPs (usually increasing), a very proper subset of the NPs of English.

Syntactically note that ↓ NPs license negative polarity items in the predicate, ↑ ones do not (Ladusaw 1983). Thus *ever* is natural in *No/Fewer than five students here have ever been to Pinsk* but not in *Some/More than five students here have ever been to Pinsk.* Often, as here, grammatical properties of NPs are determined by their Dets.

Second, many English Dets are *intersective,* in that we determine the truth of *Det Ns are Ps* just by checking which Ns are Ps, ignoring Ns that aren't Ps. Most intersective Dets are *cardinal,* in that they just depend on *how many* Ns are Ps. *Some* is cardinal: whether *Some Ns are Ps* is decided just by checking that the number of Ns that are Ps is greater than 0. Some other cardinal Dets are *no, (not) more than ten, fewer than/exactly/at most ten, between five and ten, about twenty, infinitely many* and *just finitely many. No . . . but John* (as in *no student but John*) is intersective but not cardinal. *All* and *most* are not intersective: if we are just given the set of Ns that are Ps we cannot decide if all or most Ns are Ps.

Intersectivity applies to two-place Dets like *more . . . than . . .* that combine with two Ns to form an NP, as in *More boys than girls were drafted.* It is intersective in that the truth of the S is determined once we are given the intersection of the predicate property with each of the noun properties. Other such Dets are *fewer . . . than . . . , exactly as many . . . as . . . , more than twice as many . . . as . . . , the same number of . . . as . . . .* In general these Dets are also not first-order definable (even on finite domains). Moreover, of syntactic interest, it is the intersective Dets that build NPs that occur naturally in existential *There* contexts: *There*

weren't exactly ten cats/more cats than dogs in the yard is natural but becomes ungrammatical when *exactly ten* is replaced by *most* or *all.*

Finally, we can isolate the purely "quantitative" or "logical" Dets as those whose denotations are invariant under permutations p of the domain of objects under discussion. So they satisfy $D(N)(P)) = D(pN)(pP)$, where *p* is a permutation and $p(A)$ is $\{p(x)|x \in A\}$. *All, most but not all, just finitely many* always denote permutation invariant functions, but *no student's, every . . . but John, more male than female* don't.

Cognitive and logical complexity increases with Ss built from transitive verbs (P2s) and two NPs. For example *Some editor reads every manuscript* has two interpretations: One, there is at least one editor who has the property that he reads every manuscript; and two, for each manuscript there is at least one editor who reads it (possibly different editors read different manuscripts). Cognitively, language acquisition studies (Lee 1986; Philip 1992) support that children acquire adult-level competence with such Ss years after they are competent on Ss built from one-place predicates (P1s). And mathematically, whether a sentence is logically true is mechanically decidable in first-order languages with just P1s but loses this property once a single P2 is added (Boolos and Jeffrey 1989).

But some Ss built from P2s and two NPs cannot be adequately represented by iterated application of generalized quantifiers (Keenan 1987, 1992; van Benthem 1989): *Different people like different things; No two students answered exactly the same questions; John criticized Bill but no one else criticized anyone else.* Adequate intrepretations treat the pair of NPs in each S as a function mapping the binary relation denoted by the P2 to a truth value.

Lastly, quantification can also be expressed outside of Dets and NPs: *Students rarely/never/always/often/usually take naps after lunch* (Lewis 1975; Heim 1982; de Swart 1996). Bach et al. 1995 contains several articles discussing languages in which non-Det quantification is prominent: Eskimo (Bittner), Mayali (Evans), or possibly even absent: Straits Salish (Jelinek) and Asurini do Trocará (Vieira). Recent overviews of Det type quantification are Keenan (1996) and the more technical Keenan and Westerståhl (1997).

Radical Interpretation

Radical interpretation is interpretation from scratch—as would be necessary if we found ourselves in a community whose language and way of life were completely alien to us, without bilingual guides, dictionaries, grammars, or previous knowledge of the culture. Recent interest in radical interpretation focuses on two related but significantly different sets of investigations, the first initiated by Quine (1960), the second by Davidson ("Truth and Meaning," 1967, collected with other relevant papers in his 1984). It will be convenient to start with Davidson's work which, though later, is the more immediately intelligible (as will be seen when Quine's views are presented).

If we knew what the foreigners meant by their sentences, we could discover their beliefs and desires; if we knew their beliefs and desires, we could discover what they meant. Knowing neither, "we must somehow deliver simultaneously a theory of belief and a theory of meaning" (Davidson 1984: 144). Davidson offers suggestions about both the form of a theory of meaning and how to make sure we have the correct one for a given language.

It seems reasonable to require a theory of meaning for English to tell us things like "'Snow is white' means (in English) that snow is white." To do so, it must presumably explain how the meanings of whole sentences depend on the meanings of their parts. Davidson's suggestion is that this can be done by a theory of *truth* for the given language, of broadly the type proposed by Tarski (1936). Tarski aimed to explain what it was for the sentences of a language to be true without introducing into the explanation either the notion of truth itself or other problematic notions such as reference (see SENSE AND REFERENCE; REFERENCE, THEORIES OF). To get some idea of his approach, which in detail is technical, notice that if we knew all the basic predicates of a given language, we could explain what it was for them to be *true of* things by listing "axioms," one for each basic predicate, on the lines of "'Snow' is true of *x* (in English) if and only if *x* is snow." To ensure that such a theory genuinely explained what it is for the sentences of the given language to be true, Tarski required it to entail all sentences such as:

(1) "Snow is white" is true-in-English if, and only if, snow is white.

These are the famous T-sentences. In contrast to Tarski, Davidson assumes we start with an adequate understanding of truth: "Our outlook inverts Tarski's: we want to achieve an understanding of meaning or translation by assuming a prior grasp of the concept of truth" (1984: 150).

He points out that the T-sentences may be regarded as giving the meanings of the sentences named on the left-hand side—provided the theory of truth satisfies sufficiently strong constraints. One powerful constraint is the circumstances in which the foreigners *hold true* the sentences of their language. He invokes a "principle of charity": optimize agreement with the foreigners unless disagreements are explicable on the basis of known error.

One acknowledged difficulty is that Tarski's theory as it stands applies only to formalized languages, which lack many important features such as INDEXICALS AND DEMONSTRATIVES, proper names, and indirect speech (see Davidson 1984 and essays in LePore 1986).

Davidson believes that although there will be some *indeterminacy* of interpretation, it will be superficial: just a matter of stating the facts in alternative ways, as with Fahrenheit and Celsius scales. In this and other respects, his position contrasts strongly with Quine's, which has also proved more liable to be misunderstood.

Suppose the radical interpreter has worked out a translation manual that, given a foreign sentence, enables a translation to be constructed. Quine maintains we could devise a rival manual so different that it would reject "countless" translations offered by the first. Both manuals would fit all the objective facts, yet competing versions of the same foreign sentence would not even be loosely equivalent (Quine 1960, 1969, 1990).

Here is a famous line of supporting argument. Imagine the foreigners use the one-word sentence "Gavagai" in situations where English speakers would use "Rabbit." Quine suggests that this does not establish that the native *term* "gavagai" refers to rabbits. It might refer instead to such radically different items as undetached rabbit-parts, or rabbit-phases, or rabbithood. Nor could we rule out any of these alternatives by pointing, or by staging experiments, since those operations would depend on untestable assumptions. Such "inscrutability of reference" appears to involve indeterminacy of sentence translation (Quine 1960, 1969).

All this is part of Quine's wider campaign against our tendency to think of MEANING and synonymy as matters of fact. He argues that the notion of meaning is not genuinely explanatory. It makes us think we can explain behavior, but it is a sham. It fails to mesh in with matters of fact in an explanatorily useful way. The indeterminacy thesis, if true, would powerfully support that contention.

Quine's thesis is easily confused with others. It is not, for example, an instance of the truism that there is no limit to the number of different ways to extrapolate beyond finite data. He claims that two schemes of translation could disagree with one another even when both fitted not just actual verbal and other behavior, but the totality of relevant facts. The indeterminacy "withstands even . . . the whole truth about nature" (Davidson and Hintikka 1969: 303). Nor is it any ordinary sort of scepticism. The idea is not that we cannot know we have hit on the right interpretation, but that there is nothing to be right or wrong about (Quine 1960: 73, 221; 1969: 30, 47). Nor will bilinguals help, since he thinks their translations are as much subject to the indeterminacy as others. Nor, finally, is he laboring the familiar point that in translation between relatively remote languages and cultures, nonequivalent sentences of one language will often do equally well as rough translations of a sentence of the other. This is made clear by his application of the indeterminacy thesis to the "translation" of sentences within one and the same language. We assume that for each sentence of our shared language, what you mean by it is also what I mean by it. Quine thinks that if I were perverse and ingenious I could "scorn" that scheme and devise an alternative that would attribute to you "unimagined views" while still fitting all the relevant objective facts.

Quine's indeterminacy thesis is highly contentious (see Kirk 1986 for discussions). But if correct it has profound implications for psychology and philosophy of mind. If beliefs and desires were matters of objective fact, those facts would settle significant differences over translation. So if it is a mistake to think translation is determinate, it is also a mistake to think our beliefs and desires are matters of fact. Quine and others (e.g., Stich 1983) regard his arguments as undermining intentional psychology and supporting ELIMINATIVE MATERIALISM.

Rational Agency

In philosophy of mind, rationality is conceived of as a coherence requirement on personal identity: roughly, "No rationality, no agent." The agent must have a means-ends competence to fit its actions or decisions, according to its beliefs or knowledge-representation, to its desires or goal-structure. That agents possess such rationality is more than an empirical hypothesis; for instance, as a putative set of beliefs, desires, and decisions accumulated inconsistencies, the set would cease even to qualify as containing beliefs, etc., and disintegrate into a mere set of sentences. This agent-constitutive rationality is distinguished from more stringent normative rationality standards, for agents can and often do possess cognitive systems that fall short of epistemic uncriticizability (e.g., with respect to perfect consistency) without thereby ceasing to constitute agents.

Standard philosophical conceptions of rationality derive from models of the rational agent in microeconomic, game, and decision theory earlier this century (e.g., Von Neumann and Morgenstern 1944; Hempel 1965). The underlying idealization is that the agent, given its belief-desire system, *optimizes* its choices. While this optimization model was proposed as either a normative standard or an empirically predictive account (or both), the philosophical model concerns the idea that we cannot even make sense of agents that depart from such optimality. Related ideal-agent concepts can be discerned in principles of charity for RADICAL INTERPRETATION of human behavior of W. V. Quine (1960) and of Donald Davidson (1980), and in standard epistemic logic (Hintikka 1962). To accomplish this perfection of appropriate decisions in turn would require vast inferential insight: for example, the ideal agent must possess a deductive competence that includes a capacity to identify and eliminate any and all inconsistencies arising in its cognitive system.

While such LOGICAL OMNISCIENCE might appropriately characterize a deity, prima facie it seems at odds with the most basic law of human psychology, that we are finite entities. A wide range of experimental studies since the 1970s indicate interesting and persistent patterns of our departures from ideal logician (Tversky and Kahneman 1974), for instance in harboring inconsistent preferences. A more extreme departure from reality is that for such ideal agents, major portions of the deductive sciences would be trivial (e.g., the role of the discovery of the semantic and set-theoretic paradoxes in the development of logic in this century would then cease even to be intelligible). For a COMPUTATIONAL THEORY OF MIND, where the agent's deductive competence must be represented as a finite algorithm, the ideal agent would in fact have to violate Church's undecidability theorem for first-order logic (Cherniak 1986).

The agent-idealizations—within the limits of their applicability—of course have served very successfully as simplified approximations in economic, game, and decision theory. Nonetheless, a sense of their psychological unreality has motivated two types of subsequent theorizing. One type reinforces an eliminativist impulse, that the whole framework of intentional psychology—with rationality at its core—ought to be cleared away as prescientific pseudotheory (see ELIMINATIVE MATERIALISM); a related response is a quasi-eliminativist instrumentalism (e.g., Dennett 1978), where the agent's cognitive system and its rationality diminish to no more than convenient (but impossible) fictions of the theoretician that may help in predicting agent behavior, but cannot be psychologically real. Ultimately, a sense of the unreality of ideal agent models can spur doubts about the very possibility of a cognitive science.

The other type of response to troubles with the idealizations is a *via media* strategy. After recognizing that nothing could count as an agent or person that satisfied *no* rationality constraints, one stops to wonder whether one must jump to a conclusion that the agent has to be ideally rational. Is rationality all or nothing, or is there some golden mean between unattainable, perfect unity of mind and utter, chaotic disintegration of personhood? The normative and empirical rationality models of Simon (1982) are among the earliest of this less stringent sort: the central principle is that, rather than optimizing or maximizing, the agent only "satisfices" its expected utility, choosing decisions that are good enough according to its belief-desire set, rather than perfect. Such modest coherence realistically is all that an agent ought to attempt, and all that can in general be expected. What amounts to a corresponding account for agent-constitutive rationality appears in Cherniak (1981), with a requirement of minimal, rather than ideal, charity on making sense of an agent's actions. An even more latitudinarian conception can be found in Stich (1990). Related limited-resource models are now also employed in artificial intelligence (see BOUNDED RATIONALITY).

Moderate rationality conceptions leave room for the above-mentioned widely observed phenomena of suboptimal human reasoning, rather than excluding them as unintelligible behavior. We are, after all, only human. Indeed, these more psychologically realistic models can explain the departures from correctness as symptoms of our having to use more efficient but formally imperfect "quick but dirty" heuristic procedures. Formally correct and complete inference procedures are typically computationally complex, with surprisingly small-sized problem instances sometimes requiring vastly unfeasible time and memory resources. (To an extent, this practical intractability parallels, and extends, classical absolute unsolvability; see GÖDEL'S THEOREMS.) Antinomies like Russell's paradox lurking at the core of our conceptual scheme can then be interpreted similarly as signs of our having to use heuristic procedures to avoid computational paralysis.

To conclude, some vigilance about unwarranted reification of cognitive architecture remains advisable. Just as attention has turned to evaluation of uncritical idealizing, scope continues for scrutiny of tacit assumptions in rationality models about psychologically realistic representational format (if any)—for example, the discussions reviewed above tend to presuppose agents as sentence-processors, rather than as, say, quasi-picture processors. Finally, the familiar uneasy coexistence of the intentional framework—having rationality at its core—with the scientific worldview is worth recalling. Yet probably much of the groundplan of our species' model of an agent is innate (see AUTISM and THEORY OF MIND); the framework therefore may be a ladder we cannot kick away. It is as if the scientific worldview can comfortably proceed neither with, nor without, an intentional-cognitive paradigm.

Rational Choice Theory

The theory of rational choice was developed within the discipline of economics by JOHN VON NEUMANN and Oskar Morgenstern (1947) and Leonard Savage (1954). Although its roots date back as far as Thomas Hobbes's denial that reason can fix our ends or desires (instrumental rationality), and David HUME's relegation of reason to the role of "slave of the passions," having no motivating force, via the utilitarians' definition of rationality as the maximization of "utility" and the neoclassical school of economics' theory of revealed preferences, rational choice theory (RCT) purports to be neutral relative to all forms of psychological assumptions or philosophies of mind. In this respect, its relevance for the cognitive sciences is problematic. However, its most recent developments have been marked by the discovery of paradoxes (Binmore 1987a, b; Campbell and Sowdon 1985; Eells 1982; Gauthier 1988/89; Gibbard and Harper 1985; Kavka 1983; Lewis 1985; McClennen 1989; Nozick 1969; Rosenthal 1982) whose interpretation and resolution call for the return of the repressed: an explicit psychology of DECISION MAKING and a full-blown theory of mind. No wonder more and more cognitive scientists today (philosophers, artificial intelligence specialists, psychologists) participate, along with economists and game theorists, in the debates about RCT.

It is ironic that Savage's expected utility theory, in which most economists see the perfect embodiment of instrumental rationality, is a set of axioms, admittedly purely syntactic in nature, that constrain the rational agent's ends for the sake of consistency (see RATIONAL DECISION MAKING). For instance, her preferences must be transitive: if she prefers x to y and y to z, she *must* prefer x to z. If, no matter the state of the world, she prefers x to y, she *must* prefer x to y even in the ignorance of the state of the world (*sure-thing principle*). Savage proves that an agent whose preferences satisfy all the axioms of the theory chooses *as if* she were maximizing her expected utility while assigning subjective probabilities to the states of the world. It is not at all that her choices can be *explained* by her setting out to maximize her utility, because it is tautological, by construction, that the utility of x is larger to her than that of y if she chooses x over y. The claim is that agents whose preferences were not consistent (i.e., violated the axioms) could not achieve the maximal satisfaction of their ends.

This removal of all psychological content and motivational assumptions from the theory of utility is untenable. Consider the obvious possibility that preferences may change over time. Which of one's preferences should be subjected to the coherence constraints set by the theory? Only the occurrent ones, because future preferences are not motivationally efficacious now? Should we rather postulate second-order preferences that weigh future versus occurrent first-order preferences? Or are there (noninstrumental) *external* reasons that will do the weighing? Dispensing with a theory of mind proves impossible (Hampton 1998; Hollis and Sugden 1993).

According to RCT, an act is an assignment of consequences to states of the world, and the description of a consequence must include no reference to how that consequence was brought about. The only legitimate motivations are forward-looking reasons: only the future matters. Using an equipment just because one has invested a lot in it is taken to be irrational ("sunk cost fallacy"; see Nozick 1993). Experiments in cognitive psychology reveal that most of us commit that alleged fallacy most of the time, proving that we care about the consistency between past and present, maybe for the sake of personal identity (we violate as well Savage's axioms, especially the sure-thing principle; see Shafir and Tversky 1993; cf. also JUDGMENT HEURISTICS). Does that mean that we are irrational, or just that our mind works differently from what RCT, in spite of its proclaimed neutrality, presupposes?

When RCT is applied to a strategic setting, leading to GAME THEORY, some of its implications are plainly paradoxical. In an ideal world where all agents are rational, this fact being common knowledge (everyone knows it, knows

that everyone knows it, etc.), rational behavior may be quite unreasonable: the agents are unable to cooperate in a *finitely repeated prisoner's dilemma* setting (Kreps and Wilson 1982); they don't make good on their promises when it goes against their current interest (*assurance game*; see Bratman 1992); their threats are not credible (*chain-store paradox*; Selten 1978); trust proves impossible (*centipede game* and *backward induction paradox*; Reny 1992; Pettit and Sugden 1989), etc. A remarkable feature is that a small departure from complete transparency is enough to bring back the rational close to the reasonable. Imperfect or BOUNDED RATIONALITY would be that which keeps the social world moving.

Philosophers have recently taken up these paradoxes. Although diverging, their conclusions make it clear that there is no way out without completing or amending RCT with theories of, among others, rational planning and intention-formation, belief revision, counterfactual and probabilistic reasoning in strategic settings, and even temporality and self-deception (Dupuy 1998). Some authors think it possible to ground a form of Kantian rationalism in such an expanded or revised RCT, so that to choose rationally entails that one chooses morally (Gauthier 1986).

Take as an example the assurance game. A mutually beneficial exchange is possible between you and me, but you have to take the first step and I will then decide whether I reciprocate or not. Is my proclaimed intention that I will reciprocate a good enough assurance for you to engage in the deal, and can I rationally form this intention? Forming it has positive autonomous effects for me, independent of my carrying it out (it will provide an incentive for you to cooperate), and no cost. If it were an act of the will, it would be rational for me to form it, and we might be tempted to conclude that it would also be rational to execute it. However, some authors contend, *one cannot will oneself to form an intention* any more than a belief, and it is impossible to form the intention to do *X* if one knows that when the time comes it will be irrational to do (Kavka 1983). Others maintain that it is possible to be "resolute" in this case, and rational not only to form the intention but to make good on it (McClennen 1989). Only a full-blown theory of the mind can adjudicate between these two positions.

Rational Decision Making

Rational decision making is choosing among alternatives in a way that "properly" accords with the preferences and beliefs of an individual decision maker or those of a group making a joint decision. The subject has been developed in decision theory (Luce and Raiffa 1957; see RATIONAL CHOICE THEORY), decision analysis (Raiffa 1968), GAME THEORY (von Neumann and Morgenstern 1953), political theory (Muller 1989), psychology (Kahneman, Slovic, and TVERSKY 1982; see DECISION-MAKING), and economics (Debreu 1959; Henderson and Quandt 1980; see ECONOMICS AND COGNITIVE SCIENCE), in which it is the primary activity of homo economicus, "rational economic man." The term refers to a variety of notions, with each conception of alternatives and proper accord with preferences and beliefs yielding a "rationality" criterion. At its most abstract, the subject concerns unanalyzed alternatives (choices, decisions) and preferences reflecting the desirability of the alternatives and rationality criteria such as maximal desirability of chosen alternatives with respect to the preference ranking. More concretely, one views the alternatives as actions in the world, and determines preferences

among alternative actions from preference rankings of possible states of the world and beliefs or probability judgments about what states obtain as outcomes of different actions, as in the maximal expected utility criterion of decision theory and economics. UTILITY THEORY and the FOUNDATIONS OF PROBABILITY theory provide a base for its developments. Somewhat unrelated, but common, senses of the term refer to making decisions through reasoning (Baron 1985), especially reasoning satisfying conditions of logical consistency and deductive completeness (see DEDUCTIVE REASONING; LOGIC) or probabilistic soundness (see PROBABILISTIC REASONING). The basic elements of the theory were set in place by Bernoulli (1738), Bentham (1823), Pareto (1927), Ramsey (1926), de Finetti (1937), VON NEUMANN and Morgenstern (1953), and Savage (1972). Texts by Raiffa (1968), Keeney and Raiffa (1976), and Jeffrey (1983) offer good introductions.

The theory of rational choice begins by considering a set of alternatives facing the decision maker(s). Analysts of particular decision situations normally consider only a restricted set of abstract alternatives that capture the important or interesting differences among the alternatives. This often proves necessary because, particularly in problems of what to do, the full range of possible actions exceeds comprehension. The field of decision analysis (Raiffa 1968) addresses how to make such modeling choices and provides useful techniques and guidelines. Recent work on BAYESIAN NETWORKS (Pearl 1988) provides additional modeling techniques. These models and their associated inference mechanisms form the basis for a wide variety of successful KNOWLEDGE-BASED SYSTEMS (Wellman, Breese, and Goldman 1992).

The theory next considers a binary relation of preference among these alternatives. The notation $x \precsim y$ means that alternative y is at least as desirable as alternative x, read as y is weakly preferred to x; "weakly" because $x \precsim y$ permits x and y to be equally desirable. Decision analysis also provides a number of techniques for assessing or identifying the preferences of decision makers. Preference assessment may lead to reconsideration of the model of alternatives when the alternatives aggregate together things differing along some dimension on which preference depends.

Decision theory requires the weak preference relation $\precsim$ to be a complete preorder, that is, reflexive ($x \precsim x$), transitive ($x \precsim y$ and $y \precsim z$ imply $x \precsim z$), and relating every pair of alternatives (either $x \precsim y$ or $y \precsim x$). These requirements provide a formalization in accord with ordinary intuitions about simple decision situations in which one can readily distinguish different amounts, more is better, and one can always tell which is more. Various theoretical arguments have also been made in support of these requirements; for example, if someone's preferences lack these properties, one may construct a wager against him he is sure to lose.

Given a complete preordering of alternatives, decision theory requires choosing maximally desirable alternatives, that is, alternatives x such that $y \precsim x$ for all alternatives y. There may be one, many, or no such maxima. Maximally preferred alternatives always exist within finite sets of alternatives. Preferences that linearly order the alternatives ensure that maxima are unique when they exist.

The rationality requirements of decision theory on preferences and choices constitute an ideal rarely observed but useful nonetheless (see Kahneman, Slovic, and Tversky 1982; DECISION MAKING, ECONOMICS AND COGNITIVE SCIENCE, JUDGMENT HEURISTICS). In practice, people apparently violate reflexivity (to the extent that they distinguish alternative statements of the same alternative), transitivity (comparisons based on aggregating subcomparisons may conflict), and completeness (having to adopt preferences among things never before considered). Indeed, human preferences change over time and through reasoning and action, which renders somewhat moot the usual requirements on instantaneous preferences. People also seem to not optimize their choices in the required way, more often seeming to choose alternatives that are not optimal but are nevertheless good enough. These "satisficing" (Simon 1955), rather than optimizing, decisions constitute a principal focus in the study of BOUNDED RATIONALITY, the rationality exhibited by agents of limited abilities (Horvitz 1987; Russell 1991; Simon 1982). Satisficing forms the basis of much of the study of PROBLEM SOLVING in artificial intelligence; indeed, NEWELL (1982: 102) identifies the method of problem solving via goals as the foundational (but weak) rationality criterion of the field ("If an agent has knowledge that one of its actions will lead to one of its goals, then the agent will select that action"). Such "heuristic" rationality lacks the coherence of the decision-theoretic notion because it downplays or ignores issues of comparison among alternative actions that all lead to a desired goal, as well as comparisons among independent goals. In spite of the failure of humans to live up to the requirements of ideal rationality, the ideal serves as a useful approximation, one that supports predictions, in economics and other fields, of surprisingly wide applicability (Becker 1976; Stigler and Becker 1977).

Though the notions of preference and optimal choice have qualitative foundations, most practical treatments of decision theory represent preference orders by means of numerical utility functions. We say that a function U that assigns numbers to alternatives represents the relation $\precsim$ just in case $U(x) \precsim U(y)$ whenever $x \precsim y$. Note that if a utility function represents a preference relation, then any monotone-increasing transform of the function represents the relation as well, and that such transformation does not change the set of maximally preferred alternatives. Such functions are called ordinal utility functions, as the numerical values only indicate order, not magnitude (so that $U(x) = 2\,U(y)$ does not mean that x is twice as desirable as y).

To formalize choosing among actions that may yield different outcomes with differing likelihoods, the theory moves beyond maximization of preferability of abstract alternatives to the criterion of maximizing expected utility, which derives preferences among alternatives from preference orderings of the possible outcomes together with beliefs or expectations that indicate the probability of different consequences. Let Ω denote the set of possible outcomes or consequences of choices. The theory supposes that the beliefs of the agent determine a probability measure Pr, where $Pr(\omega|x)$ is the probability that outcome ω obtains as a result of taking action x. The theory further supposes a preference relation over outcomes. If we choose a numerical function U over outcomes to represent this preference relation, then the expected utility $\hat{U}(x)$ of alternative x denotes the total utility of the consequences of x, weighting the utility of each outcome by its probability, that is

$$\hat{U}(x) = \sum_{\omega \in \Omega} U(\omega)Pr(\omega|x).$$

Because the utilities of outcomes are added together in this definition, this utility function is called a cardinal utility function, indicating magnitude as well as order. We then define $x \precsim y$ to hold just in case $\hat{U}(x) \precsim \hat{U}(y)$. Constructing preferences over actions to represent comparisons of expected utility in this way transforms the abstract rational choice criterion into one of maximizing the expected utility of actions.

The identification of rational choice under UNCERTAINTY with maximization of expected utility also admits criticism (Machina 1987). Milnor (1954) examined a number of reasonable properties one might require of rational decisions, and proved no decision method satisfied all of them. In practice, the reasonability of the expected utility criterion depends critically on whether the modeler has incorporated all aspects of the decision into the utility function, for example, the decision maker's attitudes toward risk.

The theory of rational choice may be developed in axiomatic fashion from the axioms above, in which philosophical justifications are given for each of the axioms. The complementary "revealed preference" approach uses the axioms instead as an analytical tool for interpreting actions. This approach, pioneered by Ramsey (1926) and de Finetti (1937) and developed into a useful mathematical and practical method by von Neumann (von Neumann and Morgenstern 1953) and Savage (1972), uses real or hypothesized sets of actions (or only observed actions in the case of Davidson, Suppes, and Siegel 1957) to construct probability and utility functions that would give rise to the set of actions.

When decisions are to be made by a group rather than an individual, the above model is applied to describing both the group members and the group decision. The focus in group decision making is the process by which the beliefs and preferences of the group determine the beliefs and preferences of the group as a whole. Traditional methods for making these determinations, such as voting, suffer various problems, notably yielding intransitive group preferences. Arrow (1963) proved that there is no way, in general, to achieve group preferences satisfying the rationality criteria except by designating some group member as a "dictator," and using that member's preferences as those of the group. May (1954), Black (1963), and others proved good methods exist in a number of special cases (Sen 1977). When all preferences are well behaved and concern exchanges of economic goods in markets, the theory of general equilibrium (Arrow and Hahn 1971; Debreu 1959) proves the existence of optimal group decisions about allocations of these goods. Game theory considers more refined rationality criteria appropriate to multiagent settings in which decision makers interact. Artificial markets (Wellman 1993) and negotiation

techniques based on game theory (Rosenschein and Zlotkin 1994) now form the basis for a number of techniques in MULTIAGENT SYSTEMS.

Rationalism vs. Empiricism

"Rationalism" and "empiricism" are best understood as names for two broad trends in philosophy rather than labels for specific articulated theories. "Sensationalism," "experientialism," and "empirical theory" are among other terms that have been used to denote the latter doctrine, while "intuitionism," "intellectualism," and "transcendentalism" have had currency in alluding to the former. In the traditional pantheon of philosophers, the classic rationalists are René DESCARTES, Gottfried Wilhelm Leibniz, and Baruch Spinoza; the classic empiricists are John Locke, George Berkeley, and David HUME. Immanuel Kant's transcendental theses, although removed from empiricism, do not fit readily into the rationalist picture either. Theorists are usually said to be "rationalists" or "empiricists" in light of a discerned family resemblance between one of their positions and a position championed by members of one of the traditional schools (cf. KANT).

Roughly put, empiricism is the view that all knowledge of fact comes from experience. At birth the mind is a tabula rasa. Our senses not only provide the evidence available to justify beliefs, they are the initial source of the concepts constituting these thoughts. Innate biases and dispositions may influence the ideas experience leads us to acquire, but we do not come into the world equipped with anything deserving the title of an "idea." Some ideas, the simple ones, are found directly in experience; others are derived from these by abstraction, analogy, and definition.

According to the empiricists, there are also no a priori truths, except for those analytic statements (for example, "All bachelors are unmarried," or "Triangles have three sides"), which, being matters of meaning, can be depicted in

terms of definitional, hence necessary, relations among ideas. The seemingly special status of mathematics might then be explained on the assumption that mathematical statements are analytic. Some prominent empiricists, notably John Stuart Mill (1956), argued even mathematics was empirically derived.

Knowledge of all matters of fact, however, rests on inductively gained experience. In particular, scientific knowledge is not based on a priori or necessary principles. Reason does not supply the ultimate foundation for science, nor can it enable us to achieve certainty in these areas. Reason can help to organize and see the implications of what sense offers, and logic puts constraints on appropriate patterns of reasoning, but reason on its own cannot provide the wherewithal for understanding nature.

Rationalism may be given an equally rough description in terms of its denial of these central empiricist tenets. For the rationalist, experience is not the source of all knowledge. Some concepts are neither derived nor derivable from sense experience. The mind comes equipped with a set of innate ideas. What's more, reason or intuition, when properly tapped, can provide true beliefs or principles, albeit not all or even most of those we entertain; determining the truth of mundane claims about the height of a tree or if the milk has gone bad require sense experience. Inductive exploration will also play a role in discovering empirical regularities theoretical science incorporates and seeks to explain.

Reason has a higher calling. It furnishes a priori principles that are not only true, but are necessary, and are recognizably so. These principles are not stipulative definitional truths; rather they delineate the real essences of the ideas of "God," "being," "triangle," and so on that they contain. In this way, they supply a bedrock of certainty upon which knowledge is built, and coherence with them is the sine qua non of acceptable hypotheses.

It is possible, then, to conceive of scientific theories along the lines of axiom systems in mathematics. The first principles (or axioms) of these systems of science are not established by the inductive amassing of evidence. They are intuited by reason as true and necessary. These principles provide the foundational certainty from which the rest of science can be seen to follow deductively.

The rationalist/empiricist distinction, as drawn above, is to be distinguished from the contrast between mentalistic versus behavioristic approaches to psychology and mind. Empiricists as well as rationalists were mentalists, and both placed heavy emphasis on the role of consciousness in cognition. None of these thinkers had qualms appealing to mental states, and none were committed to the view that human behavior was not mediated by and dependent upon such internal states. Descartes (*Discourse on the Method,* part 5, from Descartes 1984–85) perhaps stands out in his clear refusal to attribute CONSCIOUSNESS to animals and in his conviction that their behavior can be fully explained mechanistically without appeal to mental intermediaries. Hume, in his *Treatise of Human Nature* (1960: book I, sect. 16), forcefully argues that animals are endowed with thought and reason. Everyone agreed, however, that the coin of the mental was ideas, and the empiricists' ideas were no less

representational than those of the rationalists (cf. BEHAVIORISM and MENTAL REPRESENTATION).

Empiricists did stress and give wider scope to the role associative processes were seen to play in the acquisition and manipulation of ideas, and experienced similarity had a more prominent place in their theories. But it is a mistake to think they allowed for no other kinds of mental transitions and processing. In fact, Locke spends a chapter of his *Essay Concerning Human Understanding* (1975: book II, ch. 33) warning how too ready reliance on the happenstance of experiential co-occurrences will result in false beliefs.

At the same time, there is no reason to assume rationalists did not allow many transitions of thought and imagination were fueled by past associations or presently sensed similarities. For example, Descartes' influential theory of the emotions (*Passions of the Soul*, from Descartes 1984–85), has elements that are not only sensationalist but are behaviorist and associationist. It is also true, especially in his theory of vision (*Dioptrics*, from Descartes 1984-85), that Descartes talks of more intellectual-like reasoning and calculating that is neither conscious nor involves conscious ideas. But these processing claims are in tension with the standard interpretation of Descartes as the foremost champion of the view that *all* mental states are conscious.

Although the rationalist/empiricist dichotomy, loosely characterized, does have its uses in limited contexts, care must be taken employing it to make specific claims about specific historical figures. Further caution is warranted when their work is cited or used to support contemporary doctrines. For example, many seventeenth- and eighteenth-century arguments for innateness hinge on the claim that ideas such as "God" or "triangle" could not be acquired, because no actual instances of these sorts of concepts could possibly be found in experience. Current-day proponents of innate ideas, stressing inductive indeterminacy, extend the claim to ideas for which there clearly are observed cases. Similarly, rationalists often argued apprehension of certain principles, like the principles of noncontradiction and identity, must be a priori, because they are a prerequisite for having any thought at all. Current proponents of the INNATENESS OF LANGUAGE, for example, tend not to make comparable claims about the principles of universal grammar (cf. NATIVISM; NATIVISM, HISTORY OF; POVERTY OF THE STIMULUS ARGUMENTS).

The classic writers forged their theories in and against a background of assumptions about physics, mind, physiology, religion, and science in general that have been largely abandoned. Moreover, in the course of time, concepts and doctrines of consciousness, learning, innateness, mental states and processes versus nonmental states and processes, biological inheritance, and the like have come to be understood along new dimensions. This has led to further blurring the meaning and significance of the distinction between rationalist and empiricist positions.

In contemporary psychological literature, for instance, Hermann von HELMHOLTZ is frequently cited as the founding father of the cognitivist approach to perception. Since Helmholtz's (1950) unconscious inference model postulates mental representations and processes, his theory is said to

stand in opposition to Gestalt, behaviorist, and Gibsonian positions. Yet Helmholtz's model is strikingly similar to the one Berkeley offers in his *New Theory of Vision* (from Berkeley 1948–57), and it explicitly mirrors Mill's account of inductive inference. But whereas the staunch empiricist Mill (1973) allows that certain visual inferences may be instinctive, Helmholtz claims (1950) his main result has been to show how a range of phenomena, usually thought innate, can be explained in terms of learning and psychological processing. So, for example, on the important issue of the fusion of binocular images, Helmholtz offers a cognitive account, in opposition to the purely physiological, nativist explanation given by Descartes and other theorists (cf. GIBSON; GESTALT PERCEPTION; *see also* PARSIMONY AND SIMPLICITY).

Rationality

See BOUNDED RATIONALITY; RATIONAL AGENCY; RATIONAL CHOICE THEORY; RATIONAL DECISION MAKING

Reading

At the close of the nineteenth century, the perceptual and cognitive processes involved in reading were central topics of theory and research (e.g., Cattell 1885; Pillsbury 1897). Yet, as learning theory came to dominate academic psychology, this interest waned. Across most of the twentieth century, reading was broadly viewed by research psychologists as the product of paired-associate learning and, thus, as largely understood at least in principle, despite the heated debate in the educational arena as to whether the effective stimulus in learning to read corresponded to letters or words (e.g., Chall 1967; Flesch 1955).

This attitude changed abruptly with the onset of the cognitive era. Text, after all, was language. If bottom-up learning theories were not adequate to explain the acquisition or comprehension of oral language (see LANGUAGE ACQUISITION), then neither, by extension, were they adequate to explain the acquisition or comprehension of written language (Smith 1971). Moreover, written as opposed to oral language had the amenably investigable property that its units were discrete, lending themselves to physical alteration, substitution, and rearrangement at every level, from letters to discourse structure. Thus, according to Besner and Humphreys (1991), research on reading has filled more pages in books and journals than any other topic in cognitive psychology. In consequence, few subdomains of cognitive psychology have seen as much progress—empirical, theoretical, and applied—as has the field of reading research.

During the 1970s and 1980s, working collaboratively with the fields of linguistic science and artificial intelligence, cognitive research on reading focused on two issues: how higher-order knowledge is organized and how, by virtue of that organization, the partial and temporally messy information of text might be restructured and implemented into coherent events and images.

The results were a wealth of empirical work demonstrating that readers can interpret and evaluate an author's message only to the extent that they possess and call forth the vocabulary, syntactic, rhetorical, topical, analytic, and social knowledge that the author has presumed, as well as a number of theories and models of the psychological structures and processes involved in bringing such knowledge to bear (for review, see Anderson and Pearson 1984; Sanford and

Garrod 1981). Alongside, text was shown to differ from normal oral discourse in language, content, and communicative modes and purposes. The implications were, first, that beyond learning to listen or speak, LITERACY demands more knowledge in depth, breadth, and kind and, second, that unlike learning to listen or speak, the processes of becoming literate require reflective access to such knowledge at every level. Of applied relevance, researchers also demonstrated that among younger and poorer readers the requisite knowledge, inferential capabilities, or comprehension monitoring tendencies were generally underdeveloped to a greater or lesser extent (for review, see Baker and Brown 1984), and instructional implications of this work quickly found its way into classroom materials and practice (see METACOGNITION).

An equally important outcome of this work was that it forced the field's awareness of its explanatory limitations. First, although this work helped make explicit the syntactic and semantic infrastructure on which text comprehension depends, it begged the question of how such knowledge might be accessed in process or acquired developmentally. Second, there was the issue of words. Much of the research of this era had been designed to elucidate how skillful readers might use the higher-order constraints of text to reduce or finesse the demands of word recognition while reading. Yet, as many times and as many ways as this question was empirically probed, the results contradicted the premise. Instead, skillful readers' recognition of printed words proved itself almost wholly indifferent to the type or strength of bias introduced by researchers; only among poor readers does the speed or accuracy of word recognition tend to be measurably influenced by context (Stanovich 1980). Furthermore, poorly developed word recognition skills were shown to account for much of the difference in good and poor readers' comprehension of text (Perfetti 1985).

The invention of parallel distributed processing models of perception and memory have been key in the theoretical reconciliation of the word recognition and comprehension research (see COGNITIVE MODELING, CONNECTIONIST). These computational models have demonstrated that many of the microphenomena of word recognition—including effects of word frequency, orthographic redundancy, spelling, sound irregularities (*aisle*) and inconsistencies (*head*, *bead*), and sensitivity to syllabic and onset-rime boundaries —reflect statistical properties of the language's orthographic and orthophonological structure and, as such, emerge through associative learning (Seidenberg and McClelland 1989; see VISUAL WORD RECOGNITION). More critically, perhaps, in positing such associative learning not just among letters but also between spellings and both phonology and meaning, the models provide means of understanding how, even as the print on the page is the raw data of reading, it might serve to activate and to reinforce and extend learning of the language and meaning on which text comprehension depends (Adams 1990).

With the help of a variety of new technologies, research has now affirmed that for skillful readers, regardless of the difficulty of the text, the basic dynamic of reading is line by line, left-to-right, and word by word. Further, during that fraction of a second while the eyes are paused on any given word of text, its spelling is registered with complete, letterwise precision even as it is instantly and automatically mapped to the speech patterns it represents (Rayner 1998; see also EYE MOVEMENTS AND VISUAL ATTENTION).

Although scientists are only beginning to understand the various roles of these spelling-to-speech translations, they are clearly of critical importance to the reading process. To the extent that knowledge of spelling-to-speech correspondences is underdeveloped (as evidenced, for example, by subnormal speed or accuracy in reading nonsense words), it is strongly and reliably associated with reading delay or disability. Moreover, given an alphabetic script such as English, research affirms that learning to recognize or spell an adequate number of words is essentially impossible except as children have internalized the spelling-to-speech correspondences of the language (Ehri 1992; Share and Stanovich 1995).

Although results of the 1992 and 1994 National Assessment of Educational Progress (NAEP) indicate that more than 40 percent of U.S. fourth graders are unable to read grade-appropriate text with minimally acceptable levels of understanding or fluency (Campbell, Donahue, Clyde, and Philips 1996), research indicates that, with the exception of no more than 1–3 percent of children, reading disability can be prevented through well-designed early instruction (Vellutino et al. 1996). As in method comparison studies of past decades (e.g., Bond and Dykstra 1967; Chall 1967), contemporary investigations (e.g., Foorman et al. 1998) affirm that initial reading instruction is most effective if it includes explicit, systematic attention to phonics as well as an active emphasis on practicing and using that knowledge both in isolation and in the context of meaningful reading and writing.

In addition, building on the seminal work of A. Liberman, Cooper, Shankweiler, and Studdert-Kennedy (1967) and I. Liberman, Shankweiler, Fischer, and Carter (1974), research has amply demonstrated that learning to read an alphabetic script depends critically on the relatively difficult insight that every word can be conceived as a sequence of phonemes (see PHONOLOGY). Indeed, poorly developed phonemic awareness has asserted itself as the core and causal factor underlying most cases of severe reading disability (Lyon 1995). Conversely, for normal as well as at-risk populations, activities designed to develop children's awareness of the phonemic structure of words have been shown to ease and accelerate both reading and writing growth (see Adams, Treiman, and Pressley 1997; Torgesen 1997). The relationship between phonemic awareness and learning to read is bidirectional such that some basic appreciation of the phonological structure of words appears necessary for grasping the alphabetic principle, while instruction and practice in decoding and spelling serves reciprocally to advance the child's phonemic sensitivity. In terms of cognition and metacognition, the important lesson of this work is that, no less than for higher-order dimensions of literacy growth, productive learning about decoding and spelling necessarily builds on prior knowledge and active understanding.

Realism and Antirealism

Realism is a blend of metaphysics and epistemology. Metaphysically, realism claims that there is an observer-independent world; epistemologically, it claims that we can gain knowledge of that very world. In relation to science, realism asserts that, independently of our representations, the entities described by our scientific theories exist and that the theories themselves are objectively true (at least approximately). Opposed to scientific realism (hereafter just "realism") are a variety of antirealisms; notably positivism, empiricism, instrumentalism, and constructivism.

Twentieth-century positivism regarded realism as a pseudo-question external to science. Difficulties over the very possibility of a realist interpretation for the quantum theory of 1925–26 seemed to support this view (Fine 1996). The situation changed in the 1960s with the emergence of what came to be known as the "miracles" argument, namely,

that unless the theoretical entities employed by scientific theories actually existed and the theories themselves were at least approximately true of the world at large, the evident success of science (in terms of its applications and predictions) would surely be a miracle (Putnam 1975; Smart 1963). During the next two decades versions of this argument became so fashionable that realism was often identified with science itself.

Despite the fashion, the argument is inconclusive because, at best, scientific success can show only that something is right about science. That could mean that science is actually getting at the truth, as the miracles argument urges, or it could just mean that science is developing reliable tools for organizing experience, perhaps using flawed representations of reality. Similar difficulties beset an influential "explanationist" variant of the argument (Boyd 1992). This version asks us to explain the evident success of science and argues that realism, with its emphasis on the truth of our theories, offers the best explanation. Among other problems, this version suffers from the defect that the conclusion in support of realism depends on the principle ("inference to the best explanation") to accept as true that which explains best (Lipton 1991). Antirealisms like instrumentalism and empiricism would deny the inference. (After all, the best may well be the best of a bad lot.) Thus the explanationist version of the "miracles" argument uses a principle of inference that begs a central question at issue between realism and antirealism—whether truth, or some other merit, attaches to a good theory (Fine 1996; Laudan 1981).

In addition to these logical difficulties, realism has a problem with the history of science, which shows our best theories repeatedly overthrown. Inductively, this may support pessimism about the stability of current science (Psillos 1996). It also has a problem with the underdetermination of theory by evidence, which suggests that theories may have empirical equivalents between which no evidence can decide (Earman 1993; Laudan and Leplin 1991). Both considerations tend to undermine claims for the reality of the objects of scientific investigation and the truth of scientific theories.

In response, some philosophers have suggested that realism confine itself to a doctrine about the independent existence of theoretical entities ("entity realism") without commitment to the truth of the theories employing them. There are several proposals of this sort concerning which entities to advance as real. We might promote only those entities that are used experimentally to generate new knowledge or, more generally, only those we regard as causal agents (Cartwright 1983; Hacking 1983). We might take only those that prove fruitful enough to survive scientific revolutions (McMullin 1987), or only those essential in specific cases of explanatory or predictive success (Kitcher 1993) or only those entities that stand out as supported by especially excellent scientific evidence (Newton-Smith 1989). Finally, we might just plead that surely *some* entities must be real, without specifying which ones (Devitt 1984). Unfortunately for entity realism, it is not clear that such criteria overcome the strategies that challenge realism in general. In particular these proposals do not seem to discriminate effectively between real entities and reliable

(or useful) constructs—and so between realism and instrumentalism (Fine 1986).

A number of fresh alternatives to realism have developed recently. Principal among them are Putnam's "internal realism" (1981, 1990), van Fraassen's "constructive empiricism" (1980), and what Fine calls the "natural ontological attitude," or NOA (1996). Internal realism is a perspectival position allowing that scientific claims are true from certain perspectives but denying that science tells the whole story, or even that there is a whole story to tell. There could be other versions of the truth—different stories about the world—each of which it may be proper to believe. Van Fraassen's constructive empiricism eschews belief in favor of what he calls commitment. In contrast with realism, constructive empiricism takes empirical adequacy (not truth) as the goal of science, and when it accepts a theory it accepts it only as empirically adequate. This involves commitment to working within the framework of the theory but not to believing in its literal truth. Fine's NOA is a minimal attitude that urges critical attention to local practice without imposing general interpretive agendas on science, such as goals for science as a whole or blanket empiricist limitations on knowledge. NOA regards truth as basic but, seeing science as open, it challenges general prescriptions for scientific truth, including the perspectivalism built into internal realism and the external-world correspondence built into realism itself. Despite their differences, these alternatives share with realism a basically positive attitude toward science. A contrary suspicion attaches to constructivism (Barnes, Bloor, and Henry 1996; Galison and Stump 1996; Latour 1987; Pickering 1984; Searle 1995).

Constructivism opposes realism's claim that in order to understand science we must take scientists to be exploring a world not of their own making. Inspired by developments in the history and sociology of science, it maintains instead that scientific knowledge is socially constituted and that "facts" are made by us. Constructivism emphasizes agency and (like NOA) sees unforced judgments throughout scientific activity. In their studies constructivists bracket the truth-claims of the activity under investigation and try to address scientific practice using little more than common sense psychology and an everyday pragmatism with respect to the familiar objects of experience. To the extent to which these studies succeed in understanding science they paint a picture quite different from realism's, a dynamic and open picture that challenges not only the arguments but also the intuitions on which scientific realism rests.

Recurrent Networks

NEURAL NETWORKS are generally broken down into two broad categories: feedforward networks and recurrent networks. Roughly speaking, feedforward networks are networks without cycles (see PATTERN RECOGNITION AND FEEDFORWARD NETWORKS) and recurrent networks are networks with one or more cycles. The presence of cycles in a network leads naturally to an analysis of the network as a dynamic system, in which the state of the network at one moment in time depends on the state at the previous moment in time. In some cases, however, it is more natural to view the cycles as providing a specification of simultaneous constraints that the nodes of the network must satisfy, a point of view that need not involve any analysis of time-varying behavior. These two points of view can in principle be reconciled by thinking of the constraints as specifying the equilibrium states of a dynamic system.

Let us begin by considering recurrent networks which admit an analysis in terms of equilibrium states. These networks, which include *Hopfield networks* and *Boltzmann machines,* are generally specified as *undirected graphs,* that is, graphs in which the presence of a connection from node S_i to node S_j implies a connection from node S_j to node S_i (see figure 1). The graph may be completely connected or partially connected; we will consider some of the implications associated with particular choices of connectivity later in the article.

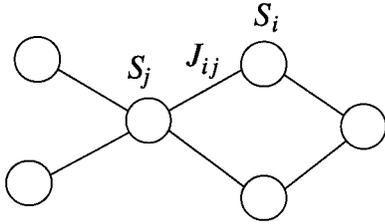
A Hopfield network is an undirected graph in which each node is binary (i.e., for each *i*, $S_i \in \{-1,1\}$), and each link is


Figure 1. A generic undirected recurrent network, in which the presence of a connection from node S_i to node S_j implies a connection from node S_j to node S_i. The value of the weight J_{ij} is equal to J_{ji} by assumption.

labeled with a real-valued *weight* J_{ij}. Because the graph is undirected, J_{ij} and J_{ji} refer to the same link and thus are equal by assumption.

A Hopfield network also comes equipped with an *energy function E,* which can be viewed intuitively as a measure of the "consistency" of the nodes and the weights. The energy is defined as follows:

$$E = -\sum_{i < j} J_{ij} S_i S_j \tag{1}$$

Consider, for example, the case in which J_{ij} is positive. If S_i and S_j have the same value, then the energy is more negative (because of the minus sign), whereas if S_i and S_j have opposite values, then the energy is more positive. The opposite statements hold when J_{ij} is negative. Negative energy is "good," that is, it means that the nodes are more consistent with each other (with respect to the weights).

Let us define the "state" of the network to be an assignment of values to the nodes of the network. For Hopfield networks with N nodes this is simply a string of N bits.

Hopfield (1982) showed that the states of minimum energy are equilibrium states of a simple dynamic law known as the *perceptron* rule. In particular, suppose that at each moment in time a particular node i is chosen and that node updates its value as follows:

$$S_i = \begin{cases} 1 & \text{if } \sum_j J_{ij} S_j > 0 \\ -1 & \text{otherwise} \end{cases} \tag{2}$$

After a finite number of such updates the network will find itself in a state that is a local minimum of the energy E and it will no longer move from that state.

Hopfield networks can be utilized to perform a number of information-processing tasks. One such task is that of CONSTRAINT SATISFACTION. Here the weights J_{ij} are set, either by design or via a learning algorithm (see MACHINE LEARNING), to encode a particular set of desired constraints between nodes. Minimizing the energy corresponds to finding a state in which as many of the constraints are met as possible. Another task is *associative memory,* in which the minima of the energy function are viewed as memories to be retrieved. The updating of the system according to Eq. (2) corresponds to the "cleaning up" of corrupted memories. Finally, Hopfield networks can be used for optimization applications; in such applications the weights are chosen by

design so that the energy E is equal to the quantity that it is desired to optimize.

The formulation of the Hopfield model in the early 1980s was followed by the development of the Boltzmann machine (Hinton and Sejnowski 1986), which is essentially a probabilistic version of the Hopfield network. The move to probabilities has turned out to be significant; it has led to the development of new algorithms for UNSUPERVISED LEARNING and SUPERVISED LEARNING, and to more efficient algorithms for Hopfield networks.

A Boltzmann machine is characterized by a probability distribution across the states of a Hopfield network. This distribution, known as the *Boltzmann distribution,* is the exponential of the negative of the energy of the state:

$$P(S_1, S_2, ..., S_N) = \frac{e^{-E/T}}{Z} \tag{3}$$

where Z is a normalizing constant (the sum across all states of the numerator), and T is a scaling constant. The Boltzmann distribution gives higher probability to states with lower energy, but does not rule out states with high energy. As T goes to zero, the lower energy states become the only ones with significant probability and the Boltzmann machine reduces to a Hopfield network.

There are three basic methods that have been used for calculating probabilities for Boltzmann machines: *exact calculation, Monte Carlo simulation,* and *mean field methods.*

Exact calculation methods are generally based on recursive procedures for transforming or eliminating nodes. One such method, known as decimation, is based on the fact that it is possible to remove, or "decimate," a node lying between a pair of other nodes, replacing the removed node with its weights by a single "effective" weight, while maintaining the same marginal probability on the remaining pair of nodes (Saul and Jordan 1994). For graphs with a chain-like or tree-like connectivity pattern, this procedure can be applied recursively to provide a general method for calculating probabilities under the Boltzmann distribution. There are interesting links between this procedure and exact algorithms for HIDDEN MARKOV MODELS and other more general probabilistic graphs known as BAYESIAN NETWORKS (Lauritzen 1996).

Monte Carlo simulation implements a stochastic search among states, biasing the search toward states of high probability (see also GREEDY LOCAL SEARCH). One simple Monte Carlo procedure is known as "Gibbs sampling" (Geman and Geman 1984). It turns out that Gibbs sampling for the Boltzmann machine is equivalent to the use of the perceptron rule [Eq. (2)] with a noisy threshold. Gibbs sampling was the method proposed in the original paper on the Boltzmann machine (Hinton and Sejnowski 1986). To speed the search, Hinton and Sejnowski also proposed the use of "simulated annealing," in which the temperature T is started at a high value and gradually decreased.

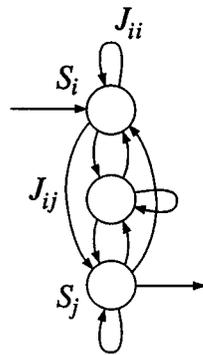
Finally, mean field methods take advantage of the fact that in networks that have dense connectivity each node has a value (under the Boltzmann distribution) that is well determined by its neighbors (by the law of large numbers). Thus it is possible to find and to exploit approximate deterministic


Figure 2. A generic recurrent network. The presence of cycles in the graph distinguishes these networks from the class of feedforward networks. Note that there is no requirement of reciprocity as in the Hopfield or Boltzmann networks.

Figure 3. An "unrolled" recurrent network. The nodes S_i in the recurrent network in Figure 2 are copied in each of $T + 1$ time slices. These copies represent the time-varying activations $S_i[t]$. The weights in each slice are time-invariant; they are copies of the corresponding weights in the original network. Thus, for example, the weights between the topmost nodes in each slice are all equal to J_{ii}, the value of the weight from unit S_i to itself in the original network.

constraints between nodes. The resulting equations of constraint, known as "mean field equations," generally turn out to once again have the form of the perceptron update rule, although the sharp decision of Eq. (2) is replaced with a smoother nonlinear function (Peterson and Anderson 1987).

Mean field methods can also be utilized with decreasing T. If T is decreased to zero, this idea, referred to as "deterministic annealing," can be applied to the Hopfield network. In fact deterministic annealing has become the method of choice for the update of Hopfield networks, replacing the simple dynamics of Eq. (2).

General recurrent networks are usually specified by drawing a *directed graph* (see figure 2). In such graphs, arbitrary connectivity patterns are allowed; that is, there is no requirement that nodes are connected reciprocally. We associate a real-valued *weight* J_{ij} with the link from node j to node i, letting J_{ij} equal zero if there is no link.

At time t, the ith node in the network has an activation value $S_i[t]$, which can either be a discrete value or a continuous value. Generally the focus is on discrete-time systems (see also AUTOMATA), in which t is a discrete index, although continuous-time systems are also studied (see also CONTROL THEORY). The update rule defining the dynamics of the network is typically of the following form:

$$S_i[t + 1] = f\left(\sum_j J_{ij} S_j[t]\right), \qquad (3)$$

where the function f is generally taken to be a smooth nonlinear function.

General recurrent networks can show complex patterns of dynamic behavior (including limit cycles and chaotic patterns), and it is difficult to place conditions on the weights J_{ij} that guarantee particular kinds of desired behavior. Thus, researchers interested in time-varying behavior of recurrent networks have generally utilized learning algorithms as a method of "programming" the network by providing examples of desired behavior (Giles, Kuhn, and Williams1994).

A general purpose learning algorithm for recurrent networks, known as *backpropagation-in-time,* can be obtained

by a construction that "unrolls" the recurrent network (Rumelhart et al. 1986). The unrolled network has $T + 1$ layers of N nodes each, obtained by copying the N of the recurrent network at every time step from $t = 0$ to $t = T$ (see figure 3). The connections in the unrolled network are feedforward connections that are copies of the recurrent connections in the original network. The result is an unrolled network that is a standard feedforward network. Applying the standard algorithm for feedforward networks, in particular backpropagation, yields the backpropagation-in-time algorithm.

Backpropagation-in-time and similar algorithms have a general difficulty in training networks to hold information over lengthy time intervals (Bengio, Simard, and Frasconi 1994). Essentially, gradient-based methods utilize the derivative of the state transition function of the dynamic system, and for systems that are able to hold information over lengthy intervals this derivative tends rapidly to zero. Many new ideas in recurrent network research, including the use of embedded memories and particular forms of prior knowledge, have arisen as researchers have tried to combat this problem (Frasconi et al. 1995; Omlin and Giles 1996).

Finally, there has been substantial work on the use of recurrent networks to represent finite automata and the problem of learning regular languages (Giles et al. 1992).

Reductionism

Reductionism is the position that holds that theories or things of one sort can exhaustively account for theories or things of another sort. So, for example, reductionism within the cognitive sciences holds that neuroscientific theories will explain the success of psychological theories and, therefore, will reveal that psychological states and processes are nothing but bodily states and processes.

Traditional reductionism within the philosophy of science (Nagel 1961/1979) especially emphasizes some theories' abilities to explain others. It focuses on theories' formal linguistic structures and endorses a model of EXPLANATION that requires that the reduced theory's laws follow deductively from the reducing theory's laws in combination with *bridge laws* that connect the two theories' predicates.

According to more ambitious reductionism, successful reductive explanation in *any* science allegedly reveals the in-principle dispensability of the reduced theory and its ontology. PHYSICALISM in the philosophy of mind anticipates a *comprehensive* reduction of just this kind for our best psychological theories. Both reductionism generally and psychology's reducibility in particular remain controversial.

Reductionistic analyses presuppose that a hierarchy of *analytical* (or *explanatory*) *levels* in science—encompassing the psychological and sociocultural sciences at its highest levels and the physical sciences at its lowest—duplicates a hierarchy of *organizational levels* in nature (Wimsatt 1976). Associated with each organizational level is a distinctive ontology and with each analytical level a distinctive set of theoretical concepts, explanatory principles, and investigative techniques. Traditional reductionism promotes a theoretical and ontological UNITY OF SCIENCE based on a series of reductive explanations of the theories at each level by the theories at the next lower level so that all theories in science, finally, are reducible to, which is to say, explained by, the theories of physics.

Bridge laws establish systematic connections between the predicates of the reduced and reducing theories. The more stringent the reductionism the more stringent the envisioned connections are. *Minimally,* bridge laws specify lower-level conditions sufficient for upper-level patterns. Such minimal bridge laws would be conditional in form; for example, if humans have a deficiency of noradrenaline in parts of their

limbic systems, then they will experience depression. Under such circumstances reduction proves limited in scope, inasmuch as such bridge laws are domain specific. (Other conditions might suffice for depression as well.)

Reductionists are often more ambitious, seeking grounds not just for explaining the upper-level theory but also for claiming that its entities are "nothing but" configurations of lower-level entities. The reducing theory should replace the upper-level theory without explanatory or ontological loss. Because conditions sufficient for a reductive explanation do not guarantee these ontological consequences (Richardson 1979), reductionists seeking ontological economies (Causey 1977) in addition to explanatory consolidation argue that only *identities* between the theories' predicates will suffice as bridge principles. Such bridge laws amount to empirical hypotheses that initiate new lines of research. Consider, for example, the wealth of new hypotheses concerning the neural mechanisms constituting consciousness.

The identity theory of mind, which resolves the MIND-BODY PROBLEM by holding that mental states simply *are* brain states, is harmonious with ambitious reductionists' goals. The identity theory avoids the explanatory and metaphysical complexities that dualism introduces. It preserves MENTAL CAUSATION by identifying mental operations with the neural processes that are causally implicated in behavior.

The identity theory presumes many of the conditions necessary for reducing psychology to neuroscience; however, two controversies surround the presumption that all psychological states can be identified with neural ones. First, proponents of non-reductive theories of consciousness insist that no sort of physical information about the brain can explain how conscious mental states *feel*. The identity theory's defenders respond by showing how neurocomputational findings explain some intuitions about the similarity and relative intensity of QUALIA (Churchland 1989).

The second controversy concerns whether most *types* of states to which commonsense or FOLK PSYCHOLOGY appeals are readily identifiable with *types* of brain states. Most philosophers think not, citing numerous considerations to defend that conclusion. The critical question concerns what they make of that failure of systematic intertheoretic mapping.

Those who hold to ELIMINATIVE MATERIALISM exceed reductionists in their confidence in the explanatory sufficiency of neuroscience. They contend that this mapping failure impugns folk psychology, which—in the face of neuroscience's superior merits and promise—deserves eradication (Churchland 1989). Like traditional reductionists, eliminativists assume that one account of intertheoretic relations suffices to model not just interlevel relations but changes in theoretical commitments within particular levels too. Some question that assumption and whether theory eradication in science on the scale that eliminativists anticipate ever actually arises in interlevel contexts (McCauley 1986).

Accepting *token identities* of the mental with the physical, others interpret this failure of systematic mapping as support not for adopting a more radical eliminativism, but for repudiating psychology's reducibility. ANOMALOUS MONISM contends that *psycho-physical laws* are impossible, because evolving ideals of rationality partially control our use of intentional concepts. Fodor (1981) argues that PSY-CHOLOGICAL LAWS are not exceptionless and that the *multiple realizability* of psychological types is widespread, resulting in uninformative bridge principles with lengthy disjunctions of neural types that might realize some psychological type. Both considerations impede reduction and favor the AUTONOMY OF PSYCHOLOGY. Because psychological explanations rely on *intentional contents,* reductionism's requirements fail to guarantee their subsumption by neuroscience. Fodor claims that reducing psychology requires demonstrating that neural states instantiate a code but that this yields a neuroscience unamenable to further reduction.

Noting reductionism's restrictiveness in accounting for cross-scientific relations, opponents of the autonomy of psychology are untroubled by mapping failures. Paul Churchland stresses approximate reduction, where lower-level theories preserve an equipotent image of upper-level theories without comprehensive mapping. Patricia Churchland (1986) emphasizes how *coevolving* theories will often prove mutually instructive—yielding progressively better mappings.

Others have adopted even more pragmatic approaches, advocating *integrative models* of cross-scientific relations (Bechtel 1986). Examining issues of discovery, evidence, method, and more, they foresee many illuminating relationships (besides possible reductions) between psychological, neurocomputational, and neuroscientific models (McCauley 1996). Within some suitably restricted domains reductions of some psychological principles *are* possible (Bickle 1995), but Bechtel and Richardson (1993) argue that the chief goal of reductionistic research is the discovery and explication of the mechanisms underlying the functioning of complex systems. Integrative modelers pursue analyses showing how upper-level research often plays central roles in *justifying* lower-level proposals (McCauley 1996), motivating innovative research at intermediate levels (such as connectionist modeling), and stimulating research in what Hardcastle (1996) calls "bridge sciences" (such as event-related potential studies). Compared to standard reductionism, these integrative models examine a wider range of the cross-scientific relations that arise in the sort of interdisciplinary research characteristic of cognitive science.

Reference, Theories of

Referential relations hold between representations and the world; in particular, they hold between parts of sentences and the world and between parts of thoughts and the world (see LANGUAGE AND THOUGHT). The most striking example of such a relation is the *naming* relation, the sort that holds between "Babe Ruth" and the famous baseballer. However, it is usual to think of reference as covering a range of semantically significant relations; for example, between the word "dead" and deadness, and between the concept <bachelor> and all bachelors. Other expressions used for one or another of these relations include: "designate," "denote," "signify," "apply," "satisfy," "instantiate," "fall under," and "about."

Reference is important because it is thought to be the core of meaning and content. Thus, the fact that "Babe Ruth" refers to that famous baseballer is the core of its meaning and hence of its contribution to the meaning of any sentence—for example, "Babe Ruth is dead"—that contains it. And the fact that <bachelor> refers to all bachelors is the core of its content and hence of its contribution to the content of any thought—for example, <Babe Ruth is not a bachelor>—that contains it.

The central question about reference is: In virtue of what does a representation have its reference? Answering this requires a theory that explains the representation's relation to its referent. There has been a great surge of interest in theories of reference in the twentieth century.

Description theories are one sort. According to these theories, the reference of a representation is determined by certain descriptions associated with it by competent speakers; these descriptions *identify* the referent. The simplest form of description theory specifies a set of descriptions each of which is necessary and all of which are sufficient for reference determination (FREGE 1893; Russell 1912); for example, the reference of "adult," "unmarried," and "male" might be jointly sufficient and severally necessary for the reference of "bachelor." This theory calls to mind what is known in psychology as the "classical" theory of concepts. According to another form of description theory, the reference is whatever is picked out by (a weighted) *most* of certain descriptions associated with the representation. On this "cluster" theory, no one description is necessary for reference fixing (Searle 1958). Cluster theories call to mind theories of CONCEPTS known in psychology as "family resemblance," "prototype," and "exemplar."

Around 1970, several criticisms were made of description theories of proper names—for example, "Babe Ruth" (Kripke 1980; Donnellan 1972)—and natural-kind words— for example, "gold" and "tiger" (Kripke 1980; Putnam 1975). Perhaps the most important are the arguments from ignorance and error. Speakers who seem perfectly able to use a word to refer are too ignorant to provide descriptions adequate to identify the referent; worse, speakers are often so wrong about the referent that the descriptions they provide apply not to the referent but to other entities or to nothing at all. Sometimes the whole speech community is ignorant or wrong about the referent. In brief, description theories of these words seem to require too much knowledge, to place too great an epistemic burden on speakers.

This is not to say that description theories fail for all representations: they still seem plausible for "bachelor," for example. But even where they work, description theories have a problem: they are *essentially incomplete.* Thus, suppose that a theory claims that the reference of "bachelor" is determined by the reference of "adult," "unmarried," and "male." We then need to explain the reference of those words to complete the explanation of the reference of "bachelor." Description theories might be offered again. But then the explanation will still be incomplete. At some point we must offer a theory of reference that does not make the reference of one word parasitic on that of others. We need

an "ultimate" explanation of reference that relates some words directly to the world. Description theories pass the referential buck. The buck must stop somewhere if there is to be any reference at all.

This deep problem for description theories is brought out by Hilary Putnam's slogan, "Meanings just ain't in the *head*," which he supported with his famous TWIN EARTH fantasy (1975: 227; see also Burge 1979). The association of descriptions with a representation is an inner state of the speaker. No such inner state can make the representation refer to a particular referent. For that we must look for some relation that language and mind have to things outside themselves—we must look for an external relation.

"Verificationist" theories of reference implicitly acknowledge this point, having a broader view than description theories of the required identification: speakers refer to whatever objects they would identify as the referents, whether by description *or by recognition.* Speakers recognize a referent by pointing it out in a crowd saying, for example, "That person." But these theories still seem to place too great an epistemic burden on speakers: we can but dimly call to mind the appearances of many objects we refer to.

Attempts to explain the external relation have appealed to one or more of three causal relations between representations and reality. First, there is the *historical* cause of a particular token, a causal chain going back to the dubbing of the token's referent. Theorists interested in this have emphasized the "reference borrowing" links in the chain: in acquiring a word or concept from others we borrow their capacity to refer, even if we are ignorant of the referent (Kripke 1980; Donnellan 1972; Putnam 1975; Devitt 1981). Second, there is the *reliable* cause of tokens of that type: a token refers to objects of a certain sort because tokens of that type are reliably correlated with the presence of those objects. The token "carries the information" that a certain situation holds in much the same way that tree rings carry information about the age of a tree (Dretske 1981; Fodor 1990). Third, there is the *teleological* cause or *function* of tokens of that type, where the function is explained along Darwinian lines: the function is what tokens of that type do that explains why they exist, what the type has been "selected for" (Millikan 1984; Papineau 1987; Neander 1995).

Reinforcement Learning

Reinforcement learning is an approach to artificial intelligence that emphasizes learning by the individual from its interaction with its environment. This contrasts with classical approaches to artificial intelligence and MACHINE

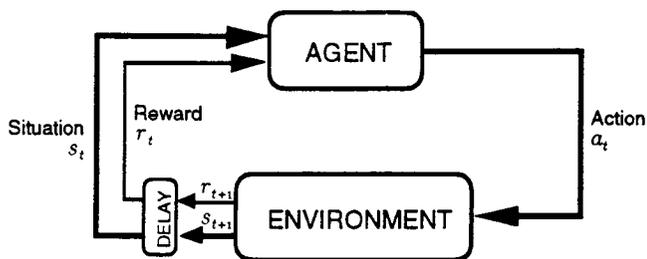
LEARNING, which have downplayed learning from interaction, focusing instead on learning from a knowledgeable teacher, or on reasoning from a complete model of the environment. Modern reinforcement learning research is highly interdisciplinary; it includes researchers specializing in operations research, genetic algorithms, NEURAL NETWORKS, psychology, and control engineering.

Reinforcement learning is learning what to do—how to map situations to actions—so as to maximize a scalar reward signal. The learner is not told which action to take, as in most forms of machine learning, but instead must discover which actions yield the most reward by trying them. In the most interesting and challenging cases, actions may affect not only the immediate reward but also the next situation, and through that all subsequent rewards. These two characteristics—trial-and-error search and delayed reward—are the two most important distinguishing features of reinforcement learning.

One of the challenges that arises in reinforcement learning and not in other kinds of learning is the trade-off between exploration and exploitation. To obtain a lot of reward, a reinforcement learning agent must prefer actions that it has tried in the past and found to be effective in producing reward. But to discover which actions these are it has to select actions that it has not tried before. The agent has to *exploit* what it already knows in order to obtain reward, but it also has to *explore* in order to make better action selections in the future. The dilemma is that neither exploitation nor exploration can be pursued exclusively without failing at the task.

Modern reinforcement learning research uses the formal framework of *Markov decision processes* (MDPs). In this framework, the agent and environment interact in a sequence of discrete time steps, $t = 0, 1, 2, 3, \ldots$. On each step, the agent perceives the environment to be in a state, s_t, and selects an action, a_t. In response, the environment makes a stochastic transition to a new state, s_{t+1}, and stochastically emits a numerical reward, $r_{t+1} \in \Re$ (see figure 1). The agent seeks to maximize the reward it receives in the long run. For example, the most common objective is to choose each action a_t, so as to maximize the *expected discounted return:*

$$E\left\{r_{t+1} + \gamma r_{t+2} + \gamma^2 r_{t+3} + \cdots\right\}$$

where γ is a discount-rate parameter, $0 \leq \gamma \leq 1$, akin to an interest rate in economics. This framework is intended to capture in a simple way essential features of the problem of


learning from interaction and thus of the overall problem of artificial intelligence. It includes sensation and action, cause and effect, and an explicit goal involving affecting the environment. There is uncertainty both in the environment (because it is stochastic) and about the environment (because the environment's transition probabilities may not be fully known). Simple extensions of this problem include incomplete perception of the state of the environment and computational limitations. Most theoretical results about reinforcement learning apply to the special case in which the state and action spaces are finite, in which case the process is called a *finite MDP.*

Reinforcement learning methods attempt to improve the agent's decision-making policy over time. Formally, a policy is a mapping from states to actions, or to probability distributions over actions. The policy is stored in a relatively explicit fashion so that appropriate responses can be generated quickly in response to unexpected states. The policy is thus what is sometimes called a "universal plan" in artificial intelligence, a "control law" in CONTROL THEORY, or a set of "stimulus-response associations" in psychology. We can define the *value* of being in a state s under policy π as the expected discounted return starting in that state and following policy π. The function mapping all states to their values is called the state-value function for the policy:

$$V^\pi(s) = E_\pi\left\{r_{t+1} + \gamma r_{t+2} + \gamma^2 r_{t+3} + \cdots | s_t = s\right\}.$$

The values of states define a natural ordering on policies. Policy π is said to be better than or equal to policy π' iff $V^\pi(s) \geq V^{\pi'}(s)$ for all states s. For finite MDPs there are always one or more policies that are better than or equal to all others. These are the optimal policies, all of which share the same value function.

The simplest reinforcement learning algorithms apply directly to the agent's experience interacting with the environment, changing the policy in real time. For example, tabular one-step Q-learning, one of the simplest reinforcement learning algorithms, uses the experience of each state transition to update one element of a table. This table, denoted Q, has an entry, $Q(s,a)$, for each pair of state, s, and action, a. Upon the transition $s_t \to s_{t+1}$, having taken action and received reward r_{t+1}, this algorithm performs the update

$$Q(s_t, a_t) \leftarrow (1 - \alpha)Q(s_t, a_t)$$
$$+ \alpha[r_{t+1} + \gamma \max Q(s_{t+1}, a_t)]]$$

where α is a positive step-size parameter. Under appropriate conditions (ensuring sufficient exploration and reduction of α over time), this process converges such that the *greedy policy* with respect to Q is optimal. The greedy policy is to select in each state, s, the action, a, for which $Q(s,a)$ is largest. Thus, this algorithm provides a way of finding an optimal policy purely from experience, with no model of the environment's dynamics.

The algorithm described above is only the simplest of reinforcement learning methods. More sophisticated methods implement Q not as a table, but as a trainable parameterized function such as an artificial neural network. This

Figure 1. The Reinforcement learning framework.

enables generalization between states, which can greatly reduce learning time and memory requirements. Another common extension, *eligibility traces*, allows credit for a good state transition to spread more quickly to the states that preceded it, again resulting in faster learning. Continuous-time reinforcement learning problems require eligibility traces just as continuous-state or continuous-action problems require parameterized function approximators.

Reinforcement learning is also a promising approach to PLANNING and PROBLEM SOLVING. In this case, a model of the environment is used to simulate extensive interaction between it and the agent. This simulated experience is then processed by reinforcement learning methods just as if it had actually occurred. The result is a sort of "anytime planning," in which the agent's policy gradually improves over time and computational effort. Reinforcement learning methods appear most suited to planning problems that are too large or stochastic to be solved by conventional methods such as HEURISTIC SEARCH or DYNAMIC PROGRAMMING. This approach has already proved very effective in applications, having produced the best of all known methods for playing backgammon, dispatching elevators, assigning cellular radio channels, and scheduling space shuttle payload processing.

Relational Grammar

Relational Grammar (RG) refers to a formal approach to SYNTAX that takes GRAMMATICAL RELATIONS like subject, direct object, and indirect object to be indispensable and primitive notions. According to Perlmutter (1980), they are indispensable for achieving three goals of linguistic theory:

1. to formulate linguistic universals
2. to characterize the class of grammatical constructions found in natural languages
3. to construct adequate and insightful grammars of individual languages

RG was motivated by syntactic work in a wide range of languages that revealed both language-particular and crosslinguistic generalizations involving subject and object. These included generalizations about morphological processes like agreement and case marking, semantic processes like the interpretation of anaphors, and grammatical processes like passive and relative clause formation. The earliest codified RG work (1974 lectures by David Perlmutter and Paul Postal; see Perlmutter and Postal 1983a, 1983b) argued that the relations subject, direct object, and indirect object were primitives because they could not be defined universally in terms of relations like linear order or dominance. These were the relations which formed the cornerstone of Transformational Grammar (TG), the prevailing theory of syntax in the early 1970s. The proposals of RG chiefly concern the relational structure of clauses.

Relational approaches to syntax were pursued in several forms during the mid-1970s, some a development of the ideas of Perlmutter and Postal, others a reaction to them (e.g., the papers in Cole and Sadock 1977). But the name "Relational Grammar" came to be associated with work that adheres to the program laid out by Perlmutter and Postal, work exemplified in Perlmutter 1983, Perlmutter and Rosen 1984, Postal and Joseph 1990; see Dubinsky and Rosen 1987 for a bibliography. RG, narrowly construed then, conceives of a clause as a network of grammatical relations. A clause might consist of a predicate, a subject, and a direct object. Under such a conception, two clauses that are superficially very different, perhaps because they are clauses from different languages, might in fact be structurally very similar. The fact that agreement, for example, is with the subject, whether the subject is clause-initial, clause-second, or clause-final, is directly statable and the parallelism between the two cases patent.

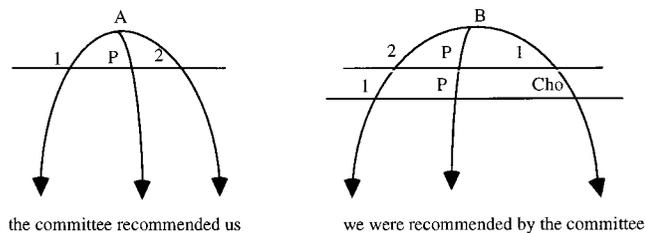
A crucial assumption of RG, inherited from TG, has been that the description of a clause refers not only to its superficial structure but also to a deeper structure and possibly to several intermediate levels of structure. In RG, these levels are called strata, and the RG position is that there is no one stratum at which all the properties associated with subject or object hold; rather these are apportioned at different strata. Relations in the initial stratum are linked to semantic role (e.g., agent, patient; Rosen 1984), whereas relations in the final stratum determine more superficial phenomena like agreement and word order. Clause pairs such as active/passive that express the same proposition in relationally different ways generally share the same initial stratum, accounting for their synonymy, but diverge in later strata (Perlmutter and Postal 1983a). The active sentence *the committee recommended us* has a single stratum, one in which *the committee* is subject and the pronoun *us* is direct object. The passive version, *we were recommended by the committee,* has, in addition, a second stratum in which *we* has been "advanced" to subject, and *the committee* "demoted" to an RG-specific relation called *chomeur* (= French "unemployed"). (This terminology reflects the relational hierarchy, a ranking of grammatical relations: subject > direct object > indirect object > other.) The diagrams in figure 1 represent these analyses. A and B are clausal nodes, and the grammatical relations borne by each element to the clause are organized into strata, represented by horizontal rows.


Figure 1. Active and Passive analyses.

Grammatical relations are represented by "1" = Subject, "2" = Direct Object, "Cho" = Chomeur, "P" = Predicate. Differences in word order and agreement between active and passive are due then to their different final strata. Universally, where grammatical relations determine word order, it is final stratum relations that are relevant. This generalization is deeply embedded in RG, which takes word order to be entirely irrelevant to nonfinal strata.

The demotion of the initial subject to chomeur in passive clauses reflects a universal principle of RG, the Stratal Uniqueness Law, which stipulates that a stratum may contain at most one subject, one direct object, and one indirect object. This law prevents the initial stratum subject in passive from persisting as subject when the direct object advances to subject. The fact that the chomeur in English passive is marked with *by* is, in contrast, a language-particular fact. RG has proposed an inventory of grammatical relations, and a set of principles ("laws") governing the well-formedness of networks (Perlmutter and Postal 1983b). The laws are linguistic universals (goal (1) above), and it is through the laws that RG proposes to characterize the class of grammatical constructions (goal (2)). Under certain conditions, the laws permit one nominal to assume the grammatical relation borne by another at a prior stratum, and they thereby define a typology of relation-changing constructions. Advancement to subject is seen in passive; advancement to direct object is also possible. In RG terms, *Every student gave the teacher a present* involves advancement of an indirect object, *the teacher,* to direct object. As direct object, it may advance further to subject in the passive version, *The teacher was given a present by every student.* The Stratal Uniqueness Law prevents the initial direct object from persisting as such when the indirect object advances to direct object. This explains why it cannot passivize: **A present was given the teacher by every student.* Also possible are demotions, as well as various kinds of clause merger (Davies and Rosen 1988). All these constructions are subject to the Stratal Uniqueness Law. The Stratal Uniqueness Law represents an empirically testable claim about syntactic organization and has not been uncontroversial (Perlmutter and Postal 1983b). Other important laws constrain the distribution of chomeurs and impose the requirement that the final stratum of every clause (but not necessarily any other stratum) have a subject (Perlmutter 1980; Perlmutter and Postal 1983b).

RG played an important part in the evolution of syntactic theory from the 1970s to the 1980s. During this period, languages other than English had significant impact on syntactic theorizing, leading to an increased appreciation of linguistic universals, and the need to distinguish more clearly between the universal and the language-particular. RG represents one early response to these issues, and it was extended in more formal work on Arc Pair Grammar (Johnson and Postal 1980). A number of ideas pioneered by RG were incorporated into other theories of the 1980s. The indispensability of grammatical relations has been a key assumption of LEXICAL FUNCTIONAL GRAMMAR, the disassociation of word order from more abstract syntactic representation was adopted in diverse guises by Lexical Functional Grammar and Generalized Phrase Structure Grammar, and the influential Unaccusative Hypothesis (Perlmutter 1978) was incorporated by Government Binding Theory (MINIMALISM). RG is currently pursued in Mapping Theory (Gerdts 1992), a relationally based typological approach to language difference.

Relevance and Relevance Theory

The notion of relevance has been used in many areas of cognitive science, including LOGIC, artificial intelligence and psychology of reasoning. This article focuses on the role of relevance in human communication, and presents a relevance-based theory of communication (Sperber and Wilson 1986/95) that has potential applications in broader domains.

The intuition that human communication is relevance-oriented is widely shared. Strawson (1964/1971: 92) put forward as a "general platitude" that he called the Principle of Relevance the claim that "stating is not a gratuitous and random human activity. We do not, except in social desperation, direct isolated and unconnected pieces of information at each other." However, recent approaches to PRAGMATICS have been sharply divided about how that intuition is to be explained. All current pragmatic treatments are influenced by the work of Paul GRICE (1967/1989), whose inferential approach to communication is fundamental.

Inferential communication succeeds when the communicator provides evidence of her intention to convey a certain thought, and the audience infers this intention from the evidence provided. Grice saw inferential intention-recognition as governed by a cooperative principle and maxims of quality, quantity, relation, and manner (truthfulness, informativeness, relevance, and clarity). He left the maxim of relation ("Be relevant") relatively undeveloped, and he acknowledged that its formulation concealed a number of problems that he found "exceedingly difficult" (Grice 1989: 46). Gazdar's comment (1979: 45), "That relevance is relevant to linguistic description is painfully apparent . . . . Equally apparent is the absence of any kind of formal treatment of the notion," reflects widespread skepticism about the possibility of progress in this area.

Theoretical accounts of relevance have taken two main forms. One links relevance to the notions of *topic, interest,* or *concern.* This approach was taken by Strawson (1964/1971: 92), whose Principle of Relevance was designed to capture the fact that we "intend in general to give or add information about what is a matter of standing or current interest or concern." Topic-based analyses have been proposed by Reinhart (1981) and Giora (1985), and criticized on the ground that the notion of topic is not only less clear but also less basic than the notion of relevance (Wilson 1998).

Another possibility is to link relevance to the notion of *required information,* following Grice's suggestion that a properly developed maxim of relevance might subsume his second Quantity maxim, "Do not make your contribution more informative than required." This approach is taken by Horn (1984), whose R-principle, "Make your contribution necessary; say no more than you must," is intended to subsume Grice's second Quantity maxim and his maxim of Relation. However, although the notions of information and degrees of informativeness are relatively easy to clarify, this approach sheds little light on what makes some information *required,* leaving the notion of relevance partially unexplained. (For discussion, see Carston 1998a.) Relevance theory (Sperber and Wilson 1986/1995) aims to remedy this defect by saying what makes information worth attending to, but without appealing to notions such as topic or interest.

Within relevance theory, *relevance* is treated as a property of inputs to cognitive processes and analyzed in terms of the notions of cognitive effect and processing effort. When an input (for example, an utterance) is processed in a context of available assumptions, it may yield some cognitive effect (for example, by modifying or reorganizing these assumptions). Other things being equal, the greater the cognitive effects, the greater the relevance of the input. However, the processing of the input, and the derivation of these effects, involves some mental effort. Other things being equal, the smaller the processing effort, the greater the relevance of the input.

On the basis of this definition, two general principles are proposed: the *cognitive principle* that human cognition tends to be geared to the maximization of relevance; and the *communicative principle* that every act of inferential communication communicates a presumption of its own optimal relevance (Sperber and Wilson 1986/1995, 1987). It follows from the cognitive principle of relevance that human attention and processing resources are allocated to information that seems relevant. It follows from the communicative principle of relevance (and the definition of optimal relevance; Sperber and Wilson 1986/1995: 266–278) that the speaker, by the very act of addressing someone, communicates that her utterance is the most relevant one compatible with her abilities and preferences, and is at least relevant enough to be worth the listener's processing effort.

Inferential comprehension starts with the recovery of a linguistically encoded logical form (see LOGICAL FORM IN LINGUISTICS); the goal of pragmatic theory is to explain how the hearer bridges the gap between the linguistically encoded logical form and the full intended interpretation of the utterance. The communicative principle of relevance motivates the following comprehension procedure, which,

according to relevance theory, is automatically applied to the on-line processing of attended verbal inputs. The hearer takes the linguistically decoded logical form; following a path of least effort, he enriches it at the explicit level and complements it at the implicit level, until the resulting interpretation meets his expectations of relevance, at which point he stops. The mutual adjustment of explicit content and implicatures, constrained by expectations of relevance, is the central feature of relevance-theoretic pragmatics. (See Sperber and Wilson 1998.)

Relevance-theoretic pragmatics differs from other Gricean approaches in three main respects. It does not treat communication as necessarily cooperative in Grice's sense: for communication to be successful, the only goal that speaker and hearer need to share is that of understanding and being understood. It is not maxim-based: the communicative principle of relevance is not a maxim that speakers need to know, but a generalization about acts of inferential communication. It follows that deliberate maxim-violation, which is central to Gricean pragmatics, has no role in relevance-theoretic comprehension, and the examples that Griceans treat as involving maxim-violation must be reanalyzed.

The relevance-theoretic approach has potential applications in wider domains: for example, in the psychology of reasoning (Sperber, Cara, and Girotto 1995) and the analysis of autism (Happé 1993). For critique and discussion, see *Behavioral and Brain Sciences* (10.4: 1987).

Religious Ideas and Practices

Religious ideas and the practices they inform show considerable variation across cultures. However, they do contain certain recurrent themes: gods that have minds and are alive but have no bodies; ancestors that, though dead, can still influence the living; and artifacts capable of revealing information about peoples' thoughts and actions. Accompanying such themes are ritual practices intended to get the gods to act, ancestors to bestow their blessings or curses, and carved blocks of wood to divine the future.

Anthropologists have typically attempted to account for the prevalence of such notions by postulating that they fill psychological and social needs, for example, social cohesion and personal integration. Symbolic anthropologists have emphasized the expressive role of religious ideas and practices in symbolizing social structure and have employed semiotic strategies in the explication of their meaning. Semiotics treats cultural symbols as surface phenomena that conceal hidden meanings requiring decoding in order to be understood. Only a few anthropologists have attempted to employ the resources of the cognitive sciences to explain the recurrence of religious ideas and practices.

Psychologists of religion have been less interested in religious ideas and practices and more interested in religious experience. Working primarily in the tradition of Wil-

liam JAMES (1902) they analyze extraordinary aspects of religious experience such as ecstatic states and altered states of consciousness and note, for example, that patients who have epileptic seizures in the left temporal lobe report extremely intense experiences of God's gaze.

Until recently neither anthropologists nor psychologists have explained how religious ideas and practices are related to garden variety cognition. The picture has now changed. Some anthropologists and psychologists have begun to employ the resources of the cognitive sciences to explain the prevalence of religious ideas and practices. The first anthropologist to approach religious ideas cognitively was Dan Sperber. In his ground-breaking work Sperber (1975) argued against the semiotic approach to religious ideas then fashionable in anthropology (cf. SEMIOTICS AND COGNITION). Whereas semioticians had searched for the hidden code, which, when specified, would, they thought, provide the interpretive key to symbolic discourse, Sperber demonstrated that symbolism in general and religious symbolism particularly could not be explained by appealing to a hidden code because the "meanings" of the symbols could not be mapped onto the putative underlying code. Symbolic "meanings" were too variable. In fact, symbolic anthropologists had long conceded the multivalence of symbolism. Turner (1969) had shown that the same religious symbol could be employed to represent many different sociocultural features. Sperber's critique of attributing meaning to symbolism in terms of an underlying code represented a major challenge to symbolists' arguments about the nature of religious ideas and practices. The symbolists' interpretations of symbolism were as symbolic as the symbols; symbolic interpretation extended symbolism rather than explicating it. Instead, Sperber argued that students of religion would do better by examining the *inferential processes* that religious people tacitly employ when they make their judgments about the world. Sperber further argued (1997) that, unlike *coevolutionary theories*, which overemphasize the supposed replication of religious ideas, an *epidemiological theory of beliefs* accounts for their cultural transmission by contagion. Sperber's goal was to develop a theory that showed how religious ideas spread and what selection forces were involved in their retention or elimination.

Pascal Boyer (1994) has furthered Sperber's claims by arguing that religious ideas can only spread if they attain a *cognitive equilibrium.* Religious ontological assumptions consist of a set of nonschematic or culturally transmitted assumptions and a set of schematic or standard commonsense assumptions. People make their inferences about the world in terms of an intuitive ontology in which categories such as person, animal, plant, and artificial object play a fundamental role. Such an intuitive ontology is common to all people (including religious ones) in all cultures. Religious ontologies differ from intuitive ontologies in very minor but significant ways by either violating one of the default assumptions of the intuitive ontology or by transferring one of these assumptions to another category. For example, if the default assumptions for "person" are intentional, biological, and physical, then the notion of a spirit violates only the ontology's physical properties. The other assumptions about persons remain in place. Or, if the

default assumption for an artifact is physical, then religious ideas involve the transfer of the property of intentionality to the category of artifact. For example, in some religions people transfer intentionality to artifacts and then regard them as knowing and thus revealing the future trajectory of the religious participant's life.

Lawson and McCauley (1990) focus more narrowly on the kinds of ideas presupposed in the practices that religious people perform. Specifically they have attempted to show that ordinary cognitive resources available for the *representation of action* are sufficient for the representation of religious ritual action by providing the framework for the representation of *agency*. For example a "transitive" action such as "Tom washes car" consists of an agent (with specific qualities) acting on a patient (with specific qualities). The representation of agents that populate religious systems (gods, ancestors, spirits, and their earthly stand-ins such as priests) differ from the representation of ordinary agents only in the special qualities they possess and in the inferences religious people make about their causal role in bringing about changes in states of affairs. Unlike ordinary causal sequences that can be driven back as far as one cares to go (back to the big bang if necessary), religious ritual actions presuppose that the causal sequence stops with the (cultural) postulation of superhuman agents (Spiro 1966). The buck stops with the gods. Lawson and McCauley also argue that where the agents are represented in the structural descriptions of religious ritual actions determines the types of rituals possible. Their theory enables them to predict the judgments that religious participants will make about matters such as their well-formedness, relative centrality, effectiveness, repeatability, substitutability, and reversibility, and a host of features about rituals concerning associated sensory stimulation, emotive responses, and mnemonic dynamics.

Very recently cognitive psychologists of religion have begun to work outside of the Jamesian tradition by focusing not on religious experience but on religious representations and have devised experiments to test the processing of religious ideas. Barrett and Keil (1996) have tested how people conceptualize nonnatural entities such as a god at various stages of cognitive development. Their results show that theological ideas such as God's omnipotence, omniscience, and omnipresence, which religious people themselves regard as essential truths, are not what are accessed when people are required to make on-line judgments about God's action in the world. Instead religious peoples' judgments are thoroughly anthropomorphic in nature.

Retina

The retina is a sheet of brain tissue lining the rear of the eye. It transduces light imaged by the lens into electrical potentials, performs substantial processing on these signals, and transmits them to the brain. This initiates visual perception.

Less than half a millimeter thick, the retina consists of five major classes of neurons in three layers (see figure 1) as well as Müller glial cells. Rod and cone photoreceptor cells use an enzymatic amplification cascade to transduce light into graded electrical potentials. Rods (100 million per eye) mediate night vision and can reliably signal the absorption of an individual photon. Cones (5 million per eye) mediate daylight vision and adaptively adjust their sensitivity to register intensity over the extraordinary range of eight orders of magnitude. Rod and cone signals are transmitted to bipolar and horizontal cells which, along with amacrine cells, further process visual information with graded electrical potentials. Retinal ganglion cells integrate inputs from bipolar and amacrine cells and send the resulting visual signals as discrete action potentials (see NEURON) along 1.2 million nerve fibers to a number of targets in the brain.

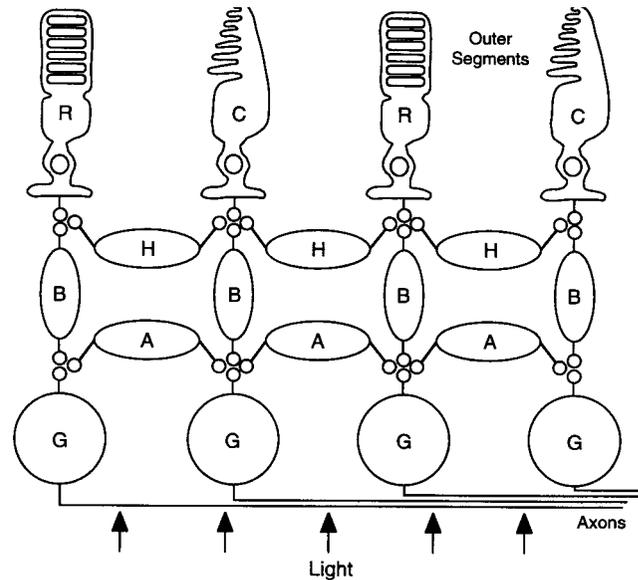
Each of these major classes of neurons can be further divided into subclasses defined by distinctive morphology, connectivity, electrical responses to light, and biochemistry (see Rodieck 1988, 1998; Wässle and Boycott 1991). For example, there are four major subclasses of photoreceptors (rods and three types of cones) and at least nine types of ganglion cells. Though the major classes of neurons appear in all vertebrates, the characteristics of the subclasses vary considerably among species. Each known subclass is distributed across the retina, forming a mosaic that samples the


Figure 1. Schematic of retinal neurons and major connections. Light traverses the mostly transparent retina before being absorbed in the outer segments of the (R)od and (C)one photoreceptors (drawn schematically) where transduction takes place. (H)orizontal, (B)ipolar and (A)macrine cells further process visual signals. (G)anglion cells integrate information from bipolar and amacrine cells and send the resulting signals to the brain via long axons.

visual world. Cones and many other neurons are concentrated in and near the fovea, the area of the retina corresponding to the center of gaze; here visual acuity is highest. Rods are absent in the fovea and concentrated in the peripheral retina.

Retinal ganglion cells provide visual information to the brain in signals that reflect spatial integration and parallel processing in the retina (see Rodieck 1973; Dowling 1987; Kuffler, Nichols, and Martin 1984; Davson 1972; Wandell 1995). A ganglion cell typically receives inputs over a roughly circular region of the visual field sampled by many photoreceptors. This region, the receptive field, usually consists of two concentric parts: a center region and a larger antagonistic surround region. In ON-center cells an increase in light intensity in the center increases the frequency of action potentials sent to the brain, while an increase in light intensity in the surround reduces action potential frequency. In OFF-center cells the effects of center and surround are reversed. This ON/OFF polarity is conferred by inputs from distinct types of bipolar cells which initiate the ON/OFF dichotomy (in photoreceptors the light response has a single polarity).

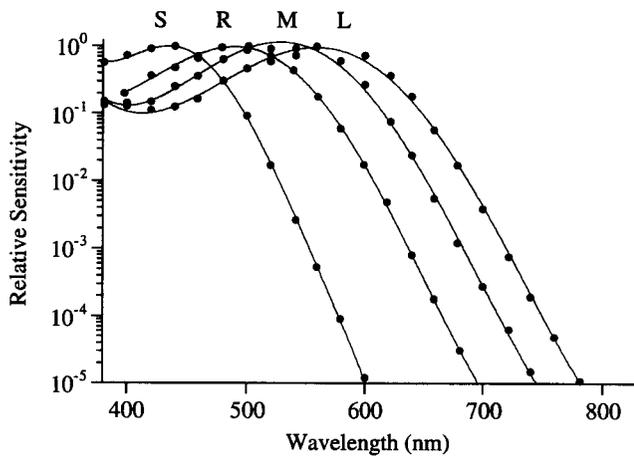
The ON and OFF pathways are examples of retinal subcircuits that carry different types of visual information. Likewise, rod and cone signals are processed by distinct types of bipolar and amacrine cells before being integrated in retinal ganglion cells. The subcircuits that give rise to other differences in the light responses of ganglion cells are less well understood. For example, some types of ganglion cells respond transiently at the onset or offset of a step of light while others respond for the duration of the step. Dif-


Figure 2. Photoreceptor spectral sensitivities. Points inidicate electrophysiologically measured relative spectral sensitivities of (R)ods and (L)ong, (M)iddle, and (S)hort wavelength-sensitive cones of the monkey, Macaca fascicularis, with peak sensitivities at about 500 nm, 561 nm, 531 nm, and 430 nm respectively. Human photoreceptors have very similar spectral sensitivities. Smooth curves are drawn through points to aid visualization. (Replotted from Baylor, Nunn, and Schnapf 1984, 1987.)

ferent types of ganglion cells also exhibit different spectral sensitivities determined by the relative strength of input from the three types of cones. As more subtle anatomical and physiological subdivisions of retinal neurons and their interconnections are elucidated (Rodieck 1988, 1998; Wässle and Boycott 1991), it is becoming clear that different visual messages are carried by a system of parallel retinal subcircuits. These messages are typically transmitted along different anatomical pathways to the brain where they may be locally processed in specific functional modules (see VISUAL PROCESSING STREAMS).

The operation of the retina limits visual performance. Spatial acuity is limited by the density of rods and cones and perhaps by spatial integration in the ganglion cells. Sensitivity to very dim lights is limited by the capacity of rods to faithfully signal absorption of single photons and by the capacity of subsquent circuits to transmit these signals uncorrupted by noise. Sensitivity to rapid variations in light intensity is limited by temporal integration in rods and cones (which occurs over intervals of about 300 msec and 50 msec respectively).

The operation of the rods and cones also establishes quantitative characteristics of color perception. Transduction in rods is initiated by a single visual pigment, rhodopsin. Rhodopsin has a characteristic probability of absorbing photons of different wavelength, giving the rod a characteristic spectral sensitivity (figure 2). However, once absorbed, all photons have the same effect on rhodopsin, so a rod cannot distinguish between one incident photon of 500-nm light and fifty-seven incident photons of 600-nm light. This property, called univariance, means that intensity and wavelength information are confounded in rod vision. Perceptual experience reflects this limitation: at night the world appears in shades of gray. Similarly, each of the three major cone types has a characteristic spectral sensitivity endowed by its visual pigment. Quantum absorptions in the three types of cones (figure 2) provide the visual system with just three distinct components of information about the wavelength composition of light. Hence human color perception is limited to sensations that can be duplicated by the superposition of three primary lights.

Why is wavelength information so poorly represented? The answer may lie in a compromise between spatial and spectral resolution. Each point in the visual field is sampled by only one photoreceptor. Additional types of photoreceptors might improve spectral resolution, but only at the cost of spatial resolution within each spectral band. Such tradeoffs have undoubtedly had a significant impact on the evolution of retinal structure and function.

Robotics

See BEHAVIOR-BASED ROBOTICS; MANIPULATION AND GRASPING; MOBILE ROBOTS; ROBOTICS AND LEARNING

Robotics and Learning

Learning will play an increasingly important role in the design and implementation of autonomous robotic systems. Robots are notoriously difficult to program, because the

correctness of their behavior depends on details of interaction with the environment, which are typically unknown to human engineers. In addition, truly flexible, robust robots will have to adapt to their specific and changing environmental conditions.

There are many opportunities for learning in a complex robotic system; the two most common are learning models and learning behavior. A robot may learn a model of its environment, in the form of a map, a kinematic or dynamical system, or an extended HIDDEN MARKOV MODEL. The model can then be used for planning, possibly using techniques of DYNAMIC PROGRAMMING. Another approach is to learn behavior, typically expressed as a mapping from perceptual input to effector outputs, directly.

A variety of MACHINE LEARNING algorithms exists, but they do not all apply well to robot learning, which is special for a number of reasons. Robots interact with their environments through physical sensors and effectors that always have some degree of noise; algorithms for robot learning must be particularly tolerant of noisy inputs and outputs. For learning to be effective, most robots must learn "on line"; that is, they learn while they are performing their task in the environment. This means that learning algorithms must be efficient and incremental (process data singly or in small batches rather than all at once) and that errors must be minimized throughout the life of the robot. Many robots are deployed in changing environments; this requires learning algorithms that can track a changing function. Finally, one of the most interesting special properties of robots is that they can often collect data actively, choosing to explore their environment in such a way as to make learning more efficient. This freedom to explore comes at the price of having to decide how to trade off gaining more information about the environment versus acting in the best possible way given the current information; this is often called the "exploration/exploitation dilemma."

Some of the most effective robot learning systems are built on SUPERVISED LEARNING, where there is a "teacher" that can supply a stream of desired outputs corresponding to the perceptual inputs of the robot. Pomerleau's ALVINN system (Pomerleau 1993) is an excellent example of supervised robot learning. A van learns to drive down a variety of roads at moderately high speeds based on visual input. The learning data is gathered with a human supervisor at the wheel, enabling the system to collect a series of input-output pairs, consisting of a computer-vision image and a desired steering angle. This data is used to train a neural network, which can then steer the car unaided.

Unfortunately, it is difficult to find such reliable supervisory information. Generally, humans are much better able to supply a "reinforcement" signal, which simply indicates when the robot is performing well or poorly. Techniques of REINFORCEMENT LEARNING can be used to learn behavior based on a reinforcement signal. This problem is much more difficult than supervised learning, because the robot is not told what outputs to generate for each input; this requires the robot to explore the space of possible actions and to be able to notice that an action taken much earlier may have been a contributing factor to current performance.

Because reinforcement learning is difficult, robot systems that make use of it must have a large amount of built-in structure. In BEHAVIOR-BASED ROBOTICS, for example, the robot may learn to switch between fixed behaviors or may learn a collection of specific behaviors given different reinforcement functions. Other robots learn a dynamical model of the world (Moore, Atkeson, and Schaal 1997) using supervised techniques, then use the model to generate actions using techniques of optimal control, which are appropriate for a restricted range of tasks.

There are still very few examples of real robotic systems that learn to behave, but this is a very active area of current research. The range of current robot learning applications and research is well documented in two collections of papers: a book edited by Connell and Mahadevan (1993) and a journal issue edited by Franklin, Mitchell, and Thrun (1996).

Rules and Representations

Rules and representations is a label applied to the classical, computational approach in cognitive science, and more often to the general conception of cognition based on that approach.

The interdisciplinary field known as cognitive science grew up with the development of the modern digital computer. Researchers from such diverse fields as computer science, neurophysiology, psychology, linguistics, and philosophy were brought together by the conviction that the digital computer is the best model of cognition in general, and consequently of human cognition in particular. (This "classical" conception of cognition is now rivaled by connectionism, the other principal branch of contemporary cognitive science; see COGNITIVE MODELING, CONNECTIONIST.)

A distinctive feature of the modern digital computer is that its processes are determined by a program—a system of *rules* that govern transitions from one state to the next. (State transitions can be nondeterministic; for instance, the rules can determine the next state on the basis of both the current state and the outcome of consulting a random number table.) Computers process information represented in "data structures" or symbols, and it is these symbolic *representations* to which the rules apply. Thus, the classical conception of cognition gives a central and fundamental role to rules—specifically, rules for the manipulation and transfor-

mation of symbolic representations. The contents of the symbolic representations are the contents of thought.

The rules executed by a digital computer can be regarded in two ways. From one perspective the rules refer explicitly to the task domain. For instance, a set of rules might assign classes to classrooms on a university campus, taking into account such constraints as the location of each classroom, the number of seats in each classroom, the number of requested seats for each class, and the time of day each class will be offered. These rules must be precise, completely explicit, and exceptionless, so that a human being who had no idea what classes or classrooms are could still determine room assignments by following the rules. To do this, one would need only the ability to follow simple instructions and the ability to perform elementary logical and mathematical operations. Terms for classes, rooms, and the like could be replaced by nonsense syllables or schematic letters.

When rules about the task domain have been made precise, explicit, and exceptionless in this way, they can be viewed from a second perspective: not as having representational content, but as purely formal symbol-manipulating rules that determine processing on the basis of nothing other than the syntactic form of the representations. The elementary operations specified in such rules can then be mirrored by simple physical devices. Hence, such rules can be put in the form of a program that will run on a conventional computer. Both the rules constituting the program and the representations to which they apply thus have two complementary "guises." The rules are purely formal, applying to representations solely on the basis of their structural-syntactic features; but the representations, and hence the rules, are also appropriately interpretable as being about objects and facts in the problem domain—classes, classrooms, class times, and so on. It is because the rules have these two guises that the syntactic and the semantic aspects of symbolic representations hang together.

Classicism maintains that the rules that determine cognitive processes in cognitive systems also have these two guises (Haugeland 1981). On one hand they are interpretable as psychological laws governing transitions among mental states. But on the other hand they are purely formal, applying directly to the syntactic structure of symbolic representations. On this classicist picture, the brain is a "syntactic engine" in which the content-appropriate processing of mental representations is accomplished by means of the structure-sensitive processing of symbol-structures in accordance with formal-syntactic rules. A program that is intended to model a human cognitive capacity—say, visual perception or parsing sentences or getting about in crowded shopping areas—is a hypothesis about the states and processes that occur when a person exercises that capacity. The explanation of the capacity itself, according to classicism, is that a person has a (possibly hardwired) system of rules for performing the task, rules that constitute a program. (Frequently in classicist cognitive science, a program intended to model a cognitive capacity will involve *heuristic* rules; see HEURISTIC SEARCH. These do not guarantee a correct or optimal outcome in every case, but employ reasonable strategies that will yield solutions in a large range of cases.)

In connectionist models, representations are activation-states of nodes in a connectionist network. (Often the representations are *distributed* activation-patterns involving multiple nodes; and sometimes the representations are *fully* distributed, in the sense that the individual nodes within a distributed representation have no determinate representational content by themselves.) Whereas classicism is firmly committed to mental representations with language-like syntactic structure, connectionist representations are not inherently syntactic. It is sometimes assumed that connectionist representations cannot exhibit syntactic structure, and that lack of syntax therefore constitutes an essential difference between connectionism and classicism (e.g., Churchland 1995). On this view, connectionist models depart from the classical "rules and representations" conception of cognition because they eschew traditional symbolic, syntactically structured representations. But in fact some connectionist models do employ syntactically structured representations and exhibit structure-sensitive processing—although syntactic constituency in these models is not a simple part-whole relation. Examples of such models include Pollack (1990), Smolensky (1990), and Berg (1992). So connectionism need not eschew syntax—and arguably should not (Horgan and Tienson 1996).

In connectionist models, rules for processing representations are not explicitly represented. It is sometimes assumed that classicism is committed to explicitly represented rules, and that lack of such rules therefore constitutes an essential difference between classicism and connectionism (e.g., Hatfield 1991). But although programs are explicitly represented as stored "data structures" in the ubiquitous general-purpose computer, stored programs are not an essential feature of the classical point of view. In some computational devices—including, for example, many hand-held calculators—the rules are all hardwired into the system and are not explicitly represented. According to classicism, cognition must conform to representation-processing rules that constitute a computer program; but a cognitive system could conform to such rules simply by being hardwired to do so. For example, from the classical perspective it is plausible to regard some innate processes as hardwired.

Classicism is committed to *representation-level* rules—that is, programmable rules that apply directly to the formal structure of the representations themselves. But connectionism, at least insofar as it employs fully distributed representations in which local node-activations do not have representational content, is not committed to such representation-level rules as a feature of cognitive architecture. The rules governing a connectionist network are local and subrepresentational, applying within and between individual nodes in the network—not to the distributed representations. Although connectionist systems sometimes conform to emergent representational-level rules over and above these node-level rules, in general there is no guarantee that rule-describability of processing will "transfer upward" from the level of individual nodes to the level of distributed representations (Horgan and Tienson 1996: 63–67; Horgan 1997). In our view, it is neither necessary nor desirable for connectionist models of human cognition to conform to programmable representation-level rules; it is

plausible that persistent problems within classicism—e.g., the FRAME PROBLEM—are a byproduct of classicism's commitment to such rules; and an appropriate nonclassical framework for cognitive science would be one in which the mathematics of dynamical systems theory replaces the classicist appeal to representation-level rules (Horgan and Tienson 1996).

Sapir, Edward

Edward Sapir (1884–1939) was a leading figure in twentieth-century linguistics and anthropology. Educated at Columbia University (B.A. 1904, Ph.D. 1909) and initially a student of Germanic philology, he became attracted to the anthropology program then newly formed by Franz BOAS. Boas's project of studying the languages and cultures of North American Indians in their own right, rather than as evolutionary precursors or deficient versions of Europeans (as in some other approaches then current), became Sapir's own. Yet, his work grew to include linguistic topics worldwide, and his contributions in theory and analysis are among the foundations of modern linguistics.

Sapir's professional career began in fieldwork and museum administration. Director of the Anthropology section of the national museum of Canada (Ottawa) from 1910 to 1925, he organized anthropological and linguistic research on Canadian native populations. Moving to a university setting (University of Chicago, 1925–31; Yale 1931–39) provided him with students, new research opportunities, and more time for theoretical concerns in linguistics, cultural anthropology, and psychology.

Sapir's contribution to American Indian linguistics lies partly in his field research, documenting a wide range of languages in grammatical analyses, texts, and ethnography. The grammar of Southern Paiute (1930a), in particular, still stands as a model of linguistic analysis and description. He also undertook comparative and historical work, including a startling new classification of North American languages (1929a) that reduced the number of independent stocks from some 55, in Powell's classification, to 6. Most importantly, his historical and methodological discussions (e.g., 1916, 1931, 1936a, 1938a) showed how linguistic evidence could address questions in cultural history and how language change in "exotic" languages can shed light on Indo-European (and vice versa). Sapir saw language as a species-wide human creation, and he pursued that vision globally, supplementing his American work with studies in Indo-European, Semitic, and African linguistics, and a project for Sino-Tibetan.

As a linguistic theorist, Sapir is known for his demonstrations of "pattern" (systematicity) in language, for his process-oriented conception of grammar (an early, though discontinuous, precursor of GENERATIVE GRAMMAR), and for his interest in the psychology of language. His classic paper "Sound Patterns in Language" (1925) explored the principles of systematicity in a language's PHONOLOGY, where a psychological organization of sound relationships functioned to distinguish word meanings. Phonology's basic unit, the phoneme, was defined by its place in the system. Not merely the linguist's construct, it had a psychological reality for the language's speakers (Sapir 1933). Similarly, in *Language* (1921) and later works, Sapir discussed grammatical configurations and their associated "form-feeling"—grammar's subjective dimension (what we might now call linguistic intuition). Linguistic patterns, he suggested, revealed creative operations of the mind, despite the largely unconscious nature of grammatical rules. That creativity was also to be seen in poetry and in language change, explainable in part as a psychological reconfiguring of linguistic patterns.

Because Sapir always emphasized the ways linguistic forms are meaningful to their users, his work in SEMANTICS tended not to fall under a separate rubric (but see Sapir 1944). His discussions of the ways meanings are distributed, how they might be associated with a configuration of formal relations in MORPHOLOGY and SYNTAX, and how these configurations differ across languages, included statements later identified with the "Sapir-Whorf hypothesis" of LINGUISTIC RELATIVITY and determinism. The "hypothesis" that a particular language's structure influences its speakers' perception and cognition owes more to Sapir's student Benjamin Lee Whorf than to Sapir himself. Still, Sapir did

maintain that a language's grammatical categories provide speakers with configurations of meaning that seem, to the speakers, to be located in the world rather than in language. He also argued that language influences what ideas are socially expressible, because communication depends on the available language and how it organizes meanings.

Sapir's linguistic psychology, with its emphasis on creativity and a level of mental patterning independent of actual behavior, contrasted sharply with the behaviorism of his Yale colleague Leonard BLOOMFIELD. Sapir was more interested in GESTALT PSYCHOLOGY and Jungian PSYCHOANALYSIS (CURRENT VIEWS), because they emphasized pattern and system in cognition and in personality organization. These interests also underlay Sapir's contributions in culture theory and cultural psychology.

Sapir shared with his fellow Boasians a view of culture as a system of configurations rather than a collection of traits. He differed from them, however, in emphasizing the role of individual psychology, experience, and creativity in shaping a personal world of meanings and actions. The "subjective side" of culture could be individually variable, therefore, even though the outward forms of behavior were shared. This distinction between collective and personal perspectives on culture posed methodological and epistemological problems that Sapir found especially interesting. His 1917 debate with Alfred Kroeber on the "superorganic" was the first of many discussions of these themes. Despite anthropologists' legitimate concern with abstracting cultural patterns from observable behavior, Sapir argued, they must not ignore the individual participant's life history and subjective experience.

In his later essays on culture and personality, Sapir again criticized approaches that failed to distinguish between collective and individual levels of analysis, and scholars who confused conventional behavior patterns with the personality patterns of actual individuals. Subjective experiences and meanings were to be carefully distinguished from the public symbols and social conventions prescribing the forms a person's behavior takes. Late in his life, influenced by his collaboration with psychotherapist Harry Stack Sullivan, Sapir began (1937, 1993) to explore the analysis of social interaction as the locus of cultural dynamics.

Sapir's conceptions of culture and of anthropological method were always influenced by his work in linguistics. Though better known today as linguist than as anthropologist, he saw these efforts as conjoined. Language was, for him, the cultural phenomenon par excellence. It offered the prime example of cultural difference and cultural systematicity, it provided the ethnographer with the terminological key to native concepts, and it suggested to its speakers the configurations of readily expressible ideas. Moving among linguistics, anthropology, psychology, and the humanities, Sapir's work transcended particular disciplines while contributing to their foundations.

Saussure, Ferdinand de

Ferdinand de Saussure (1857–1913) is usually considered to be the father of modern linguistics. Born in Geneva into an illustrious family that included famous natural scientists, Saussure trained as a comparative philologist, studying (1876–78) in Leipzig, the main center of the Neogrammatical movement. There he gave precocious proof of his genius with a *Mémoire* (1879) containing insights that lie at the root of some of the most interesting twentieth-century developments in comparative philology. After a period of studying and teaching in Paris (1880–91), Saussure was called in 1891 to teach Sanskrit in Geneva. He published relatively little in his lifetime (see his *Recueil* 1922). Between 1907 and 1911, he taught three courses in general linguistics to small groups of students. After his death, two of his colleagues (Charles Bally and Albert Sechehaye, with the help of one of his students, Albert Riedlinger), on the basis of students' lecture notes and some of Saussure's own jottings, compiled a coherent *Cours de linguistique générale* (*CLG;* 1916). It proved to be perhaps the most influential text in linguistics, at least up to the publication of Noam Chomsky's work.

Before looking at some of Saussure's ideas, one needs to comment on the difficulties posed by their interpretation. As the text was not written by Saussure, the problem of establishing what certain passages of the *CLG* meant exactly and how far they represented the ideas of the "author" grew so complex that it became difficult to take a fresh look at questions without becoming embroiled in a specialized hermeneutic apparatus. The most useful contributions are Godel (1957), Engler (1967–74), De Mauro (1967), and the publication of sets of individual students' notes (see the volumes of the journal *Cahiers Ferdinand de Saussure*).

A further difficulty was added by the spread of postmodern attitudes (some claiming, ironically, a Saussurean inspiration) according to which it is impossible in this case, and anyway illegitimate in principle, to try to establish the correct meaning of a text, because texts are inevitably constructed by readers. "Semiological" readings of the *CLG* were proposed, which sometimes appeared more stimulat-

ing than convincing. To this we can finally add the fact that several linguistic movements refer to Saussure as the source of some of their insights, so that it has become difficult to separate Saussure's own ideas from those belonging to his followers (Lepschy 1982). We can quote the Genevan School of his immediate successors, the Danish Glossematic group of Louis Hjelmslev, some members of the Prague Circle (in particular Roman JAKOBSON and Nikolaj Sergeevic Trubeckoj), and many of the French trends that are loosely associated under the banner of "structuralism" or "post-structuralism," from Roland Barthes's semiology, to Jacques Lacan's brand of psychoanalysis, to Althusser's variety of Marxism, to Claude LÉVI-STRAUSS' structural anthropology, to Michel Foucault's cultural archaeology, to Jacques Derrida's deconstructionism. In the tradition of American linguistics, however, the influence of Saussure was limited from the start and further restricted by his being (misleadingly) associated with structural linguistics, which, in its post-Bloomfieldian incarnation, had next to nothing in common with Saussure.

Some of the main ideas that are central in the *CLG* are rooted in the debates current at the turn of the century concerning the nature of scientific explanation, the relation between natural sciences and the humanities (*Naturwissenschaften* vs. *Geisteswissenschaften*), the distinction between nomothetic and idiographic disciplines, and the place of linguistics within this intellectual map. The *CLG* introduced a series of dichotomies that are still, in one way or another, present in current research. The main ones are the following four.

1. Synchronic versus diachronic viewpoint: In the early twentieth century it was taken for granted that the scientific study of language had to be diachronic. Saussure's position was crucial in redressing the balance and in establishing synchronic study as a fully legitimate activity, indeed the one in which the most important insights of modern linguistics were to be obtained.
2. Syntagmatic versus associative (or, as it was later called, paradigmatic): Based on the psychological theories of the time, this was made into a basic distinction between two Cartesian axes: on the horizontal one the linear succession of units constituting the message, on the vertical one the set of items constituting the code.
3. *Langue* versus *parole*: The former refers to what is abstract (form), general, and social; the latter to the concrete (substance), specific, and individual speech acts.
4. Signifier versus signified: This is a more strictly semiotic dichotomy. The linguistic sign has two sides, expression and content, which do not exist without each other and yet can be separately analyzed; their relation is arbitrary, not in the traditional sense of a conventional relation between word and thing, as illustrated by the very existence of different languages, but in a deeper, more radical sense, referring to the split that runs through the very nature of language.

In the context of cognitive views as embodied in GENERATIVE GRAMMAR one can observe an analogy (which is obviously not an identity) between the langue/parole distinction and that of competence/performance, and a link between the notion of the arbitrary nature of the sign and that of the distance between surface and deep structures. An

aspect that sets Saussure's views apart from those of contemporary linguistics is that whereas for him SYNTAX has a marginal and unclear status (linked mainly to the structure of individual acts of *parole*), nowadays it is thought to have a central and creative function.

Schemata

Schemata are the psychological constructs that are postulated to account for the molar forms of human generic knowledge. The term *frames*, as introduced by Marvin Minsky (1975), is essentially synonymous, except that Minsky used frame as both a psychological construct and as a construct in artificial intelligence. *Scripts* are the subclass of schemata that are used to account for generic (stereotyped) sequences of actions (Schank and Abelson 1977).

Although the term *schema* was used by the philosopher Immanuel KANT and the developmental psychologist Jean PIAGET, the direct line of intellectual descent for this construct in cognitive science is through the work of British psychologist Sir Frederic BARTLETT. Bartlett (1932) was investigating the recall of folktales and noticed that many of the errors that occurred in the recall protocols tended to make the recalls more conventional than the original text. In order to account for this class of memory errors, Bartlett proposed that human beings have substantial amounts of generic knowledge in the form of unconscious mental structures (schemata) and that these structures interact with incoming information to produce schematized (conventionalized) errors in recall. Bartlett's schema construct was not compatible with the world view that was dominant in psychology at the time (see BEHAVIORISM), and therefore the schema concept was not incorporated into mainstream MEMORY research in psychology (cf. Brewer and Nakamura 1984).

The schema construct was reintroduced into modern cognitive science through the work of the computer scientist Marvin Minsky (1975). Minsky was attempting to develop machines that would show humanlike intelligence. Minsky read Bartlett's book on memory (Bartlett 1932) and concluded that much of human intelligent behavior derived from the use of generic knowledge. This led Minsky to argue that in order to make machines intelligent it would be necessary for them to be provided with large amounts of knowledge. This proposal had an enormous influence on the development of the field of artificial intelligence (cf. Dyer, Cullingford, and Alvarado 1990; Maida 1990).

Minsky's more specific proposal was to introduce the construct of frames to represent knowledge of ordinary aspects of the world (e.g., rooms). Frames are knowledge structures that contain fixed structural information. They have slots that accept a range of values; each slot has a default value that is used if no value has been provided from the external world. For example, if a person or a machine is trying to represent a particular college classroom the generic classroom frame will contain the fixed information that the room will have walls, a ceiling, and a door. The frame will contain a slot for type of lighting. If no information is provided about this aspect of the world (e.g., if an individual has just glanced at a room without looking up to see the lights) then the frame provides a default value (in this case, that the lights are fluorescent). Thus the frame construct can be used to give an account for why someone walking into a room without a ceiling will be surprised and why an individual might recall that a particular classroom had fluorescent lights when it actually did not. Note that in this example there is a generic frame for classrooms in long-term memory, and to represent a specific classroom the generic frame is instantiated by a specific episodic representation. In general, Minsky's frames provided a much more structured account of KNOWLEDGE REPRESENTATION than previous proposals.

Work on frames in artificial intelligence has had a strong impact on psychological investigations of knowledge representation. Rumelhart (1980) developed a psychologically based theory of schemata derived from Minsky's work. (Psychologists working on these topics usually use the term *schema*, plural *schemata*, for these forms of knowledge representation.) In both psychology and artificial intelligence there has been much controversy over the relationship of schemata to other "simpler" forms of representation such as propositions, semantic nets, and CONCEPTS. In general, schema theorists (Minsky 1975; Rumelhart 1980) have made an ontological argument that there are molar phenomena (e.g., events, spatial scenes, discourse structure) in the (psychological?) world, and that schemata are the appropriate forms of knowledge representation for these molar phenomena (cf. Brewer and Nakamura 1984; Davis, Shrobe, and Szolovits 1993).

Schema theories have had a wide impact on empirical work in cognitive psychology. They provided an account for earlier work such as the finding of Bransford and Johnson (1972) that recall for an opaquely written passage is much improved when it is given with a schema-relevant title. They also generated much new research, such as the finding by Bower, Black, and Turner (1979) showing high rates of script-based intrusions in recall of script narratives, and the work of Brewer and Treyens (1981) showing schema-based intrusions in the recall of visual scenes (see Brewer and Nakamura 1984 for an extensive review of these empirical findings).

How are schema theories to be viewed within the overall study of knowledge representation in cognitive science? The original papers on frames and schemata invite the inference that schemalike representations will account for most of human and machine knowledge. Subsequent work has shown that although schema representations provide a powerful account for generic forms of knowledge, this type of representation is only a part of the total repertoire of human knowledge. It now seems clear (cf. Brewer 1987) that MENTAL MODELS (Johnson-Laird 1983), naive theories (Gopnik and Wellman 1992) and many other forms of representation (e.g., Schank 1982) are needed to give a comprehensive account of human and machine knowledge.

Science, Philosophy of

See INTRODUCTION: PHILOSOPHY; REALISM AND ANTIREALISM; REDUCTIONISM; UNITY OF SCIENCE

Scientific Thinking and Its Development

Scientific thinking refers to the thought processes that are used in science, including the cognitive processes involved in theory generation, experiment design, hypothesis testing, data interpretation, and scientific discovery. Many of these aspects of scientific thinking involve cognitive processes that have been investigated in their own right, such as INDUCTION, DEDUCTIVE REASONING, CAUSAL REASONING, ANALOGY, EXPERTISE, and PROBLEM SOLVING. Research on scientific thinking uses many different methodologies such as analyzing historical records, conducting experiments on subjects that are given scientific problems, and building computer programs that make discoveries. Another focus of research on scientific reasoning has been its development. Research on children has been concerned with discovering how children design experiments and link theory and data, and with describing children's theories of the natural world and science. There has been a tremendous amount of research on scientific thinking over the past forty years. One way of classifying research in this area is in terms of experimental, computational, and real world investigations of scientific thinking. Other important areas not covered in this entry are historical and philosophical approaches to scientific thinking (see Nersessian 1992; Thagard 1992 for research in these areas).

The hallmark of experimental investigations of scientific thinking has been to take one aspect of scientific thinking that is thought to be important and investigate it in the laboratory. The three aspects of scientific thinking that have been most actively investigated are problem solving, hypothesis testing, and concept acquisition.

Scientific Thinking as Problem Solving

According to this view, scientific thinking can be characterized as a search in various problem spaces (Simon 1977). Simon has investigated a number of scientific discoveries by bringing subjects into the laboratory and getting them to rediscover a scientific concept (Qin and Simon 1990). He has then analyzed the verbal protocols that subjects generate and mapped out the types of problem spaces that the subjects search in (such as a space of possible mathematical functions when finding patterns in a set of numbers). In a similar vein, Klahr and Dunbar (1988) characterized scientific thinking as a search in two problem spaces, a hypothesis space and an experiment space. The goal of the researchers using this approach has been to identify the types of search strategies or heuristics that are used in scientific thinking.

Scientific Thinking as Hypothesis Testing

Many researchers have regarded hypothesis testing as a core attribute of scientific thinking. Much of this work has been concerned with Karl Popper's idea that the best way to test a hypothesis is to attempt to disconfirm it. Using this approach, researchers have found that subjects usually try to confirm their hypotheses rather than disconfirm their hypotheses. That is, subjects will conduct an experiment that will generate a result that is predicted by their hypothesis. This is known as confirmation bias. Many researchers have shown that it is very difficult to overcome this type of bias. Mynatt, Doherty, and Tweney (1977) devised a task in which subjects had to conduct experiments in an artificial universe and found that subjects attempt to confirm their hypotheses. Dunbar (1993) has found that although subjects do try to confirm hypotheses, their hypotheses will change in the face of inconsistent findings. Klayman has argued that people possess a positive test bias—people attempt to conduct experiments that will yield a result that is predicted by their current hypothesis, and that under certain circumstances, this is a good strategy to use (Klayman and Ha 1987). Summaries of work on hypothesis testing can be found in Tweney, Doherty, and Mynatt (1981) and Gorman (1992).

Scientific Thinking as Concept Discovery

Many researchers have noted that an important component of science is the generation of new CONCEPTS and modification of existing concepts. Starting with Bruner, Goodnow, and Austin (1956) researchers focused on the idea that scientists must formulate new concepts and theories. Whereas this work focused on strategies that are used to generate new concepts, later work focused on the ways that scientific concepts are represented and change with expertise (Chi, Felto-

vitch, and Glaser 1981). There has also been a considerable amount of work on CONCEPTUAL CHANGE—the radical restructuring of concepts in COGNITIVE DEVELOPMENT and science (Brewer and Samarapungavan 1991; Wiser and Carey 1983). This research has uncovered the types of external events that precede conceptual change and the ways that scientific concepts change over time.

Experimental Approaches to the Development of Scientific Thinking

Many researchers have noted that children are like scientists; they have theories, conduct experiments, and revise their theories. Thus, although most researchers agree that scientists and adults have much more complex knowledge structures than children do, the developmental question has been whether there are differences between children's and adults' abilities to formulate theories and test hypotheses. Inhelder and PIAGET (1958) demonstrated that children of different ages have different abilities in testing hypotheses and interpreted their results in terms of Piaget's stage theory of cognitive development. Early research focused on different stages in the development of scientific thinking, but the idea of stages has largely disappeared from recent theorizing on this issue. Some researchers such as Deanna Kuhn (1989) have demonstrated differences in the ability of children to design experiments at different ages. Other researchers, such as Sodian, Zaitchik, and Carey (1991) have showed that even young children can design good experiments that test hypotheses. Klahr, Fay, and Dunbar (1993) have argued that when a scientific thinking task involves searching in one problem space, few if any developmental differences will be found, but if the task involves use of a number of problem spaces, then there will be developmental differences. Recent research, such as that of Schauble (1996), has tracked children's ability to test hypotheses over periods of time and found that children do change their experimentation strategies with experience. Research on children's theories of biological mechanisms reveals that preschoolers have coherent representations of many biological processes that, at certain levels, resemble those of adults (Wellman and Gelman 1997). Overall, recent research on the development of scientific reasoning indicates that, once amount of knowledge is held constant, there are few radical differences between children's and adults' abilities to form hypotheses, test hypotheses, and design experiments.

Computational Approaches

Computational approaches provide specific models of the cognitive processes underlying scientific thinking. Early computational work consisted of taking a scientific discovery and building computational models of the reasoning processes involved in the discovery. Langley et al. (1987) built a series of programs that simulated discoveries such as those of Copernicus and Stahl. These programs have various inductive reasoning algorithms built into them and, when given the data that the scientists used, were able to propose the same rules. Computational models since the mid 1980s have had more knowledge of scientific domains built into

the programs. For example, Kulkarni and Simon (1990) built a program that represented knowledge of biology and experimental techniques. This program simulated Krebs's discovery of the urea cycle. The incorporation of scientific knowledge into the computer programs has resulted in a shift in emphasis from using programs to simulate discoveries to building programs that are used to help scientists make discoveries. A number of these computer programs have made novel discoveries. For example, Valdes-Perez (1994) has built systems for discoveries in chemistry, and Fajtlowicz has done this in mathematics (Erdos, Fajtlowicz, and Staton 1991). See Darden (1997) for a summary of work on computational models of scientific discovery.

Real-World Investigations of Science

Most psychological research on scientific thinking has been based on implicit assumptions and preconceptions about what is important in scientific thinking. Other than historical records and scientists' recollections, little is known about what scientists really do in their research. Thus we do not know how relevant the cognitive processes investigated by cognitive scientists are to real world science. Using techniques from verbal protocol analysis, Dunbar (1995, 1997) analyzed the "on-line" thinking of molecular biologists and immunologists at work in their laboratories. These data include important scientific discoveries that occurred "on-line." He found that more than 50 percent of the findings that the scientists obtained were unexpected and that much of the scientists' reasoning is concerned with interpreting these findings. As a consequence, scientists have developed specific strategies for dealing with unexpected findings that are very different from the strategies seen in the hypothesis testing literature. Dunbar has also found that scientists use analogies from related rather than unrelated domains in proposing new hypotheses. Furthermore the scientists distribute reasoning among members of a laboratory. For example, one scientist may add one fact to an induction, another scientist adds another fact, and yet a third scientist might make a generalization over the two facts. This type of research on real world science is now making it possible to see what aspects of scientific thinking are important. By fusing together findings from real world science with the results of the more standard experimental methods, it should be possible to build detailed models of scientific thinking that, when implemented, can be used by scientists to help make discoveries.

Self

Questions about the self are typically posed as questions about persons or minds, about such self-reflexive capacities as SELF-KNOWLEDGE and self-reference, or about the semantics and pragmatics of "I." For example, we think of the self or person as something that endures through changes in its mental states; but what is it that makes us the same person now who we were ten years ago? Among those who reject the idea of a nonphysical substance or soul, the debate has focused on the relative importance of bodily continuity (especially continuity of the brain) and psychological continuity (Williams 1973; Parfit 1984). Because the focus on psychological continuity entails that there could in principle be more than one person in a single human body, the debate has clear implications for controversies in clinical psychology such as that surrounding multiple personality subjects (Hacking 1995). More recently the debate has expanded to include such normative issues as the nature of the justification of the sacrifices that we ordinarily make for our future selves (White 1991; Rovane 1997), raising the question whether personhood is a metaphysical or a normative concept.

Besides thinking of ourselves as enduring, we have the idea of ourselves as agents—as subjects of actions and not merely objects to which things happen. This raises the issue of whether we could make sense of agency, freedom, and responsibility if all our actions were causally determined or, indeed, whether we could do so even if they were uncaused and random. Compatibilists hold that free will is not a matter of our actions being uncaused but of their being caused in the right way—for example, by a process of deliberation that is uncoerced, uncompelled, and so forth (Ayer 1954). But this leaves open the question how we could be justified in allocating and accepting responsibility for actions that were determined to happen long before we were born (Strawson 1962; White 1991). Another issue that compatibilism leaves unresolved is over the nature of the experience that grounds our concepts of freedom and agency. This topic has been addressed extensively in the existentialist and phenomenological traditions and is currently under investigation in psychology (Heidegger 1962; Sartre 1956; Merleau-Ponty 1962; Neisser 1993: Introduction).

Our concept of the self, however, is not simply that of an enduring entity to which certain mental events and actions are ascribed. We normally assume that our knowledge of ourselves as subjects is nonobservational and noninferential and thus unlike our knowledge of ordinary physical objects. One reason is that our thoughts about ourselves as subjects (thoughts expressed in terms of "I") seem to enjoy an immunity to error that those regarding external objects lack. Although one might be mistaken about whether a body that one could observe was one's own, there is no possibility of losing track of oneself as a subject or of mistaking another subject for oneself or another mind for one's own (Shoemaker 1968). But though our knowledge of ourselves as subjects is apparently not a matter of external observation, it seems that anything to which we could have introspective access would be a mental state and not the enduring subject that has that state. David HUME (1888) concluded on this basis that we have no access to an enduring self and indeed that none exists, a position subsequently taken up by Ernst Mach (1939) and Moritz Schlick (1949).

Self-reference raises some of the same problems as self-knowledge and provides similar reasons for skepticism about the self. How does the term "I" refer? Evidently not through any associated linguistic descriptions, in that we can imagine experiencing amnesia while anesthetized in a sensory deprivation chamber and thinking "I won't let this happen again!" (Anscombe 1975). In such a situation we could not frame a description that would pick us out uniquely. Nor is it adequate to say simply that "I" refers demonstratively, because we normally perceive the object that we demonstrate. Anscombe (1975) has argued on the basis of considerations of this kind that "I" does not refer.

But neither the claim that "I" does not refer nor its denial answers the most basic question underlying the issues of self-reference and self-knowledge and the most basic question associated with the self—How *are* we given to ourselves when our access to ourselves is most immediate? One approach to this question is suggested by work in phenomenology and by contemporary psychologists influenced by James Jerome GIBSON (Heidegger 1962; Sartre 1956; Gibson 1986; Neisser 1988). These theorists hold that what we are given is a pragmatically structured world of opportunities and liabilities. These are perceived directly and immediately; they are not interpretations imposed on a neutral sensory field the perception of which is more direct or immediate. Gibson's term for what is given in such experiences is AFFORDANCES.

As both Sartre and Gibson make clear, in being given a world of human possibilities and things to be done—of doorways that we can walk through and streetcars we can catch if we hurry—we are given ourselves *implicitly*. A world of affordances is one in which we are necessarily implicated. To see the chair as something to sit on is to be given to ourselves (implicitly) as having a certain size, weight, and shape and a certain capacity for movement and action. And our perceiving the speeding car as a threat says as much about our vulnerabilities and liabilities to destruction as it does about automobiles (Warren and Whang 1987; Mark 1987).

The notion of a self implicit in our perceptual experience of the external world raises the question how such a self is related to our explicit conception of ourselves as objective entities. Strawson (1959) poses a similar question by asking how we can have a conception of an entity to which we ascribe both mental and physical properties. And the question how we can ascribe both mental and physical properties to ourselves raises many of the same issues as the question how we can ascribe the same mental properties to ourselves and to others. The problem is that our basis for the ascription of mental properties to others (observation of behavior) is so radically different from our basis for self-ascription that a commitment to the idea of meaning as use suggests that mental predicates must change their meanings from first-person to third-person contexts. This, in other words, is one version of the problem of other minds.

If views like those of Gibson and the phenomenologists that take the agential perspective as basic are correct, however, this way of posing the problem may exaggerate the asymmetries between ourselves and others. Recent research suggests that our capacity to engage in joint or complementary actions with others is in place at birth in the form of a capacity to engage in and recognize mimicry and slightly later in the ability to share affect in expressive exchanges (Meltzoff and Moore 1995; Stern 1985). This points to the possibility that our access to the other subjects' agential characteristics may be at least as direct as our access to their objective makeup. For example, just as we are given ourselves implicitly in the possibilities we see for individual action, the possibilities we see for acting jointly may give us an implicit other—a notion similar to Sartre's (1956: part III, chap. 1) understanding of Heidegger's "being-with." Alternatively, what we perceive most immediately may be a relation of INTERSUBJECTIVITY—"an appropriate match between the nature/direction/timing/intensities of two people's activities" (Neisser 1988: 41). If this general approach can be sustained, then the question how we can ascribe mental properties to an objectively characterized other is misleading. From the agential perspective the problem is rather one of acquiring a more objective conception both of one's partner and of oneself. And, as a large body of contemporary work in psychology suggests (Neisser 1993; Cicchetti and Beeghly 1990; Butterworth 1982), this reformulation may prove more tractable than the original problem.

Self-Knowledge

The beginning Socratic injunction "Know thyself" dates to the very beginning of the Western intellectual tradition, and self-knowledge in its many forms has been a central concern ever since. A wide variety of cognitive states fall under its conceptual umbrella. The sort of self-knowledge acquired through cognitive psychotherapy, for example, might include explicit beliefs about the motives of one's behavior couched in the concepts of folk psychological intentional discourse and available for application in the control or modification of future personal action. Alternatively, the Chomskyan self-knowledge that humans are alleged to have of the structure of their language processing systems is largely implicit, subpersonal, innate, and limited in application to the specific process of language-learning.

The types of self-knowledge vary along four main parameters:

- Content
- Manner or mode of representation
- Domain of application
- Means of acquisition

Although the four are importantly interdependent, each presents its own set of issues.

The content of self-knowledge essentially concerns what a cognitive agent knows about its own nature or organization. Though paradigm cases involve knowledge about one's psychological nature, any property or feature of the agent can be its object. One can have self-knowledge of the size, state, and orientation of one's body as well as of one's beliefs and emotions. Despite this breadth, it is the cases of metapsychological cognition that are of greatest interest; for it is they that provide the opportunity for radical increases in mental sophistication. It is virtually impossible to create a system with highly sophisticated mental abilities without building in a significant degree of metapsychological understanding. This point can be overlooked if one focuses exclusively on cases of explicit human self-knowledge of the sort that could be verbally reported. However, if one recognizes the wealth of implicit self-knowledge that must be implicitly embodied in the systems of self-monitoring and self-regulation required by any sophisticated cognitive agent, it becomes readily apparent that self-knowledge of one sort or another will be the pervasive and central feature of all but the most minimally minded systems. Even simple organisms and robots require some measure of self-knowledge to function as cognitive actors. Without knowledge of one's goals and abilities, it would be impossible to carry out multiple stage actions. And no learning would be possible in a system that totally lacked understanding of the function and organization of the processes to be modified. The requisite self-knowledge might all be implicitly embedded in the structure of the learning mechanisms, but that organization in itself counts as a form of self-knowledge insofar as it adaptively reflects the nature of the processes that are changed through learning.

Explicit human self-knowledge nonetheless remains of great interest to philosophers and psychologists. Adult humans have unique abilities to reason about their mental lives and generally reliable insight into their inferential processes, motives, and preferences. This enhances their ability to regulate their mental lives and to interact with others in social contexts. Empirical studies have nonetheless shown glaring gaps in human metacognitive powers; in specific test situations adult subjects show ignorance of the factors governing their choices, their sources of information, and the rules underlying their reasoning.

The degree to which explicit self-knowledge may be present in children or in nonhuman primates is controversial. Children under the age of three fail to distinguish between their own beliefs about a situation and those that an agent with different access would have; they seem unable to conceptualize their own view of reality as such, that is, as one among many possible views. Tests, especially those involving deceptions, on chimpanzees seem to show some grasp of explicit mental concepts, but only of the most limited sort. Other studies, such as those using mirror recognition tasks, give evidence that chimps and orangs have some type of self concept, but again of only a limited sort. Further research is needed to resolve these issues. In a surprising

twist, the psychologist Alan Leslie has proposed that an inability to engage in METACOGNITION is the primary deficit in AUTISM and the source of most of the disabling symptoms associated with it.

Cases of self-knowledge vary not only in their objects but also in how they conceptualize or categorize their objects. Explicit human self-knowledge of the aims of one's behavior is likely to be conceptualized in the folk psychological notions of belief, desire, and intention, but such concepts are not likely to figure in the self-knowledge one's retrieval system has of the structure and organization of one's memory nor in a cat's knowledge of its current needs and goals. Indeed, there may be no public-language words or concepts that adequately capture the content of such implicit knowledge. But insofar as it partitions its pyschological objects in similarity classes and generates aptly matched responses, even such procedural self-knowledge must involve categorization or conceptualization.

Self-knowledge can be explicitly represented and stored as is likely the case with the propositional knowledge that humans have of their intentions and beliefs. The psychologist Philip Johnson-Laird has argued that the planning and control of intentional action requires a self model that explicitly represents one's goals, abilities, options, and current state. But significant self-knowledge can also be implicitly represented in the structure of a network or in the organization of a metacontrol system as is probably true of that embodied in many learning processes. The mechanism by which rats learn to avoid foods that have been followed by bouts of nausea several hours after feeding provides an apt example. One need not suppose that the rat has any explicit awareness of the processes that regulate its feeding behavior or taste sensations, yet its nervous system clearly carries information about those factors as shown by its ability to alter those mechanisms in just the way needed to produce the desired behavioral change.

Procedurally embodied self-knowledge will often be more limited in its scope of application; the metapsychological understanding carried in a learning process may have no impact outside the context of the specific modifications it is designed to produce. The rat can not reflect on the organization of its feeding mechanisms nor make open-ended use of that information, as one might if one had explicit propositional knowledge of them. The difference, however, is one of degree. Procedural self-knowledge can have a relatively broad range of application, and even explicit beliefs about one's mental state are limited in their impact to some degree by the larger context within which they occur.

Self-knowledge can arise in many ways. Traditional Cartesian mentalism treated the mind as fully transparent and open in all its significant properties to a faculty of conscious INTROSPECTION or reflection, which was conceived of by later empiricists as a form of inner perception. Though introspection is now regarded as fallible, incomplete, and theory-laden, it nonetheless remains a major source of self-knowledge. Though internal monitoring, like external monitoring through the senses, is subject to error, it still provides a regular ongoing supply of information about the current state and operation of at least some aspects of one's mind.

The development of self-knowledge depends on both cultural and biological sources. Some theorists argue that the child's mastery of mental concepts involves building a behaviorally based theory of mind; others see it more as a matter of projection from first person-based concepts. In either case, both innate information and culturally based learning will be involved. Children must acquire from their social context many of the concepts needed to categorize their mental states and processes, but folk psychology is likely also to embody an innate scheme of mental categories. Moreover, the neural mechanisms that underlie introspection probably depend on innate implicit self-knowledge in the same way that our perceptual processes depend on such knowledge about the environment.

Though self-knowledge has many obvious benefits, it may not always be adaptive. Ignorance of one's limitations may enhance one's ability to mobilize oneself to action, and a lack of self-knowledge may signal a happy freedom from narcissistic self-absorption. This creates a new puzzle about self-deception. The old puzzle was to explain how deceiving oneself was even possible, given the apparently self-defeating identity of deceiver and deceived. If self-deception is often adaptive, a new more normative problem arises. Must we abandon our intuition that self-deception in itself is a bad thing? Must we qualify the Socratic "Know thyself" with the proviso "but only when it's useful"?

Self-Organizing Systems

Self-organization refers to spontaneous ordering tendencies sometimes observed in certain classes of complex systems, both artificial and natural. Such systems have a large number of components that interact simultaneously in a sufficiently rich number of parallel ways; are at best only partially decomposable; are sensitive to initial conditions when they are in the chaotic regime; are constrained away from their most probable state; and exhibit nondeterministic bifurcations in their dynamic trajectories. Self-organization occurs in these systems when chance fluctuations are spontaneously amplified by nonlinear feedback. This sort of spontaneous ordering has been observed in computational systems that are programmed for nonlinear, parallel interactions under local constraints. Examples in nature range from dust devils and hurricanes to certain sorts of chemical and biological systems, such as Benard cells and chemical oscillators (see below). The topic of self-organization has also been explored under other rubrics, such as "emergent structuring," "self-assembly," "autocatalysis," and "autopoiesis." In each case, the contrast emphasized is between the additive building of structures from elemental building blocks in a decomposable or nearly decomposable system (in the sense defined by Simon l962) by means of measured increments of force and the spontaneous emergence of nonadditive, nonlinear, highly integrated, highly interactive wholes in less decomposable systems.

Ilya Prigogine's model of dissipative structures, which obey the second law precisely by building structures that increase the entropy of their surroundings while decreasing it within their own boundaries, has facilitated both the recognition of self-organizing structures and their explanation (Prigogine l973). The wider significance of Prigogine's work has been made known by Isabelle Stengers, Erik Jantsch, Jeffrey Wicken, and C. Dyke (Prigogine and Stengers l984; Jantsch l980; Wicken l987; Dyke l988). Stuart Kauffman has been prominent among those who have argued that the self-ordering properties of cellular AUTOMATA provide good dynamic models for self-organizing biological systems (Kauffman l993). Cellular automata were originally developed by John VON NEUMANN and Warren MCCULLOCH as tools for analyzing NEURAL NETWORKS.

The line between genuinely self-organizing systems and the self-ordering properties of a wider class of complex systems is difficult to draw. Those who stress the autocatalytic, self-promoting aspect of self-organizing systems, in which a reaction feeds on itself, and the far-from-thermodynamic-equilibrium locus of paradigmatic instances of it, may hesitate to recognize the self-assembly of microtubules, for example, as any more than a case of crystalline self-ordering. Similarly, a distinction might well be drawn between self-organizing systems generally and "autopoietic" systems, in the sense of Maturana and Varela's use of the term (Maturana and Varela l980). The latter term connotes the kind of agency that appears when a complex dissipative system is coupled to its environment through autocatalytic feedback in such a way that it is capable of changing the parameters that govern its interactions with its surroundings. (Maturana and Varela suggest that the ability of some living things to represent their environment, and in some cases even themselves, to themselves is a function of self-organization, which creates a bond between self and environment that is more intimate than our philosophical tradition has hitherto allowed.)

One ought not, however, be too rigid about such definitional matters. Research into these issues is only in an early stage, and usage is in flux. Nonetheless, it is highly significant that the computational revolution has now given science mathematical tools to track and display the dynamics of systems that do not reduce either to ordered simplicity, as in classic mechanics, or to disordered complexity, as in statistical mechanics and thermodynamics. This allows the ordered complexity of phenomena that have hitherto remained beyond the reach of science itself, or that have been subjected to inappropriately reductionist forms of analysis, to be brought within the charmed circle of mathematized knowledge.

The best understood cases of natural self-organization occur in physical and chemical systems that are stabilized far from thermodynamic equilibrium. Benard cells are a classic example of self-organizing physical systems. A honeycomb of hexagonal cells forms at the bottom of the pan when a thin layer of oil is heated from below. This happens because the kinetic energy of the molecules becomes insufficient to dissipate the energy flux when it exceeds a certain threshold value. Macroscopic order then emerges in which billions of molecules move coherently in a convection stream, thereby more efficiently dissipating the energy gradient and increasing the entropy of the surroundings of the system. Increasing the gradient further can lead to a development of still more complex convection cells. Ultimately, however, excessive gradient will result in turbulence.

The Belouzov-Zhabotinskii, or BZ, reaction is a well-known example of self-organization in a chemical system. In a BZ reaction, citric acid, sulfuric acid, potassium bromate, and an iron salt, when combined in certain proportions, produce sudden and repeated alternations between blue and red states in stirred solutions. In thin layers, circular or spiral chemical waves of color can result. As in the case of Benard cells, increasing the gradient produces nondeterministic bifurcations and more complex patterns. But when the energy gradient (which in this case inheres in the chemical bonds between constituents) grows too steep, chaotic behavior results.

Chemical oscillators, such as the BZ reaction, may have implications for self-organization in biological systems, particularly in development. Alan TURING's paper on limit cycle solutions to reaction-diffusion equations has long been thought by some to model certain aspects of embryogenesis (Turing l952). The life cycle of slime molds, a sort of colonial amoeba, also appears to embody a self-organizing pattern. It alternates between mere aggregation when food is plentiful and differentiation into a cellulose base and a fruiting body when it is scarce. The fruiting body eventually bursts, scattering spores that begin the cycle over again (Garfinkel l987).

As these examples show, self-organization is potentially relevant to fundamental questions about EVOLUTION. One

issue is whether life itself came into existence through a self-organizing process. Those who have used computers to explore the mathematically self-ordering properties of complex adaptive systems have studied this subject under the rubric of ARTIFICIAL LIFE. Those whose definition of life is less formal have looked for chemical conditions in the early history of the planet in which some form of prebiotic selection might have amplified the autocatalytic properties of self-organizing protocells into functional, adapted traits. Such studies begin with the plausible insight that life probably did not originate solely in the accidental assembly of nucleic acids, but in the coevolution of proteins and nucleic acids, with protein evolution perhaps playing the leading role. Sidney Fox's pioneering work on proteinoid microspheres reveals them to be spontaneously self-organized systems that might have provided the hydrophobic boundaries within which the subsequent coevolution of protein and nucleic acids can take place (Fox 1984). Harold Morowitz's and David Deamer's notion of abiotically forming vesicular amphiphile bilayers provides another possible such "cradle" for the emergence of life (Morowitz, Heinz, and Deamer 1988). Manfred Eigen's notion of hypercycles provides a model of how this interaction might have occurred. One can think of a hypercycle as a system of linked autocatalytic cycles, in which each member is catalyzed by at least one other member (Eigen and Schuster 1979.)

A second issue is the relationship between natural selection and self-organization once life is up and running. On the face of it, self-organization rivals natural selection as the basis of both individual development and of the larger contours of phylogenetic order. For the acquisition of functional traits by self-amplifying feedback is not the same thing as selection-by-consequences by means of a forcelike "selection pressure" that operates against an inertial, and indeed inert, dynamic background, which is how natural selection is usually conceived. The notion that self-organization and natural selection are rivals has been defended by several authors (Goodwin 1994; Oyama 1985; Salthe 1993). A more integrative, mutually reinforcing approach is, however, possible. Recognizing that when any system analogous to Boolean networks is set into motion it can be expected spontaneously to explore its space of future states and if mild "fitness" conditions are imposed it can be expected to reach peaks on "adaptive landscapes." Kauffman, Holland, and others who have studied genetic algorithms and EVOLUTIONARY COMPUTATION have suggested that "spontaneous order is available to natural selection for the further selective crafting of well-wrought designs" (Kauffman 1993: 1; Holland 1995). One might readily imagine, in accord with this suggestion, that natural selection has stabilized the self-organized life cycle of slime molds, and in the process has conferred an explicitly biological function on a spontaneously generated pattern. Kauffman himself argues that the regulatory systems of genetic networks, among whose many nodes much connectivity and parallel processing are at play, are self-organizing, functionally decomposable (see FUNCTIONAL DECOMPOSITION) systems that have been stabilized by natural selection in this way. Weber and Depew have argued that, considered as a natural phenomenon in its own right, natural selection emerges only in autocatalytic chemi-

cal systems that have managed to internalize information in macromolecules, the error rate of which provides the fuel of natural selection (Weber and Depew 1996). In this account, genes have the function of enhancing and stabilizing the coupling between organism and environment that self-organization first generates.

The human brain has about 10^{10} neurons, any of which can have up to 10^4 connections with other such neurons, stimulated and regulated by a large number of chemical neurotransmitters. This fact alone brings the study of cognitive and other psychological phenomena within hailing distance of the study of self-organizing complex systems. This distance has been reduced by those advocating DYNAMIC APPROACHES TO COGNITION, who recognize that learning is a process that occurs only in systems that are "environmentally embedded, corporeally embodied, and neurally entrained" by feedback (see Port and Van Gelder 1995; Smith and Thelen 1993; Kelso 1995; Cook and Murray 1995). If digital computationalism gives way to more dynamical studies of connectivity in neural networks, self-organization can be expected to play a more prominent role in both the ontogeny and phylogeny of mental functions. The purely adaptationist stories people like to tell about the Pleistocene origins of localized mental functions (Barkow, Cosmides, and Tooby 1992), as well as the inclination to model neurological development closely on Darwinian mechanisms (Edelman 1987), might then give way to a more nuanced view, in which neural organization is taken to be governed in part by self-organization working through intense feedback between organism and environment.

Semantic Memory

See EPISODIC VS. SEMANTIC MEMORY

Semantic Networks

See FRAME-BASED SYSTEMS; SCHEMATA

Semantics

Semantics is the study of MEANING. It is not surprising that "semantics" can "mean" different things to different researchers within cognitive science. Notions relating to meaning have had long (and often contentious) histories within the disciplines that contribute to cognitive science, and there have been very diverse views concerning what questions are important, and for what purposes, and how they should be approached. And there are some deep foundational and methodological differences within and across disciplines that affect approaches to semantics. These have partly impeded but also stimulated cooperative discussion and fruitful cross-fertilization of ideas, and there has been great substantive progress in semantics, in the sister field of PRAGMATICS and at the SYNTAX-SEMANTICS INTERFACE in recent decades.

The logico-philosophical tradition divides semiotics (the study of signs, applicable to both natural and constructed languages) into syntax, semantics, and pragmatics (Morris 1938). On this view, SYNTAX concerns properties of expressions, such as well-formedness; semantics concerns relations between expressions and what they are "about" (typically "the world" or some model), such as reference; and pragmatics concerns relations between expressions and their uses in context, such as IMPLICATURE. Some approaches reject the characterization of semantics as dealing with relations between language and something external to language, especially between language and "the world" (see (1) and (2) below). And many approaches have challenged, in different ways, the autonomy of semantics from pragmatics implied by the traditional trichotomy. We return to some of these foundational issues below.

One of the basic issues that any theory of semantics must deal with is how we can understand the meanings of novel sentences. Syntax describes the recursive part-whole structure of sentences; semantics must account for how the meanings of smaller parts are combined to form the meanings of larger wholes (see COMPOSITIONALITY and LOGICAL FORM). There are many controversial issues surrounding the principle of compositionality, which contains several crucially theory-dependent terms: *The meaning of an expression is a function of the meanings of its parts and of how they are syntactically combined*. But most explicit semantic theories, especially formal semantics, accept it as a basic working principle. The extension of compositional semantics beyond the level of the sentence, to the interpretation of DISCOURSE, has been of increasing importance.

Another basic issue for semantic theory is the nature of the meanings of the smallest meaningful units of language,

words or morphemes (or even smaller units if some mor-
phemes are viewed as decomposable into submorphemic
"features"). Lexical semantics has an even longer history
than compositional semantics and is connected with the
most fundamental problems in the philosophy of language
and the psychology of CONCEPTS (see REFERENCE, THEO-
RIES OF and LEXICON).

Crucial *interfaces* include the syntax-semantics inter-
face and the interfaces of semantics with pragmatics, with
encyclopedic and common-sense knowledge, and perhaps
directly with PHONOLOGY (e.g., with respect to the
semantic/pragmatic interpretation of PROSODY AND INTO-
NATION). Other important areas of research concern
acquisition, human semantic processing, and computa-
tional semantics.

Among the most important semantic properties of lin-
guistic expressions that need to be accounted for, most
semanticists would include the following:

Ambiguity: Having more than one meaning. Strongly com-
positional theories require all semantic ambiguity to reflect
either *lexical* or *structural* (syntactic) AMBIGUITY.

Vagueness: A challenge for some theories of the nature of
word meanings as well as to classical theories of concepts.
Drawing the distinction between ambiguity and VAGUENESS
is a classic problem (Quine 1960; Zwicky and Sadock
1975).

Anomaly: Some expressions, like the famous *Colorless
green ideas sleep furiously* (Chomsky 1957), are judged to
be *semantically anomalous* although syntactically well-
formed. The lines between semantic and other sorts of
anomaly are crucially theory-dependent and often debated.

Entailment: Sentence A *entails* sentence B if sentence B is
true in every possible state of affairs in which sentence A is
true. Entailment has always been a central semantic concern
in LOGIC and the philosophy of language, and remains so in
POSSIBLE WORLDS SEMANTICS. Cognitive semanticists
replace concern with logical entailment by concern with
human inference; formal semanticists see the relation of
entailment to actual human inference as indirect. But most
semanticists are concerned with some notion of entailment
or inference, and many agree about the importance of revis-
ing (incrementally or radically) the formal logics invented
by logicians to model the "natural logic(s)" implicit in the
semantics of natural languages.

Presupposition: A precondition for the felicity or truth-
valuedness of an expression in a context. PRESUPPOSITION
research has been important in theorizing about the relation
between (or possible integration of) semantics and pragmat-
ics.

Context: Expressions are interpreted in the (linguistic) con-
text of other expressions, and in the (nonlinguistic) context
of an utterance situation in which the participants have vari-
ous beliefs and intentions. Any approach to semantics has to
take a stand on the relation of "semantics proper" to various
aspects of context, including the treatment of INDEXICALS
AND DEMONSTRATIVES (Kaplan 1977). One important trend
in formal semantics has been the shift from "meanings as

truth conditions" to "meanings as functions from contexts to
contexts" (with truth conditions as a corollary; Heim 1982);
see CONTEXT AND POINT OF VIEW, SITUATEDNESS/EMBED-
DEDNESS, DYNAMIC SEMANTICS.

Referential opacity: The construction exemplified in "Jones
is seeking—" is *referentially opaque*, because the substitu-
tion of one coreferential expression for another in that con-
text does not always preserve the truth-value of the whole. It
may be true that Jones is seeking the president and false that
Jones is seeking Mary's father even though the president is
Mary's father. Frege's distinction between SENSE AND REF-
ERENCE, Carnap's distinction between intension and exten-
sion, and Montague's intensional logic all treat the
phenomenon of referential opacity, pervasive in PROPOSI-
TIONAL ATTITUDE constructions.

Other issues important to semantics include ANAPHORA,
negation and QUANTIFIERS, TENSE AND ASPECT, and modal-
ity; other issues important for semantics and pragmatics
together include topic-FOCUS structure and the interpreta-
tion of questions, imperatives, and other speech acts.

Many foundational issues of semantics are relevant to
cognitive science; some are particularly linguistic, others
overlap heavily with issues in the philosophy of language
and philosophy of mind. We mention a few central issues
that divide different approaches to semantics.

1. The nonpsychologistic tradition of "objective"
(though abstract) meanings (Frege 1892; Carnap 1956;
Montague 1973) versus the psychologistic view of mean-
ings "in the head" (Fodor 1975; Lakoff 1987; Jackendoff
1983; and all psychologists). Do expressions refer to
objects or to concepts? Is semantics a branch of mathemat-
ics, or is it (as on the Chomskyan view of all of linguistics)
a branch of psychology? Classical formal semanticists,
who take the first disjunct in these choices, distinguish
semantics from knowledge of semantics (Lewis 1975),
making semantic competence interestingly different from
syntactic competence. Jackendoff (1996), following
Chomsky (1986) on "I-language" and "E-language," dis-
tinguishes "I-semantics" (internalized semantics, semantic
competence) from "E-semantics" (an abstract relation
external to language users), and characterizes his own Con-
ceptual Semantics as well as COGNITIVE LINGUISTICS
(Lakoff 1987) as studying the former whereas formal
semantics studies the latter. Many today seek an integration
of these two perspectives by studying mind-internal intui-
tions of mind-external relations such as reference and
truth-conditions. See Putnam 1975 for an influential philo-
sophical perspective.

2. Model-theoretic versus representational approaches.
Many linguists think of semantics in terms of a "level of
representation" of expressions analogous to a syntactic or
phonological level. Psychologists generally think of
semantics as relating expressions to concepts, regarding
concepts as something like elements of a LANGUAGE OF
THOUGHT. In AI, semantic interpretation is sometimes
expressed in a language of KNOWLEDGE REPRESENTATION.
A representational view of semantics is quite congenial to
the popular COMPUTATIONAL THEORY OF MIND (Jackendoff
1983). The contrasting model-theoretic view sees semantic

interpretation relating expressions to elements of models (possibly MENTAL MODELS) defined in terms of constituents such as possible situations, entities, properties, truth-values, and so on. Intensional objects may be modeled, for instance, as functions from possible worlds or situations to extensions (see POSSIBLE WORLDS SEMANTICS). The question of the mental representation of such model-theoretic constructs is open (see Johnson-Laird 1983); the inclusion of Marrian "2½-D sketches" in Conceptual Structure in Jackendoff 1995 suggests the possibility of mixed approaches.

3. The issue of Natural Language Metaphysics (Bach 1986) or the "naive picture of the world" (Apresjan 1974) and its role in semantics. What presuppositions concerning the constitution and structure of the world as humans conceive it are built into human languages, and how, and which are universal? (See LINGUISTIC RELATIVITY HYPOTHESIS, NAIVE PHYSICS, FOLK BIOLOGY.) These questions may concern both semantic structure and semantic content, from the semantic difference between nouns and verbs to the content of color terms. Their investigation may challenge the lines between semantic knowledge and commonsense, encyclopedic, or other kinds of knowledge. Formal semantics, following the logical tradition, has employed relatively "austere" model structures; recent investigations, particularly into lexical semantics, tend to invite richer models.

4. The semantic atomism question: Are all meanings decomposable into combinations of "semantic atoms," "semantic primitives," or "atomic concepts" drawn from some fixed, universal, and presumably innate set? The affirmative view goes back at least to Leibniz (Kretzmann 1967), and is popular in cognitive science in spite of little progress on identification of a suitable set of primitives (see Wierzbicka's work, e.g., Wierzbicka 1985, for the most sustained attempt). A "yes" answer implies that lexical semantics will take the form of semantic decomposition; a "no" answer is compatible with various approaches to word meaning including the use of meaning postulates or a FUNCTIONAL ROLE SEMANTICS approach to word meaning.

5. The relation between meaning and use. The distinction between "sentence meaning," the literal meaning of a sentence abstracted away from any particular context, and "speaker's meaning," the intended interpretation of a particular utterance of a given sentence, presupposes a boundary between semantics and pragmatics, sometimes disputed. One traditionally influential approach (Austin 1962) is based on the identification of meaning and use.

Semantics, Acquisition of

One area of research in the acquisition of semantics investigates children's use of logical connectives such as *and* and *or*, and QUANTIFIERS such as *every* and *some*. The main goal of this research is to determine the extent to which children assign a semantics to logical words that conforms to classical LOGIC. We will return to this topic. Another area of research investigates children's knowledge of semantic universals (see LINGUISTIC UNIVERSALS AND UNIVERSAL GRAMMAR). Semantic universals are often cast as constraints against certain linguistic forms or meanings. For example, a constraint on form prevents negative polarity items such as *any* from appearing in certain linguistic environments (the asterisk indicates deviance):

(1) * Every linguist fed any squirrel. Cf. No linguist fed any squirrel.

A second example is a constraint on meaning, called *closure.* Closure prevents pronouns from referring back to particular kinds of quantificational NPs that have appeared earlier in a discourse (e.g., Chierchia 1995). Thus, the pronoun *he* in (2) cannot be linked to the quantificational NP *every linguist*—the pronoun can refer to *Chomsky,* or it can refer to someone who is not mentioned in the DISCOURSE.

(2) Every linguist went to Chomsky's party. He was happy.

Suppose that children's grammars lack these constraints at some stage of development. If so, the language generated by their grammars would produce sentence forms that are illicit for adults, such as (1), and their grammars would permit illicit links between pronouns and quantificational NPs, as in (2). In the absence of systematically available negative semantic evidence (e.g., parental correction), it is difficult therefore to see how children could *learn* constraints. Embracing the conclusion of the argument from the-poverty-of-the-stimulus, we are led to consider an alternative source: innate specification (see POVERTY OF THE STIMULUS ARGUMENTS).

Among the hallmarks of innate specification are universality and the early emergence of a linguistic principle despite the absence of decisive evidence from experience (see INNATENESS OF LANGUAGE and NATIVISM). Research in the acquisition of semantics is directed at the early emergence hallmark of innateness. For example, 4- to 5-year-old children's understanding of negative polarity items was examined using an elicited production task (O'Leary and Crain 1994). One experimenter acted out stories with toys and props; a second experimenter manipulated a puppet, Kermit the Frog. Following each story, Kermit told the child what he thought happened in the story. The child's task was to decide whether or not Kermit "said the right thing" and, if not, to explain "what really happened." One of Kermit's (false) statements was (3).

(3) Only two squirrels got any food.

In light of what actually happened in the story, children consistently corrected Kermit's statement, producing sentences like "No, every squirrel got some food." Despite Kermit's

own use of *any* in examples like this, children never (re)produced a negative polarity item. This is evidence of children's early mastery of the semantic constraint that regulates the appearance of these items.

Children's adherence to the closure constraint was examined by comparing their responses to discourse sequences like (2) and ones like (4) (Conway and Crain 1995; Conway 1997).

(4) A linguist wandered into Chomsky's kitchen. He
       cooked some pasta.

Example (4) shows that a pronoun can refer back to the indefinite NP *a linguist,* which appears earlier in the discourse. Using a comprehension task, it was found that 3- to 5-year-old children adhere to the closure constraint. They accepted coreference between pronouns and indefinite NPs in discourses like (4) but not between pronouns and other quantificational NPs (e.g., *every linguist*) in discourses like (2).

This brings us to the acquisition of logical reasoning. An extensive literature on this topic has led to the view that children's reasoning is not the same as that of adults. For example, studies of children's understanding of the universal quantifier, *every,* has resulted in the widespread belief that children younger than 7 lack adult-like competence. This belief is based in part on the finding that younger children reject sentences like (5) in circumstances with "extra squirrels", that is, ones that were not fed by a linguist (e.g., Bucci 1978; Inhelder and Piaget 1964).

(5) Every linguist fed a squirrel.

Children's nonadult responses have been interpreted as evidence that their grammars authorize nonadult domain restrictions for the universal quantifier, extending the domain of quantification beyond the boundary conditions established in the adult grammar (e.g., Barwise and Cooper 1981). By contrast, other research presented sentences like (5) in contexts that are arguably more felicitous, yielding consistent adult-like responses from children as young as 4 (Crain et al. 1996; Brooks and Braine 1996).

Studies of other logical words have led some researchers to conclude that children's logical reasoning does not conform to that of classical logic. A study by Neimark and Chapman (1975) found that children as old as 10 do not tolerate "*Some A are B*" as a description of a situation in which A and B are equivalent sets. Research findings have also led to the view that children lack the inclusive sense of *or* (see Braine and Rumain 1983). In making judgments about sentences with logical words, however, people are not only influenced by their semantic knowledge (the literal meanings of words) but also by the pragmatic norms they follow (how words are used in conversational contexts; see PRAGMATICS). For example, the statement "*Some boy is swimming*" is true in situations where every boy is swimming, but this fact is often difficult even for adults to see, because speakers tend to avoid using *some N* when the use of *every N* provides a more accurate description of the situation. Similarly, statements of the form *A or B* do not logically entail exclusivity, but this reading is often inferred (e.g., Chierchia and McConnell-Ginet 1990).

The presence of pragmatic implicatures masks the semantic contribution of logical words in ordinary circumstances, but these implicatures are canceled in certain contexts, such as when a speaker is making a bet or a prediction and, hence, does not know what the actual outcome will be. The conclusion that children's logical reasoning is not consistent with classical logic is based on research that has not systematically investigated children's use of logical expressions by manipulating the pragmatic context, so as to cancel the relevant implicatures (see IMPLICATURE). Therefore, it is premature to infer that children lack proper understanding of the truth conditions associated with logical words in standard logic. The critical investigations of children's logical reasoning are now underway (e.g., Chierchia et al. 1997). When the findings are in we will be in a better position to say how well the acquisition of semantics comports with conclusions based on linguistic research.

Semantics-Syntax Interface

See SYNTAX-SEMANTICS INTERFACE

Semiotics and Cognition

Although the term "semiotics" has come into common usage only in this present century, the discipline of semiotics itself is much older and may be traced back to Greek philosophy. The first formulations of the notion of the so-called semiotic triangle may be found already in Aristotle, where three elements are seen as constitutive of signs: pragmata ("the things to which the sign refers"), the expressive element ("that which is in the voice"), and thoughts ("that which is in the mind"). This third element alludes to a level that we today would call the level of mental representations and, as such, is that aspect of the sign that is directly concerned with cognition. We could therefore say that semiotics is constitutively connected with cognition right from its historical roots.

In modern times, there seem to be two main directions in semiotic research projects: interpretative semiotics inspired by the work of Charles Sanders Peirce (1931–58), and structural semiotics, sometimes referred to as "semiology" following the terminology introduced by the Swiss linguist Ferdinand de SAUSSURE (1906–11). Their concerns with the issue of cognition and their possible connections with related works on contemporary cognitive science map onto different areas of interest, and I will discuss them separately.

It is certainly within Peircean semiotics that the most straightforward link between semiotic processes and processes of cognition can be found, so much so that this direction in semiotics is often referred to as cognitive semiotics. According to Peirce, KNOWLEDGE ACQUISITION and thought are never immediate, direct processes but are always mediated through signs, or interpretants, which are more developed signs and which thus allow the subject to know more than she knew before, in an endless process of interpretation known as unlimited semiosis. Interpretants, which are the central element in the sign process, are first of all mind-internal signs, that is to say mental representations. In this way, thought, signs, and cognition become one and the same thing. "All thought is in signs" (*Collected Papers* 5: 252), but because each interpretant sign adds something new to the process of thinking and knowing, cognition is strongly characterized as an inferential process.

Peirce's philosophy has strongly influenced Umberto Eco's semiotic theory of signs and interpretational processes (Eco 1976, 1984). Eco stresses in his theories the Peircean notion of semiosis as an inherently inferential process. Signs are not regulated by some kind of equivalence rule between expression and content but are always considered as inferential devices, even in cases where the inferential relation between the two has became so stabilized as to appear to be a purely automatized correlation. In this way, Eco, not unlike Peirce, considers that sign processes will always, and necessarily, imply the factual occurrence of some form of internal reasoning and inferencing process, so making the sign process that is the object of study of his semiotics functionally indistinguishable from cognition.

The particular type of thought process involving inferences based on the interpretation of signs is referred to by Peirce as "abduction," which he distinguishes from INDUCTION and deduction on the basis of their fundamental logical forms. Abductive inference is considered as constituting the core of cognition itself, because it is the only type of inferential process that actually contributes to an increase in our knowledge of the object and, without deriving logical truths, only possible ones.

Abductive reasoning has recently received growing attention in cognitive circles, especially in relation to modeling in Artificial Intelligence (AI), where abduction is seen as a theory-forming or interpretative inference. In their textbook on AI, Charniak and McDermott (1985) claim that everyday reasoning as well as medical diagnosis, story understanding, and vision are all abductive processes. Many AI systems are presently being developed around various forms of abductive inference in order to model different areas of cognition (see Josephson and Josephson 1994), from perception to natural language understanding and even METAPHOR (Hobbs 1992) and translation (Hobbs and Kameyama 1990). In particular, abduction has been considered in relation to interpretation by both AI researchers (e.g., Hobbs et al. 1993) and by semioticians (Eco 1979, 1990). According to Eco (1979), no text can make all its premises explicit; in this sense, a text can be seen as a lazy machine asking the reader to fill in a whole series of gaps. In order to fully understand a text, the reader has to make a series of abductions (known as "inferential walks") on the basis of both her general knowledge of the world and specific textual scripts. Such an approach appears highly consistent with most of the cognitive work done in the field of READING comprehension of text (see among others Schank 1982; van Dijk and Kintsch 1983).

Turning now to the structuralist semiotic perspective developed along the lines of Saussure and Hjelmslev, one could say that this latter approach is far less interested in issues related to cognition. However, there is at least one area that brings to light some interesting similarities with work in cognitive science, and this is the study of narrative structure. Since the seminal work of Vladimir Propp (1928), structural semiotics has focused on the analysis of the structural properties of any kind of narrative text, developing a highly complex and articulated model to account for the different levels of structural organization (see Greimas 1970, 1983). This line of research could be compared to work done in the cognitive area on story grammar (Rumelhart 1975, 1980; Thorndyke 1977), which also aims to individuate an underlying structure in stories and to define the nature of concepts such as *state* and *event*, despite the fact that these two traditions seem, unfortunately, to ignore each other.

Finally, another line of research that also should be mentioned here in respect to the relationship between semiotics and cognition is that represented by some recent developments in what is usually referred to as dynamic semiotics or semio-cognitive morphodynamics (Petitot 1985, 1992; Brandt 1994, 1995). The basic hypothesis of these works is that there exist syntactico-semantic infrastructures of topo-

logical and dynamic nature that constitute universals underlying language, perception, and action. Such a line of thought is consistent with the basic tenets of much work being done in COGNITIVE LINGUISTICS today (see, for instance, Langacker 1987). Dynamic semiotics aims, however, not only to individuate the schematic structures that underlie meaning in different types of systems but also to model them through a qualitative mathematics based on the catastrophe theory developed by the French mathematician René Thom (1975), where states, events, acts, and processes are understood formally in terms of force topologies and where form is dynamically represented as based on opposing forces. Dynamic models can therefore be of help in reformulating the findings of structural semantics in dynamic terms, in a way that is very close to approaches used in more recent work in cognitive semantics, where the role and function of image schema and force-dynamic schema have been investigated (see Talmy 1988; Lakoff and Johnson 1980).

Sensations

Sensations are mental states normally caused by the stimulation of sense organs. They are a varied lot. Even though philosophers have traditionally tended to give sensations a unified theoretical treatment, it is not obvious that this is either possible or desirable. Sensations are usually taken to be the paradigmatic bearers of qualitative appearance, but proprioceptive sensations do not seem to have a qualitative character at all. Furthermore, sensations' own nature as mental states is not readily apparent: sensations of hunger or pain appear to us as states of our bodies, and colors and visually presented shapes appear to us to be features of objects before the eyes. The differences among "bodily" and "distance" sensations are marked by common speech, which countenances, for example, "burning sensation," but rarely "visual sensation." The latter must rather be understood as a term of art used principally by philosophers and psychologists, to be justified by its theoretical utility.

Although it is plausible to say of sensations in this extended sense of the term that they are the sources, as well as the ultimate arbiters, of all claims about matters of fact (one form of a doctrine known as *empiricism*), they, unlike the items of the material world as scientifically understood, are qualitative in character and directly accessible only to the person who has them. This creates two closely related problems that have vexed philosophers from the seventeenth century until the present day. The first problem concerns how each of us may, beginning with our own sensations, obtain knowledge of the material world. The second problem is whether we can reconcile the private and qualitative nature of our sensations with our nature as material beings.

The first problem was widely discussed in the nineteenth and the first part of the twentieth century by philosophers as well as psychologists (Boring 1942), although it has more recently fallen into the background. Here is how it goes. Physics tells us that the world consists of elementary particles and fields. Our sensations inform us that the world contains not only strawberries, but also the colors, tastes, and smells of strawberries. Yet although the strawberry can be

understood to be an assemblage of elementary particles, its red color, just like its characteristic smell and taste, is not reducible to physical properties (Hardin 1993). If colors and tastes have no place in the physical world, they must be sensations in our minds, perhaps generated by our brains, though not states of our brains, because our brains are themselves physical objects. But if the strawberry's color is a mental property, must not the shape that it delineates be likewise a mental property? Following this line of thought to its conclusion, Ernst Mach (1897) and some of the earlier positivists held that we are directly aware only of our sensations and can never be entitled to infer the existence of a world of matter that is distinct from those sensations. The world of perceivable physical objects, including our brains, must be understood to be a construction from actual and possible sensations. The unobservable entities of physics are to be regarded as convenient theoretical fictions that enable us economically to represent and predict our sensations.

One alternative to such a radical conclusion is to maintain that we can infer the existence and nature of a material world distinct from our sensations as the best explanation of their characteristics; some of our sensations, such as those of shape, resemble the properties of the objects that cause them, whereas others, such as smell or color, have causes but no counterparts in the external world (Russell 1914). However, it is not clear that an empiricism that uses sensations and the relationships among them as its basis can allow the required conceptions of cause, explanation, or resemblance, all of which require transcending that basis.

Another way to penetrate the epistemic wall of sensations is to deny that they are the direct objects of awareness, and thus the inescapable foundation of our knowledge of matters of fact. James J. GIBSON (1966), for example, effectively argues that our sensory awareness is in many cases best described as picking up unmediated information about the environment (see AFFORDANCES). Although Gibson does suggest how we might have direct access to some features of the physical world, he does not show how experiences that do have a qualitative character could arise simply by having perceptual systems extract information from the environment. Many instances of sensory apprehension seem to involve the awareness of something that cannot be identified with any item in the external world that acts upon the senses (Perkins 1983). How, for example, can a "direct contact" theory account for feeling a PHANTOM LIMB, or seeing a colored afterimage? It seems implausible to assert that in such cases one is either experiencing nothing at all, or else simply misperceiving some item that is outside of one's nervous system.

Our second principal problem is whether sensations can be identical to brain states (see PHYSICALISM), or functions of brain states (see FUNCTIONALISM), and thus find a place in the physical world after all, or whether a scientific psychology could make do without positing sensations (see ELIMINATIVE MATERIALISM). Either of these alternatives is consistent with a materialist view of the world. By contrast, mind-body dualists (see MIND-BODY PROBLEM) suppose that although sensations are caused by brain states, they are in no way reducible to them. This set of issues, nowadays known as the problem of QUALIA, has been of great interest to philosophers and to many psychologists during the second half of the twentieth century. A related question is whether any materialist solution to the problem of qualia must be confronted with an EXPLANATORY GAP. For even if it is in fact true that sensations are identical to brain states or functions, will it ever be possible for us to understand why this must be so? Perhaps our understanding can do no better than record de facto correlations between sensations and brain states. On the other hand, it has been argued that close attention to the character of explanations currently offered by PSYCHOPHYSICS will show that the gulf between sensory qualities and the functional organization of sensory systems is not as wide as has often been thought (Clark 1993). Finally, under what conditions would it make sense to ascribe sensations to machines, or extraterrestrial aliens (Lewis 1980), or closer to home, and perhaps more fruitfully, to other animals (Thompson 1995)?

Sense and Reference

The terms *sense* and *reference* in their technical meanings originate in the work of Gottlob FREGE, translating his "Sinn" and "Bedeutung" respectively (Frege 1967). According to Frege, every significant linguistic expression has both sense and reference, these being different kinds of semantic properties.

The reference of an expression is what it contributes to the truth or falsity of sentences in which it appears. Frege construed reference as a relation between the expression and some real object, the expression's *referent.* The referent of a singular term is what one would intuitively think the term stands for. The referent of both "Bill Clinton" and "The President of the United States in 1997" is the man, Bill Clinton. The referent of a sentence is its *truth value,* the True or the False, these being existent abstract objects. Predicative expressions refer to functions from objects to truth values. For example, the one-place predicate "runs" refers to a function that, given any object, x, as an argument, yields the value True if x runs and False if x does not run. In general, an n-place predicate refers to a function from ordered n-tuples to truth values. For example, the two-place predicate "likes" refers to a function from ordered pairs of objects, $<x, y>$ to truth values; True if x likes y, False if x does not like y.

Reference is *compositional* in that the reference of a complex expression is determined by the reference of its parts and their syntactic mode of combination. Consider, for example, "Bill Clinton likes Al Gore." The two names provide the pair <Clinton, Gore>, and this pair is the argument to the function referred to by "likes." The referent of the sentence is then the value of that function, given <Clinton, Gore> as argument: True if Clinton likes Gore, False otherwise.

Frege applied a similar analysis to complex sentences built up from simpler ones. For example, a conjunction of the form "S1 and S2" has the value True, if S1 and S2 both have the value True, and False otherwise. So "and" refers to a function from pairs of truth values to truth values: it yields True given the pair <True, True> and False given any other pair.

Because an expression's referent is what it contributes to determining the truth values of sentences, reference is governed by principle (P):

(P) Co-referring expressions may be inter-substituted in any sentence without altering the truth value of that sentence.

For example, given that "Hesperus" and "Phosphorus" refer to the same thing (Venus), these terms ought to be intersubstitutable in any sentence without altering its truth value. (P) appears to be correct for many cases. However, as will be seen in a moment, there are also apparent counterexamples, and it is partly to deal with these that Frege introduced the notion of sense.

An expression's sense is an aspect of its SEMANTICS that is not accounted for in terms of reference. The referential properties of "Hesperus is Hesperus" and "Hesperus is Phosphorus" are identical. But whereas the former is a tautology, the latter carries empirical information and so has different cognitive value. Frege invoked sense to account for this cognitive value.

The sense of an expression is a "mode of presentation" of its referent, a way in which the referent is presented to the mind. The senses of the significant expressions in a sentence compose to form the sense of the sentence, which Frege called a "thought" ("Gedanke"). Thoughts are the contents of PROPOSITIONAL ATTITUDES. If, for example, someone believes that every even number is the sum of two primes, then they stand in a believing relation to the thought that every even number is the sum of two primes. If someone hopes that every even number is the sum of two primes, they stand in a hoping relation to the same thought.

In spite of their cognitive role, senses and thoughts are objective and mind-independent, in Frege's view: "When one apprehends . . . a thought one does not create it but only comes to stand in a certain relation . . . to what already existed beforehand" (1967: 30).

Because propositional attitudes are relations to thoughts, sentences ascribing propositional attitudes involve reference to thoughts. Notice that (P), above, appears to fail for (1) and (2), because one might be false while the other is true.

(1) Galileo believed that Hesperus is a planet.

(2) Galileo believed that Phosphorus is a planet.

Frege addressed this problem by proposing that in certain contexts (often called "referentially opaque contexts," after Whitehead and Russell 1925) words do not refer to their normal referents. Rather they refer to their normal senses. Thus (P) is preserved, because "Hesperus" and "Phosphorus" do not refer to the same thing in (1) and (2).

Sense also has a role in explaining reference. It is because an expression has its sense that it has its reference. Equally, a speaker's capacity to refer to or think about something is explained in terms of sense: a thinker thinks about a particular object by grasping a sense that presents that object (Evans 1982; Burge 1977; Dummett 1973).

It is sometimes thought that a further reason why Frege invoked senses was to account for the meaningfulness of expressions that lack a referent, such as "Vulcan" or "The largest prime." There is probably some truth in this, as Frege did allow that nonreferring expressions could have a sense. However, it is not clear that Frege should have allowed this, given the fundamental role of reference in his philosophy of language. (See Dummett 1973: 185; Evans 1982: chap. 1 for discussion.)

Frege's theories of sense and reference have been criticized in many ways. Most commentators have tended to propose modifications to the overall picture, rather than reject it outright. For example, it is a popular move to keep much of the account of reference in place, without insisting that truth values are objects or that predicates refer to functions. One replaces "refers to the True" by "is true," and replaces talk of predicates referring to functions by talk of predicates applying to objects under specified conditions, as in, for instance, "red" applies to any object x if and only if x is red (Davidson 1967; Evans 1982; McDowell 1977).

The account of sense is often criticized on the grounds that no one kind of thing can play all the roles that Frege assigned to sense. For example, it is often held that cognitive value does not determine reference, because two expressions might refer to different things, yet share the same cognitive value. For example "That man" might be used once to refer to Castor and then, on a separate occasion, to refer to Castor's identical twin, Pollux. The way in which the speaker thinks of Castor might be just the same as

the way he thinks of Pollux, so the cognitive values of the expressions might be the same, although their referents differ (Burge 1977; Kaplan 1990; Perry 1990; for a defense of Frege, see Evans 1990).

Frege himself was primarily concerned with the development of symbolic LOGIC and semantics for formal languages of mathematics and science, rather than with a theory of natural language. Nevertheless, he provides a theory of content that can be applied to propositional attitudes and the other psychological states that are the subject matter of the cognitive sciences. Frege's work raises fundamental questions that lie at the heart of cognitive science and the philosophy thereof. Perhaps the most basic is whether the notion of content in cognitive science can be assimilated with either sense or reference or both (cf. PRAGMATICS; Segal 1995; Fodor 1994; Millikan 1997; Chomsky 1995).

Sentence Processing

One of the reasons that reading a good novel or listening to an interesting lecture can be a pleasurable experience is because we are (blissfully) unaware of the cognitive work we do in understanding individual sentences and relating them to the discourse context. Research in sentence processing investigates the cognitive mechanism (or mechanisms) responsible for the real-time computation of the structural representation that underlies comprehension of visual or auditory language input. Sentence processing involves the rapid integration of various types of information (lexical, structural, discourse, etc.) and research in this area is necessarily interdisciplinary, drawing on work in theoretical linguistics, computer science, and experimental psychology (for reviews, see Mitchell 1994 and Fodor 1995)

A basic finding (that accords with our intuition) is that computation is "incremental." That is, we structure the words as they are perceived rather than store them as a list that is later combined when there is a pause in the input. Incremental structuring has the clear benefit of keeping short-term memory burdens to a minimum. For example, try to memorize a list of twelve random words versus a twelve-word sentence. Even a complex sentence such as "Not all of the targets were hit by some of the arrows" is easier to remember than a random array of words (e.g., "arrows by were of not of targets all the some hit the"), precisely because we can structure the sentence as we read or hear it (even in isolation, and despite the interpretive difficulties). But there is a potential cost to incremental processing if, as is quite common in human language, the input is ambiguous and processing must proceed in advance of relevant infor-

mation. In fact, one of the most remarkable characteristics of the human sentence processing mechanism (commonly termed "the parser") is its ability to structure ambiguous input in an efficient manner.

One major focus of research in parsing theory, and one that serves as a good illustration of work in a wide-ranging, complex field, is the study of the incremental processing of temporarily ambiguous word sequences. A sequence is ambiguous if it is compatible with more than one well-formed structural representation. A temporary ambiguity is one that is resolved later on in the sentence. Consider the sentences in (1).

(1) a. Ian knew the schedule . . .
    b. Ian knew the schedule by heart.
    c. Ian knew the schedule was wrong.
    d. Ian knew that the schedule was wrong.

The sequence in (1a) is temporarily ambiguous—that is, the noun phrase *the schedule* after the verb may function either as the nominal object of the verb (as in (1b)), or as subject of a clause (e.g., *the schedule was wrong* in (1c,d)). Each function has a distinct structural representation. The ambiguity is due to the following properties of English: (i) verbs such as *know* may take either noun-phrase or clausal objects; and (ii) the word *that,* which can be an indicator of a clause, is not always obligatory (as a comparison of (1c) and (1d) illustrates). Given incremental processing, the sequence in (1a) presents the parser with a choice. It may either structure the phrase "the schedule" as the object of the verb or as the subject of a new clause. If it takes the first option, then the appearance of a verb (such as *was* in (1c)) will prove this choice to have been the wrong one. On the other hand, if it takes the clausal option, then the failure of a verb to appear (as in (1b)) may cause processing difficulty.

To investigate the parser's operations in ambiguities such as (1a), Rayner and Frazier (1987) used an eye-tracking technique to take precise recordings of subjects' eye movements as they read temporarily ambiguous sentences such as those above, with the (d) sentences serving as an unambiguous control. What they found was a significant slow down in reading rate ("fixation durations") after the noun phrase in the (c) sentences, compared to the (b) and (d) sentences. They interpreted this comparatively slow reading rate as evidence that the parser had incrementally structured the postverbal noun phrase as a direct object in the ambiguous (b) and (c) sentences, but they had to revise this analysis in the (c) sentences when the input after the noun phrase showed it to be incorrect. The comparison of reading times after the noun phrase in the (c) and (d) sentences is particularly informative. The presence of *that* in (1d), in conjunction with the following *the,* serves as an unambiguous indicator of a new clause. The fact that a slowdown in reading rate is only observed in the (c) sentences supports the hypothesis that this slowdown is due specifically to the parser's response to the ambiguity in (c) and not to the need to process a second clause in the sentence.

These results are consistent with the hypothesis that the parser operates in accord with a Minimal Attachment principle (Frazier and Fodor 1978). Minimal Attachment states that, when faced with an ambiguity, the parser structures (or,

attaches) new input to the current representation with the minimal amount of additional structure. A direct object attachment of a postverbal noun phrase is less complex than an attachment that would require the additional structure associated with a new clause. Therefore, it is the one pursued by the parser. Frazier and Fodor (1978) argued that Minimal Attachment follows from the temporal processing advantage enjoyed by minimal structures compared to their more complex competitors. Gorrell (1995) has argued that Minimal Attachment effects are due to the parser incrementally reflecting a central property of syntactic structure: economy of representations (Chomsky 1995). The preference for minimal structure has been demonstrated for numerous structural ambiguities in English, as well as German (Gorrell 1996), Italian (DeVincenzi 1991), and Japanese (Inoue and Fodor 1995).

But syntactic structure is just one factor in the processing of ambiguous sentences (clearly demonstrated in a seminal paper by Bever 1970). Work within the constraint-based framework, inspired, in part, by computational models adopting a connectionist architecture, has stressed the contribution of specific lexical information rather than more general structural preferences in sentence processing (e.g., MacDonald, Pearlmutter, and Seidenberg 1994). This interest in the contribution of specific lexical information to the resolution of structural ambiguities can be illustrated with a brief description of the experimental results reported by Osterhout, Holcomb, and Swinney (1994). They recorded event-related brain potentials (ERPs) elicited while subjects read sentences similar to those in (1). ERPs are measured voltage changes in an electroencephalogram that occur within a specified time after the presentation of a particular word or other input. The particular ERP of interest here is the P600, so called because it is a positive-going waveform that peaks approximately 600 milliseconds after the event of interest. The P600 has been associated with the processing of input that represents either a syntactic violation or a disconfirmation of a prior structural choice.

Although a first experiment replicated the major findings of Rayner and Frazier (1987), the results of a second experiment, in which verb preference (for either a noun phrase or clausal object) was manipulated, reveal the important role of lexical information in processing ambiguous input. In this experiment, temporarily ambiguous sentences containing verbs which prefer noun-phrase objects (e.g., *understand* in *The student understood the answer was easy*) were contrasted with sentences containing verbs that prefer clausal objects (e.g., *guess* in *The student guessed the answer was easy*). Osterhout, Holcomb, and Swinney (1994) found that the P600 was elicited as a function of verb type rather than as a function of comparative structural complexity. Demonstrations of the parser's incremental utilization of specific verb information, which typically occurs before potential objects in English, highlights the importance of studying the processing of verb-final clauses, a common property of many of the world's languages (Schriefers, Friederici, and Kuhn 1995; Mecklinger, Schriefers, Steinhauer, and Friederici 1995).

In addition to syntactic and lexical factors, work by Crain and Steedman (1985), St. John and McClelland

(1990), Altmann, Garnham, and Dennis (1992), and others have highlighted the important influence exerted by DIS-COURSE context on the process of resolving structural ambiguities. For example, consider the sentences in (2).

(2) a. The fireman told the woman that he had risked his life for many people in similar fires.
    b. The fireman told the woman that he had risked his life for to install a smoke detector.

In (2a), the phrase *that he had risked his life for many people in similar fires* is an assertion being told to some woman. In (2b), the phrase *that he had risked his life for* is a phrase specifying which woman was being addressed. As in (1), the sentences here display a temporary ambiguity between the two structures. Minimal Attachment predicts an initial preference for the assertion analysis in (2a). Altmann, Garnham, and Dennis (1992), using the eye-tracking technique, indeed found a reading-time advantage for sentences such as (2a) over (2b). But it is significant that they only found this in particular situations. That is, they found that the discourse context played an important role in determining how these sentences were read. Consider the fact that, if two women are mentioned in a conversation, then the use of distinguishing modification, as in (2b), would aid the listener in determining which woman was being referred to in a particular sentence. By testing sentences in contexts in which modification was useful in this way, Altmann, Garnham, and Dennis report that the initial reading time advantage for (2a) over (2b) disappeared. This indicates the rapid influence of discourse context on sentence processing.

Studies such as these indicate that sentence processing necessarily involves the efficient use of many different types of information. Exactly how these various information types interact in sentence processing is an important question in cognitive psychology. Sentence processing is center stage in the "modularity" debate—that is, the extent to which information processing is accomplished by specialized subprocessors or by more general mechanisms (Fodor 1983; Marslen-Wilson and Tyler 1987; Friederici 1990). In addition to lexical, structural, and discourse information, the role of prosodic factors is also an increasing focus of experimental research (Ferreira and Anes 1994; Warren 1996).

Another important research topic, inspired by the work of Baddeley and colleagues (Baddeley 1986), is the role of short-term memory in sentence processing. As noted, the limited capacity of short-term memory is one driving force in incremental processing, and many researchers accord it a significant role in the processing of ambiguous or complex sentences (Just and Carpenter 1992; Waters and Caplan 1996).

Sexual Attraction, Evolutionary Psychology of

Evolutionary psychology is evolutionary biology applied to the brain's adaptations. An adaptation is a phenotypic feature, psychological or otherwise, whose ultimate cause is some type of historical Darwinian selection (Thornhill 1997). Genes, physiology, development, and environment are proximate causes of each adaptation. Because adaptations are the products of past selection, they exhibit functional or purposeful design. Evolutionary psychology's focus is on identifying and characterizing psychological adaptations, which are functionally designed for processing information about survival and reproductive success in human evolutionary history.

Humans make aesthetic judgments in numerous domains, and for theoretical and empirical reasons, these judgments are viewed as reflecting domain-specific psychological adaptations, not general-purpose ones (Thornhill 1998). Thus, it is proposed that there is special-purpose adaptation for assessing sexual attractiveness, and further,

that in this domain are numerous psychological adaptations, each functionally designed for assessing a component of attractiveness that corresponded to a marker of the reproductive value of an individual to the mate chooser during human evolutionary history. Aesthetic judgments in the domain of sexual attraction are sometimes sex specific because males and females, consistently throughout human evolutionary history, faced sex-specific adaptive problems in mate selection, and therefore have sex-specific psychological adaptation. For example, women value resources and status of potential mates more, and physical attractiveness and youth in a potential mate less, than men do (Symons 1979; Grammer 1993; Buss 1994).

Cross-cultural research has shown that although men place more value on physical attractiveness of a mate than women do, both sexes value it highly (Grammer 1993; Buss 1994; cf. HUMAN UNIVERSALS). Physical beauty is a health certification (Thornhill and Gangestad 1993; Symons 1995). In human evolutionary history, individuals who saw as sexually attractive body traits of health outreproduced other individuals because the formers' preferred mates survived better, had genetic health, and were better able to provide investment. Two important categories of physical beauty traits identified in recent research are the hormone markers and developmental stability/bilateral symmetry (Thornhill and Gangestad 1996), which are the focus of the rest of this article.

The adult human form is an array of sex-specific, sex hormone-mediated secondary sexual traits that signal health. These traits apparently evolved for the reason that health signalers outreproduced less healthy individuals, because the most healthy were preferred mates. Men's and women's faces differ in the size of the lower face. Largeness in the lower face is attractive in men's faces, whereas smallness is attractive in women's faces (Symons 1995; Thornhill and Gangestad 1996). High estrogen at puberty caps the growth of the adult female face. Testosterone facilitates the sex difference in muscle mass, body size, and athleticism, and largeness and athleticism are attractive in men. Estrogen facilitates the redistribution and increased deposition of fat on the bodies of females at adolescence, giving rise to the relatively small waist and large hips in women. Low waist-to-hip ratio in women connotes hormonal health, fertility, youth and relative freedom from a diversity of diseases (Singh 1993).

The hormone-facilitated facial features and the other hormone markers mentioned not only display information about an individual's hormonal health, but apparently also his/her immunocompetence, because both sex hormones are immunosuppressors (Thornhill and Gangestad 1993). Attractive expressions of secondary sexual traits require high hormone titers during their construction, and thus can be afforded only by immunocompetent individuals. Disease organisms are important in human attractiveness (reviewed in Thornhill and Møller 1997). For example, the value placed on physical attractiveness in choice of a long-term mate in each sex correlates positively with the prevalence of parasitic diseases across human societies (Gangestad and Buss 1993).

Developmental stability connotes developmental health in humans (Thornhill and Møller 1997). Developmental

stability occurs when the adaptive developmental trajectory is achieved despite environmental and genetic perturbations during development. Developmental instability is most often measured as fluctuating asymmetry because fluctuating asymmetry is a highly sensitive measure of developmental disturbance. Fluctuating asymmetry is deviation from perfect bilateral symmetry in normally bilaterally symmetrical traits. These deviations are random in direction, typically small in any one trait, and found in every individual to some degree. Fluctuating asymmetry may be the best measure available of phenotypic and genetic quality of the individual. It reflects the individual's ability to resist environmental (e.g., parasites, low food quantity and quality, environmental toxins) and genetic perturbations during development, or an absence of genes that disrupt development (Møller and Swaddle 1997). Accordingly, low fluctuating asymmetry is associated in a wide range of species with rapid growth rate, reduced parasitism, longevity, fecundity, and sexual attractiveness (Møller and Swaddle 1997). It also shows significant heritability across species (Møller and Thornhill 1997).

Symmetry is a component of sexual attractiveness in humans. In both sexes, faces with high bilateral symmetry are more attractive than less symmetrical faces (e.g., Grammer and Thornhill 1994; review of studies in Møller and Thornhill 1998). Also, symmetry in body features such as fingers, elbows, ankles, and feet correlates with facial symmetry and attractiveness (Gangestad and Thornhill 1997). Interestingly, facial symmetry in each sex correlates with the sex-specific attractive expression of the facial secondary sex traits (e.g., symmetry positively correlates with lower face size in men and negatively with lower face size in women; Gangestad and Thornhill 1997). Moreover, women with symmetrical breasts report higher age-independent fertility (number of children) and earlier onset of child bearing, and breast-size symmetry positively affects women's attractiveness (Møller, Soler, and Thornhill 1995; Singh 1995; Manning et al. 1997).

Numerous studies show that nonfacial body symmetry of men positively correlates with their mating success. This pattern is not seen in women. Compared to men with high body fluctuating asymmetry, men with low asymmetry report having had more sex partners and more extra-pair-bond sex partners, are chosen as extra-pair partners more often by women in committed relationships, and begin sex earlier in their life history and in their romantic relationships (Thornhill and Gangestad 1994; Gangestad and Thornhill 1997). Also, the mates of symmetrical men show the most reported copulatory orgasms (Thornhill et al. 1995). The female copulatory orgasm seems to be a female choice adaptation. It increases sperm retention and may be involved in selective sperm retention (Baker and Bellis 1995). Also, it may affect selective bonding as a result of associated oxytocin (Thornhill et al. 1995). Finally, there is evidence that secondary sexual traits of the body in men such as musculature, athleticism, and body size correlate positively with their body symmetry (Gangestad and Thornhill 1997).

Social psychology had demonstrated earlier in research beginning in the 1960s the profound importance of physical attractiveness in human everyday life (e.g. Jackson 1992). Only relatively recently have evolutionary psychologists asked why the importance in the first place and what kinds of body features are expected to play central roles given the nature of the evolutionary process. Physical attractiveness signals the individual's ability to cope with stresses from reproductive hormones during puberty and adolescence, from disease organisms, and from the many environmental and genetic perturbations that throw off the development of bilateral symmetry. This is attractiveness described in terms of evolved human preferences. How these preferences interact with other criteria of sexual and romantic interest (e.g., status, age, need of investment) and through compromises or trade-off generate actual romantic choices is under investigation (Cunningham, Druen, and Barbee 1997; Gangestad and Thornhill 1997; Graziano et al. 1997).

Shape Perception

This article concerns shape perception, so it is natural to consider what is meant by "shape." Most readers undoubtedly have an intuitive feel for the meaning of the term, sensing its relatedness to such concepts as form and structure. Nevertheless, a precise definition of shape has proved elusive. Instead, experimenters have adopted the working definition that shape is an aspect of a stimulus that remains invariant despite changes in size, position, and orientation. For example, 2-D visual stimuli have the same shape if there exists a transformation of spatial scale (e.g., magnification) or a rotation in the picture plane that renders them identical. Similarly, 3-D objects have the same shape if their volumes can be equated by size changes or a combination of rotations about three spatial axes.

Although our world is filled with objects and patterns, most studies of shape perception have used only 2-D stimuli. This emphasis reflects the belief that perception of 3-D form depends on the shape of 2-D regions in the retinal image. The fact that line drawings can evoke vivid percepts of 3-D form (see figure 1a) supports the idea that 2-D and 3-D shape perception are related, but how they are related is still debated (cf. Attneave 1954; GIBSON 1950; Hochberg 1964; Koffka 1935; MARR 1982). Furthermore, variables that affect LIGHTNESS PERCEPTION (e.g., shading) and DEPTH PERCEPTION (e.g., binocular disparity and relative motion) also affect form perception. How these variables interact with 2-D shape to yield a 3-D percept is not well understood.

In most viewing conditions, a pattern's shape is closely related to the spatial arrangement of its contours. Thus, shape perception depends in part on feature extraction processes that encode edges and elementary features in the retinal image, and on processes that group elements into higher-order units (see GESTALT PERCEPTION). In the latter case, we can perceive both the shape of the individual elements, as well as the global shape of the grouped elements (figure 1b). Despite the close connection between contours and shape, simultaneous presentation of contours is neither necessary nor sufficient for shape perception. It is not necessary because shape is perceived even when only isolated parts of contour are presented. For example, in anorthoscopic stimuli a visual pattern is moved behind a stationary slit in an opaque screen: although only a small dot or line is visible at any one time, observers often perceive the shape of the hidden pattern. Simultaneous presentation of contours is not sufficient for shape perception because observers do not necessarily attend to everything in the visual field. Although some attributes of an unattended object, such as its presence, location, and color, can be perceived, ATTENTION appears to be required for shape perception (Rock and Gutman 1981; Rock et al. 1992). Other top-down processes also affect shape perception, as is shown by ambiguous figures like the duck/rabbit pattern in figure 1c: The contours remain constant, but perceived shape depends on the interpretation of the figure. In some cases, the allocation of attention to particular stimulus features can bias the percept of ambiguous figures (Peterson and Gibson 1991).

Although clearly related to HIGH-LEVEL VISION phenomena such as OBJECT RECOGNITION, shape perception is better classified as an aspect of MID-LEVEL VISION because the perception of shape does not require recognition: One can perceive the shapes of novel stimuli that have no a priori meaning (figure 1d), and an observer can recognize objects based on surface properties like TEXTURE or color (Humphrey et al. 1994; see also SURFACE PERCEPTION). Nevertheless, shape provides important clues about an object's identity, as well as information that is critical to manipulating objects and determining their functional properties or AFFORDANCES (e.g., Can I stand on this object?). Thus, it is not surprising that visual mechanisms encode shape rapidly and accurately. For example, the response time needed to name line drawings of familiar objects, or to determine if two novel polygons have the same shape, is approximately 1 sec (Larsen 1985). Although these response times are short,

they probably overestimate the time needed to perceive shape. For instance, observers can identify letters and line drawings of familiar objects presented for only 50 msec (Biederman and Ju 1988; Jolicoeur and Landau 1984). Other studies have shown that observers are exquisitely sensitive to shape differences that are much more subtle than those shown in figure 1e, even when the stimuli being compared differ substantially in size (De Valois et al. 1990; Regan and Hamstra 1992).

Further evidence of the versatility of shape perception comes from the fact that a stimulus need not be completely visible for observers to perceive shape accurately. In the everyday world, objects frequently occlude parts of neighboring objects, yet our visual systems are able to complete missing shape information (figure 1f). Although shape completion appears effortless and immediate, it is *not* instantaneous, and the way in which shapes are completed depends on factors such as stimulus regularity and symmetry (Sekuler 1994; Sekuler and Palmer 1992). A phenomenon related to visual completion is that of illusory contours, in which the percept of a shape is induced by other visible shapes (figure 1g; Kanizsa 1975).

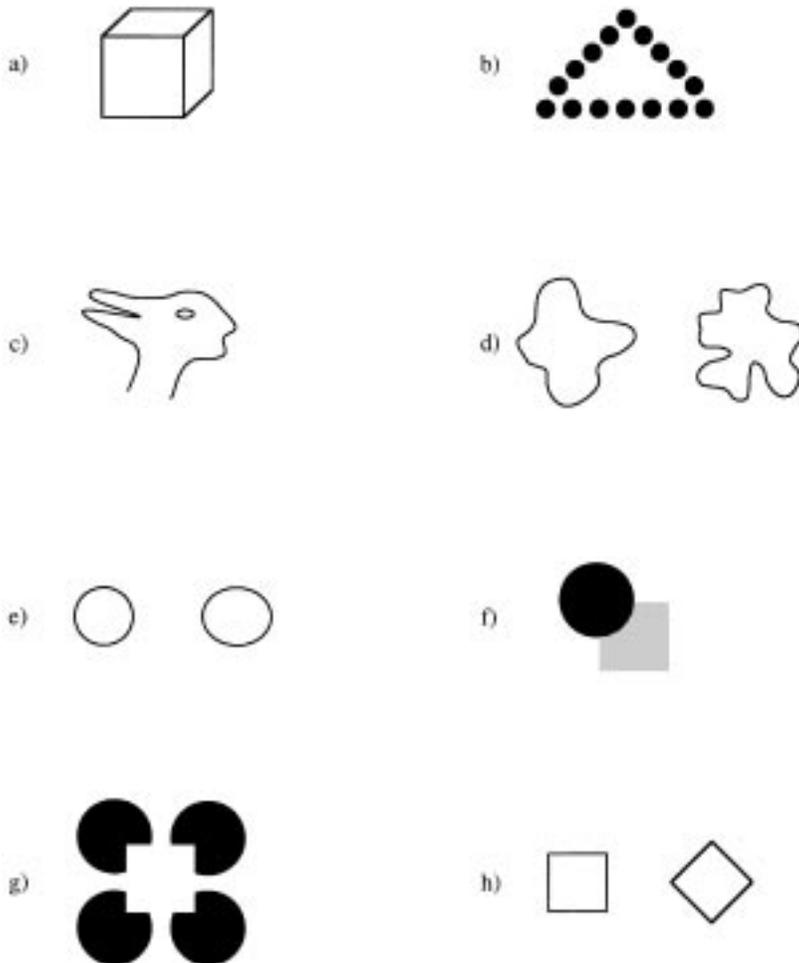
At the beginning of this article we defined shape as that aspect of a stimulus that remained invariant despite changes in size and orientation. Thus, one might expect that per-ceived shape would not depend on stimulus orientation or size. This suggestion seems intuitively obvious, and it is consistent with our experience in everyday tasks in which objects are recognized (in part on the basis of shape) despite substantial changes in retinal size and orientation. Nevertheless, there is ample evidence that our perception of shape is *not* invariant across spatial scales and orientations. For example, it is more difficult to recognize line drawings of familiar objects and abstract patterns presented in unfamiliar sizes or orientations (Edelman and Bülthoff 1992; Jolicoeur 1987; Rock, Schreiber, and Ro 1994; Tarr and Pinker 1989). Furthermore, it takes significantly more time to determine if two patterns have the same shape when they differ in size or orientation (Larsen 1985; Sekuler and Nash 1972). Finally, there are several demonstrations that phenomenological shape varies significantly with orientation. Mach's classic demonstration of the effect of orientation on the perceived shape of a square is shown in figure 1h. In Mach's words, "Two figures may be geometrically congruent, but physiologically quite different, . . . [these figures] could never be recognized as the same without mechanical and intellectual operations" (Mach 1959: 106; see also MENTAL ROTATION). These effects of size and orientation on shape perception have important implications for theories of object recognition. Specifically, they raise the possi-


Figure 1. (a) Although this image is two-dimensional, observers perceive a three-dimensional cube. **(b).** Shape perception can occur after perceptual grouping. Observers can perceive both the global (triangle) and the local (circle) shapes. **(c).** Perceived shape is influenced by top-down processes. When one stimulus has multiple interpretations, perceived shape changes even with no stimulus change. This figure can be seen as a duck (facing left) or as a rabbit (facing right). When the percept changes, so does the interpretation of specific parts of the stimulus (e.g., what was a beak becomes ears). **(d).** We perceive shapes of unfamiliar figures that have no a priori meaning. Observers can discriminate these two shapes, although we have no memory association for either. **(e).** Quite small shape differences can be perceived. The length of this oval is just 20% longer than the diameter of the circle. Most observers can discriminate even more subtle differences in shape. **(f).** Shape perception proceeds even in the absence of complete stimulus information. This figure is consistent with both a circle partially occluding a square (in two depth planes), and a circle next to a notched square (in one or more depth planes). Most people perceive the former—filling in missing shape information. **(g).** We can perceive the shapes of completely invisible objects. In this example of an illusory figure, observers see a white square on top of four black circles. Although the edges of the square appear highly salient, they do not physically exist. **(h).** Mach's original demonstration that phenomenological shape can vary with orientation. The two stimuli have the same physical shape, but observers perceive the left shape as a square and the right as a diamond (if the reader tilts his or her head 45 degrees clockwise, the percepts reverse).

bility that an object is recognized by comparing it to multiple, viewpoint-dependent representations in long-term memory, rather than to a single, viewpoint-independent representation.

Relatively little is known about the physiological mechanisms underlying shape perception, but researchers have located neurons in the inferotemporal cortex (IT) that respond better to some shapes than to others, even when these shapes are not identified with specific previously learned objects. Whereas the primary VISUAL CORTEX initially codes basic features such as orientation, size, and color, area IT codes much more complex features such as particular shapes, or combinations of shapes and colors (Tanaka 1993). Neurons in area IT also have similar shape selectivity regardless of the cue that defines the shape (e.g., luminance-, texture-, or motion-defined shapes; Sary et al. 1995), the size and position of the shape (Ito et al. 1995; Logothetis, Pauls, and Poggio 1995), or the presence or absence of partially occluding contours (Kovacs, Vogels, and Orban 1995). These recent discoveries suggest that area IT plays a significant role in shape constancy and recognition, but other cortical areas may be involved in the use of shape to guide the manipulation of objects (Goodale and Milner 1992; see also VISUAL PROCESSING STREAMS). Additional physiological and psychophysical research in the next few years undoubtedly will increase our understanding of the physiological processes underlying shape perception.

Sign Language and the Brain

Two prominent issues concerning brain organization in deaf users of SIGN LANGUAGES are whether deaf individuals show complementary HEMISPHERIC SPECIALIZATION for language and nonlanguage visuo-spatial skills, and whether classical language areas within the left hemisphere participate in sign-language processing. These questions are especially pertinent given that signed languages of the deaf make significant use of visuo-spatial mechanisms to convey linguistic information. Thus sign languages exhibit properties for which each of the cerebral hemispheres show specialization: visuo-spatial processing and language processing. Three sources of evidence have commonly been used to investigate brain organization in signers: behavioral studies using tachistoscopic visual half-field paradigms, studies of signers who have incurred focal brain damage, and, more recently, neural imaging studies of normal signing volunteers. Many of these studies have investigated American Sign Language (ASL), which is but one of the many naturally occurring signed languages of the world. These studies have provided insight into the determination of hemispheric specialization and the contribution of environmental and biological factors in the establishment of neural systems mediating human language.

The behavioral literature on cerebral lateralization for sign language is based largely upon tachistoscopic visual half-field studies. As a whole, these studies yield inconsistent and contradictory findings, ranging from reports of right-hemisphere dominance, left-hemisphere dominance, and no hemsipheric asymmetries for sign language processing in the deaf. Methodological factors such as variability in inclusion criteria for deaf subjects (e.g., etiology and degree of hearing loss), variability in language background and schooling (e.g., native signers, nonnative signers, oral schooling, sign-based schooling) and stimulus characteristics (e.g., manual-alphabet handshapes, static drawings of ASL signs and moving signs) contribute to the wide range of findings. Discussion here will be limited to studies using profoundly deaf, native signing adults as subjects. Poizner, Battison, and Lane (1979) compared the contribution of movement in sign language stimuli. They reported a left visual field (LVF) advantage for static signs and no hemispheric asymmetry for moving signs. In a study comparing depth of processing, Grossi et al. (1996) reported no hemisphere asymmetry for judgments of signs based on physical characteristics. However, a significant RVF advantage emerged when subjects were asked to make judgments of

handshapes that matched in morphological relationships to one another. Emmorey and Corina (1993) tested hemispheric specialization using a lexical decision paradigm for moving signs that varied in imagability. Deaf signers and hearing English speakers both showed a left-hemisphere advantage for abstract lexical items. English speakers exhibited no visual field effect for imageable words; however, deaf signers showed a significant right-hemisphere advantage for imageable signs. These studies suggest that hemispheric asymmetries are more likely to be elicited from moving sign stimuli as well as when deaf subjects are engaged in higher level lexical processing of sign stimuli. Under these constraints, patterns of left-hemisphere dominance for language may emerge.

In 1878, Hughlings Jackson wrote, "No doubt by disease of some part of his brain the deaf-mute might lose his natural system of signs" (p. 304). Since this time, roughly 25 individual case studies of signers with brain injury have been reported (see Corina 1998 for a recent review). However, many of the early case studies were compromised by a lack of understanding of the relationships among systems of communication used by deaf individuals. For example, several of the early studies compared disruptions of fingerspelling and only briefly mentioned or assessed sign-language use. More recently, well-documented case studies have begun to provide a clearer picture of the neural systems involved in sign-language processing. From these later studies, it becomes evident that right-handed deaf signers, like hearing persons, exhibit APHASIA when critical left-hemisphere areas are damaged (Poizner, Klima, and Bellugi 1987). Approximately one dozen case studies provide sufficient detail to implicate left-hemisphere structures in sign-language disturbances. A subset of cases provide neuro-radiological or autopsy reports to confirm left-hemisphere involvement, and they provide compelling language assessment to implicate aphasic language disturbance. As well, five cases of signers with right-hemisphere pathology have been reported. All five of these signers showed moderate to severe degrees of nonlinguistic visuo-spatial impairment accompanied by relatively intact sign-language skills. In contrast, none of the left-hemisphere–damaged signers tested on nonlinguistic visuo-spatial tests were shown to have significant impairment. Taken together, these findings suggest that deaf signers show complementary specialization for language and nonlanguage skills. These studies demonstrate that the development of hemispheric specialization is not dependent upon exposure to oral/aural language.

Disruptions in sign-language ability following left-hemisphere damage are similar to those patterns found in hearing users of spoken languages. For example, execution of speech movements involves the cortical zone encompassing the lower posterior portion of the left frontal lobe (Goodglass 1993). Left-hemisphere posterior frontal regions also are implicated in sign-language production. A representative case is that of Poizner, Klima, and Bellugi's (1987) subject G. D., who had damage to Broadman's areas 44 and 45 of the left frontal lobe. This subject's signing was effortful and dysfluent, reduced largely to single-sign utterances, but her sign-language comprehension remained unimpaired. In

hearing individuals, severe language comprehension deficits are associated with left-hemisphere posterior temporal lesions. Similar patterns have been observed in users of signed languages. For example, W. L., who suffered damage to the posterior temporal area, was globally aphasic for ASL (Corina et al. 1992). W. L. evidenced marked comprehension deficits and showed a gradation of impairment, with some difficulty in single-sign recognition, moderate impairment in following commands, and severe problems with complex ideational material. W. L.'s sign production remained moderately fluent, but he made numerous sign-language "phonemic" paraphasias. Phonemic paraphasias arise from substitutions or omissions of sublexical phonological components. In ASL, sublexical structure refers to the formational elements that comprise a sign form: hand-shape, location, movement, and orientation. A common form of sign paraphasic error involves the incorrect use of handshape for a given sign. Importantly, W. L. also showed intact production and comprehension of nonlinguistic panto-mime. Thus, although profoundly aphasic for linguistic properties of ASL, W. L. was motorically facile and capable of producing and understanding nonlinguistic pantomime. Taken together, these findings provide evidence that language impairments following stroke in deaf signers follow the characteristic pattern of left frontal damage leading to nonfluent output with spared comprehension, whereas left posterior lesions yield fluent output with impaired language comprehension. Dissociation between nonlinguistic panto-mime skills and language use further demonstrates that these impairments are aphasic in nature and do not reflect general problems in symbolic conceptualization or motor behavior.

Functional imaging techniques have been used to examine sign-language representation in the brain. Comparisons of sentence processing for written English and ASL reveal both commonalties and differences across hearing nonsigners and native users of sign language. A functional MAGNETIC RESONANCE IMAGING (fMRI) study by Neville et al. (1998) shows that when hearing or deaf subjects process their native languages (ASL or English), classical anterior and posterior language areas within the left hemisphere are recruited. This finding is consistent with data from studies of spoken- and sign-language aphasia. These results suggest that the early acquisition of a fully grammatical, natural language is important in the specialization of these systems. However, unlike patterns observed for English processing, when deaf and hearing native signers process sentences in ASL, robust activation is also observed in right hemisphere prefrontal regions and posterior and anterior parts of the superior temporal sulcus. These findings imply that the specific nature and structure of ASL results in the recruitment of the right hemisphere into the language system. Recent electrophysiological studies of neurologically intact native signers also indicate that both the left and right hemispheres are active during ASL sentence processing (Neville et al. 1997). These results suggest that activation within the right hemisphere may be specifically linked to the linguistic use of space. The degree of right-hemisphere activation observed in these studies is surprising given the lack of significant aphasic symptomology reported in right-hemisphere–damaged signers.

Taken together, studies of the neural basis of sign-language processing highlight the presence of strong biases that left inferior frontal and posterior temporal parietal regions of the left hemisphere are well suited to process a natural language independent of the form of the language, and they reveal that the specific structure and processing requirements of the language also, in part, determine the final form of the language systems of the brain.

Sign Languages

Sign languages (alternatively, signed languages) are human languages whose forms consist of sequences of movements and configurations of the hands and arms, face, and upper torso. Typically, sign languages are perceived through the visual mode. Sign languages thus contrast, of course, with spoken languages, whose forms consist of sounds produced by sequences of movements and configurations of the mouth and vocal tract. More informally, then, sign languages are visual-gestural languages, whereas spoken languages are auditory-vocal languages.

Most linguistic research has focused on spoken languages. Indeed, for many years all human languages were mistakenly believed to be spoken languages; signed languages (for example, those used by deaf people interacting with one another) were thought either to be pantomime or to be simple gestural codes representing the surrounding spoken language. However, recent linguistic work has shown these beliefs to be incorrect: natural signed languages show all the structural properties of other human languages yet have evolved independently of the spoken languages that surround them.

Signed languages typically appear as the primary communication systems of people for whom the use of spoken languages is blocked, either by deafness or muteness. The best-known sign languages are used by profoundly deaf people, but sign languages have also been noted (though less well studied) in non-deaf members of occupational or cultural groups where hearing or speaking is impossible (e.g., sawmill workers, monks taking vows of silence, cultures where speech is prohibited for long periods during mourning or surrounding puberty; Johnson 1978; Kendon 1988). Under any of these circumstances, sign languages appear to arise quite commonly: probably every known group of nonspeaking deaf people observed around the world uses some sign language, and even isolated deaf individuals have been observed to develop a sign language to communicate with hearing relatives and friends (Goldin-Meadow and Mylander 1984; Coppola et

al. 1997). Thus, although it is probably fair to say that the auditory-vocal (spoken) medium is biologically dominant for language in humans (in the sense that all groups for whom spoken language is viable seem to choose this medium), the visual-gestural (sign) medium is a robust, and therefore biologically normal, alternative.

One important distinction is between "natural sign languages" and "devised or derivative sign languages." Natural sign languages are those that have arisen spontaneously through time by unrestricted interactions among people who use them as a primary communication system. These are the sign languages on which most linguistic research has focused, because they offer the clearest evidence about the natural tendencies of humans to develop communicative structure in the visual-gestural mode. The natural sign languages of deaf communities are typically named by the region in which they have evolved—for example, American Sign Language (used in the United States and parts of Canada), British Sign Language (used in Great Britain), French Sign Language/Langue des Signes Française (used in France).

In contrast, devised or derivative sign languages (perhaps more properly termed "sign systems") are those that have been intentionally invented by some particular individuals (e.g., educators of deaf children), typically not the primary users of the language, and whose structures are often based directly on a spoken language. These devised systems are typically named by the spoken language on which they are based. One example is a set of sign systems devised by educators of the deaf in the 1970s to represent spoken English, known as Manually Coded English (similar but slightly different variants of MCE are called Signing Exact English, Seeing Essential English, and Linguistics of Visual English). Because these devised systems are invented by committees, rather than arising spontaneously among users, they do not offer the opportunity to observe the unfettered natural tendencies of humans to develop gestural languages. In fact, those sign systems studied by linguists have been found to violate the universal structural principles of both spoken and signed natural languages (even though the systems are intended to match a particular spoken language), probably because the inventors were unfamiliar with linguistic principles and performed their invention process outside of the implicit constraints and forces of the (natural) processing circumstances in which natural languages evolve. One interesting finding concerning these devised languages is that, presumably because of violating natural structural principles for human languages, children do not readily acquire these languages (Supalla 1986, 1990). Therefore use of these devised systems tends to be confined to the classrooms in which their use is required and does not spontaneously spread to a wider community or to broader employment in everyday communication.

As noted above, most research has focused on natural sign languages, asking whether natural sign languages are organized and learned in ways that are similar to or different from natural spoken languages. The largest amount of linguistic and psycholinguistic research on natural sign languages has been conducted on American Sign Language (Stokoe, Casterline, and Cronbach 1965; Klima and Bellugi

1979; Siple and Fischer 1990). More recent research has begun to investigate other natural sign languages, to compare unrelated sign languages to one another in an attempt to determine the universal properties and the range of language variation across sign languages, and to compare the outcome to that found in crosslinguistic research on spoken languages (Supalla 1997). Although our knowledge of American Sign Language is fairly detailed, our understanding of other signed languages and also of sign language universals is just beginning.

Like research on other languages, research on American Sign Language (ASL) focuses primarily on its structure, use, and acquisition among those signers for whom it is a native language, acquired from exposure in the home from earliest infancy. These are typically congenitally and profoundly deaf individuals whose parents are also deaf and who themselves acquired ASL early in life. (In contrast to spoken language communities, these native users are very rare and constitute only about 5 percent of the signing community.) Linguistic analyses of (natively acquired) ASL have revealed that it is a language with a quite different type of structure than that of English, but one that is found among other spoken languages (for example, it shares certain typological similarities with Navajo). Word structure in ASL is quite complex, particularly in verbs. Typical verbs are marked morphologically for agreement in person and number with both subject and object, and for temporal aspect and other grammatical features common to verbs in other languages. Verbs of motion are particularly complex, with stems involving morphemes for path, manner of motion, orientation, and classifier morphemes marking the semantic category or size and shape of both the moving object and a secondary object with respect to which the movement path occurs. As is common in spoken languages with complex MORPHOLOGY, word order in ASL is relatively free, with an unmarked SVO order but a number of ordering-changing syntactic structures commonly used (e.g., topicalization of the object, subject, or VP). Moved constituents are obligatorily marked by grammaticized facial expressions, which are produced throughout the signing of the words of that constituent. When verbs are marked for agreement and/or when discussing subjects and objects which have already been mentioned, both the subject and the object NP may be omitted from the sentence (i.e., the language permits null arguments). In short, the grammatical properties of ASL are unlike those of English, but are quite familiar to students of other languages of the world. This body of findings thus suggests that principles of word and sentence structure are, at least to some degree, common to both signed and spoken languages and are not inherently connected to the auditory-vocal mode.

Studies of the on-line processing of ASL by fluent adult signers, of the representation of ASL in the brain, and of the acquisition of ASL by native-speaking deaf children also show many similarities with the principles of processing, neurological organization, and acquisition of spoken languages of the world. For example, ASL is acquired on approximately the same timetable as spoken languages with similar TYPOLOGY. Acquisition begins with manual babbling appearing at around 10 months or earlier (Petitto and Marentette 1991); first signs appear at about one year of age; two-sign sentences appear during the second year; and each of these stages show structural characteristics like those of other languages (Meier and Newport 1990; Newport and Meier 1985). Adult signers process ASL using the same types of parsing strategies as those used in the processing of spoken languages (Emmorey 1991) and, like speakers of auditory-vocal languages, represent ASL in the left hemisphere of the brain (Poizner, Klima, and Bellugi 1987; Neville 1995).

As noted earlier, a highly unusual feature of signing communities is that native users are so rare; 95 percent or more of deaf signers are first exposed to their language beyond infancy and sometimes not until late childhood or even adulthood. These demographics result from the fact that most deaf children are born into hearing families and also from the fact that, until recently, hearing parents were often discouraged from learning sign language in the hopes that avoidance of sign language and therapeutic presentation of speech would result in improved spoken-language acquisition. Research does not suggest, however, that the avoidance of sign languages does improve speech abilities; in fact, much evidence suggests that, among the profoundly deaf, better speech, lipreading, and reading abilities are shown by native signers (Meadow 1966) and, more generally, that spoken language abilities depend much more on the ability to hear than on the availability (or avoidance) of signing (Jensema 1975; Quigley and Paul 1986). In recent years, it has therefore begun to be more common practice to encourage hearing parents of deaf children to learn to sign, and to expose deaf children to sign languages from early in life.

In the meantime, however, the presence of a large number of signers who have acquired their primary language beyond infancy has presented an unusual research opportunity: the study of the effects of age of exposure on the mastery of a primary language. A number of such studies have shown that there is a substantial effect of age on the acquisition of ASL: native and early ASL learners show much more fluency, consistency, and complexity in the grammatical structures of the language, and more extensive and rapid processing abilities, than those who have acquired ASL later in life (Emmorey 1991; Mayberry and Fischer 1989; Newport 1990). These effects persist even after as much as 50 years of daily use of ASL as a primary language (Newport 1990). Together with the work of Lenneberg (1967) and Curtiss (1977), and also comparable effects of age of exposure on the acquisition of English as a second language in hearing foreigners (Johnson and Newport 1989), these results provide important evidence of a critical, or sensitive, period for LANGUAGE ACQUISITION.

All of these findings on ASL suggest that the cognitive abilities supporting language and its acquisition in humans are not restricted or specialized to speech but rather permit the development of signed as well as spoken languages. One might ask, then, whether there are any effects of modality on language structure or acquisition. The answer to this question from the study of this one sign language appears to be no, but a more definitive answer awaits the results of research on a large number of unrelated sign languages. With further research we will be able to determine whether

the universal similarities among spoken languages of the world, and also the range of differences and variation among them, are also characteristic of the signed languages of the world (Supalla 1997; Newport 1996).

Signal Detection Theory

Signal detection theory (SDT) is a model of perceptual DECISION MAKING whose central tenet is that cognitive performance, limited by inherent variability, requires a decision process. Applying a statistical-decision approach developed in studying radar reception, W. P. Tanner and J. A. Swets proposed in 1954 a "decision-making theory of visual detection," showing how sensory and decision processes could be separated in the simplest perceptual task. Extensive early application to detection problems accounts for the name of the theory, but SDT is now used widely in cognitive science as a modeling tool and for analyzing discrimination and classification data (see PSYCHOPHYSICS).

In detection, an observer attempts to distinguish two stimuli, *noise (N)* and *signal plus noise (S + N)*. These stimuli evoke not single percepts, but trial-to-trial distributions of effects on some relevant decision axis, as in figure 1a. The observer's ability to tell the stimuli apart depends on the overlap between the distributions, quantified by d', the normalized difference between their means. The goal of identifying each stimulus as an example of *N* or *S + N* as accurately as possible can be accomplished with a simple decision rule: Establish a *criterion* value of the decision axis and choose one response for points below it, the other for points above it. The placement of the criterion determines both the *hits* ("yes" responses to signals) and the *false alarms* ("yes" responses to noise). If the criterion is high (strict), the observer will make few false alarms, but also not that many hits. By adopting a lower (more lax) criterion (figure 1b), the number of hits is increased, but at the expense of also increasing the false alarm rate. This change in the decision strategy does not affect d', which is therefore a measure of *sensitivity* that is independent of *response bias.*

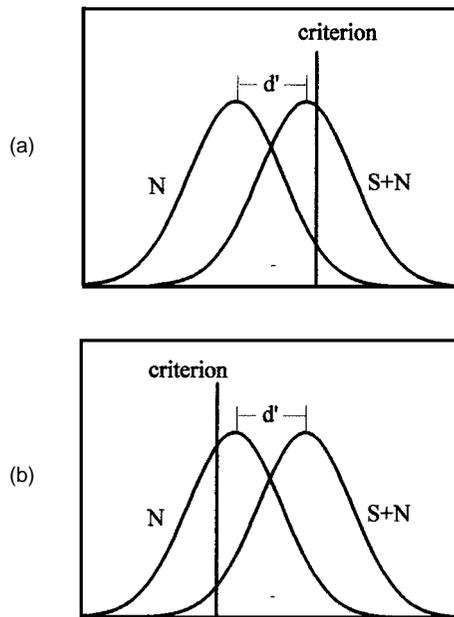
The statistic d' is calculated by assuming that the underlying distributions in the perceptual space are Gaussian and have equal variance. Both of these assumptions can be


Figure 1. Distributions assumed by SDT to result from N and $S + N$; the normalized difference between their means is d'. Criterion location is strict in (*a*), lax in (*b*), but d' is unchanged.

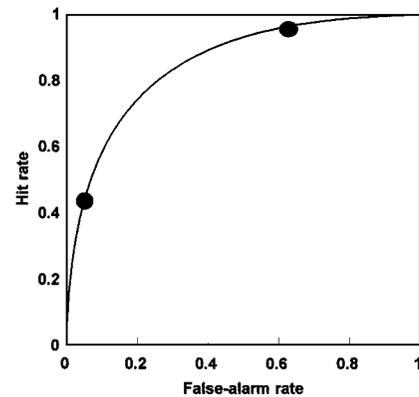
Figure 2. An ROC curve, the relation between hit and false-alarm rates, both of which increase as the criterion location moves (to the left, in figure 1).

tested by varying the location of the criterion to construct an *ROC* (receiver operating characteristic) curve, the hit rate as a function of the false-alarm rate (figure 2). ROCs can be obtained by varying instructions to encourage criterion shifts; or more efficiently by using *confidence ratings,* interpreting each level of confidence as a different criterion location. Most data are consistent with the assumption of normality (Swets 1986) or the very similar predictions of logistic distributions, which arise from choice theory (Luce 1963). For data sets that reveal unequal variances, accuracy can be measured using the area under the ROC, a statistic that is nonparametric (makes no assumptions about the underlying distributions) when calculated from a full ROC rather than a single hit/false-alarm pair (Macmillan and Creelman 1996).

The source of the variability in the underlying distributions can be internal or external. When variability is external (as, for example, when a tone is presented in random noise), the statistics of the noise can be used to predict d' for *ideal observers* (Green and Swets 1966: chap. 6). Similarly, the decision rule adopted by the observer depends on experimental manipulations such as the frequency of the signal, and the optimal criterion location can be predicted using Bayes's rule. Ideal sensitivity and response bias are often not found, but in some detection and discrimination situations they provide a baseline against which observed performance may be measured. The stimulus noise is much harder to characterize in other perceptual situations, such as X-ray reading, where N is healthy tissue and $S + N$ diseased (Swensson and Judy 1981). Most of the many applications of SDT to memory invoke only internal variability. For example, in a recognition memory experiment (Snodgrass and Corwin 1988) the $S + N$ distribution arises from old


items and the N items from new ones. Klatzky and Erdelyi (1985) argued that the effect of hypnosis on recognition memory is to alter criterion rather than d', and that distinguishing these possibilities requires presenting both.

The examples so far use a one-interval experimental method for measuring discrimination: in a sequence of trials, N or $S + N$ is presented and the observer attempts to identify the stimulus, with or without a confidence rating. This paradigm has been widely used, but not exclusively: In *forced-choice* designs, each trial contains m intervals, one with $S + N$ and the rest with N, and the observer chooses the $S + N$ interval; in *same-different,* two stimuli are presented that may be the same (both $S + N$ or both N) or different (one of each); *oddity* is like forced-choice, except that the "odd" interval may contain either $S + N$ or both N; and so on. Workers in areas as diverse as SPEECH PERCEPTION and food evaluation have argued that such designs are preferable to the one-interval design in their fields.

In the absence of theory, it is difficult to compare performance across paradigms, but SDT permits the abstraction of the same statistic, d' or a derivative, from all (Macmillan and Creelman 1991). The basis of comparison is that d' can always be construed as a distance measure in a perceptual space that contains multiple distributions. For the one-interval design, this space is one-dimensional, as in figure 1, but for other designs each interval corresponds to a dimension. According to SDT, an unbiased observer with $d' = 2$ will be correct 93 percent of the time in two-alternative forced-choice but as low as 67 percent in same-different. Some tasks can be approached with more than one decision rule; for example, the optimal strategy in same-different is to make *independent observations* in the two intervals, whereas in the *differencing* model the effects of the two intervals are subtracted. By examining ROC curve shapes, Irwin and Francis (1995) concluded that the differencing model was correct for simple visual stimuli, the optimal model for complex ones.

Detection theory also provides a bridge between discrimination and other types of judgment, particularly identification (in which a distinct response is required for each of m stimuli) and classification (in which stimuli are sorted into

subclasses). For sets of stimuli that differ along a single dimension, such as sounds differing only in loudness, SDT allows the estimation of d' for each pair of stimuli in both identification and discrimination. The two tasks are roughly equivalent when the range of stimuli is small, but increasingly discrepant as range increases. Durlach and Braida's (1969) theory of resolution describes both types of experiments and relates them quantitatively under the assumption that resolution is limited by both sensory and memory variance, the latter increasing with range.

For more complex stimulus sets, a multidimensional version of SDT is increasingly applied (Graham 1989; Ashby 1992). In natural extensions of the unidimensional model, each stimulus is assumed to give rise to a distribution in a multidimensional perceptual space, distances between stimuli reflect resolution, and the observer uses a decision boundary to divide the space into regions, one for each response. The more complex representation raises new issues about the perceptual interactions between dimensions, and about the form of the decision boundary; many of these concepts have been codified under the rubric of generalized recognition theory, or GRT (Ashby and Townsend 1986). Multidimensional SDT can be used to determine the optimal possible performance, given the MENTAL REPRESENTATION of the observer (Sperling and Dosher 1986). For example, Palmer (1995) accounted for the set-size effect in visual search without assuming any processing limitations, and Graham, Kramer, and Yager (1987) predicted performance in both uncertain detection (in which $S + N$ can take on one of several values) and summation (in which redundant information is available) for several models. In a more complex example of information integration, Sorkin, West, and Robinson (forthcoming) showed how a group decision can be predicted from individual inputs without assumptions about interaction among its members. In all of these cases, as for the complex designs described earlier, SDT provides a baseline analysis of the situation against which data can be compared before specific processing assumptions are invoked.

Similarity

An ability to assess similarity lies close to the core of cognition. In the time-honored tradition of legitimizing fields of psychology by citing William JAMES, "This sense of Sameness is the very keel and backbone of our thinking" (James 1890/1950: 459). An understanding of PROBLEM SOLVING, categorization, memory retrieval, inductive reasoning, and other cognitive processes requires that we understand how humans assess similarity. Four major psychological models of similarity are geometric, featural, alignment-based, and transformational.

Geometric models have been among the most influential approaches to analyzing similarity (Torgerson 1965), and are exemplified by multidimensional scaling (MDS) models (Nosofsky 1992; Shepard 1962). The input to MDS routines may be similarity judgments, confusion matrices (a table of how often each entity is confused with every other entity), probabilities of entities being grouped together, or any other measure of subjective similarity between all pairs of entities in a set. The output of an MDS routine is a geometric model of the entities' similarity, with each entity of the set represented as a point in N-dimensional space. The similarity of two entities i and j is taken to be inversely related to their distance, $D(i, j)$, which is computed by

$$D(i, j) = \left[\sum_{k=1}^{n} |X_{ik} - X_{jk}|^r \right]^{(1/r)}$$

where n is the number of dimensions, X_{ik} is the value of dimension k for entity i, and r is a parameter that allows different spatial metrics to be used. A Euclidean metric ($r = 2$) often provides good fits to human similarity judgments when the entities are holistically perceived or the underlying dimensions are psychologically fused, whereas a city-block metric ($r = 1$) often provides a better fit when entities are clearly divisible into separate dimensions (Garner 1974). Shepard (1987) has made a compelling case that cognitive assessments of similarity are related by an inverse exponential function to distance in MDS space.

Geometric models standardly assume minimality [$D(A, B) \geq D(A, A) = 0$], symmetry [$D(A, B) = D(B, A)$], and the triangle inequality [$D(A, B) + D(B, C) \geq D(A, C)$]. Amos TVERSKY (1977) criticized geometric models on the grounds that violations of all three assumptions are empirically observed. Minimality may be violated because not all identical objects seem equally similar; complex objects that are identical (e.g., twins) can be more similar to each other than simpler identical objects (e.g., two squares). Asymmetrical similarity occurs when an object with many features is judged as less similar to a sparser object than vice versa; for example, North Korea is judged to be more like China than China is to North Korea (Tversky 1977). The triangle inequality can be violated when A (e.g., "lamp") and B ("moon") share an identical feature (both provide light), and B ("moon") and C ("ball") share an identical feature, but A and C share no feature in common (Tversky and Gati 1982).

Although geometric models can be modified to correct these assumptions (Nosofsky 1991), Tversky suggested an alternative approach, the contrast model, wherein similarity is determined by matching features of compared entities, and integrating these features by the formula

$$S(A,B) = \theta f(A \cap B) - \alpha f(A - B) - \beta f(B - A).$$

The similarity of A to B, $S(A,B)$ is expressed as a linear combination of the measure of the common and distinctive features. The term $(A \cap B)$ represents the features that items A and B have in common. $(A - B)$ represents the features that A has but B does not. $(B - A)$ represents the features that B, but not A, possesses. The terms θ, α, and β reflect the weights given to the common and distinctive components, and the function f is often simply assumed to be additive. Other featural models calculate similarity by taking the ratio of common to distinctive features (Sjoberg 1972).

Neither geometric nor featural models of similarity are well suited for comparing things that are richly structured rather than just being a collection of coordinates or features. Often it is most efficient to represent things hierarchically (parts containing parts) and/or propositionally (relational predicates taking arguments). In such cases, comparing things involves not simply matching features, but determining which elements correspond to, or align with, one another. Matching features are aligned to the extent that they play similar roles within their entities. For example, a car with a green wheel and a truck with a green hood both share the feature *green,* but this matching feature may not increase their similarity much because the car's wheel does not correspond to the truck's hood. Drawing inspiration from work on analogical reasoning (Gentner 1983; Holyoak and Thagard 1989; see ANALOGY), in alignment-based models, matching features influence similarity more if they belong to parts that are placed in correspondence, and parts tend to be placed in correspondence if they have many features in common and if they are consistent with other emerging correspondences (Goldstone 1994; Markman and Gentner 1993).

A fourth approach to modeling similarity is based on transformational distance. The similarity of two entities is assumed to be inversely proportional to the number of operations required to transform one entity so as to be identical to the other (Hahn and Chater 1997; Imai 1977). For example, XXXXO requires only one transformation to become XXXOO (change an O to an X), but requires two transformations to become OOXXX (change an O to an X, and reverse string), and consequently is more similar to XXXOO.

Although testing between these four approaches to similarity is an ongoing topic of research, another major issue concerns the role of similarity in other cognitive processes. For example, although several models of categorization are completely similarity-based (see CONCEPTS and CATEGORIZATION), other researchers have argued that

people's categorizations cannot be exhaustively explained by similarity but also depend on abstract, theoretical knowledge (Rips and Collins 1993; Murphy and Medin 1985). Likewise, Goodman (1972) raised philosophical objections to the explanatory role of similarity, arguing that "X is similar to Y . . ." is totally unconstrained until it is completed by "with respect to property Z," and that it is this latter clause that performs all of the explanatory work. However, other researchers have argued that even without the additional clause, similarity is constrained by perceptual processes, by the manner in which multiple properties are integrated together (Goldstone 1994), by the compared items themselves (Medin, Goldstone, and Gentner 1993), by default properties that are applied irrespective of context (Barsalou 1982), and by a natural tendency to perceive overall similarity across many properties rather than similarity with respect to a single property (Smith 1989).

Another caveat to the explanatory role of similarity is that similarity may not be a unitary phenomenon. Similarity assessments are influenced by context, perspective, choice alternatives, and expertise (Medin, Goldstone, and Gentner 1993; Tversky 1977). Different processes for assessing similarity are probably used for different tasks, domains, and stimuli. The choice of features, transformations, and structural descriptions used to describe entities will govern the predictions made by similarity models as much as do the model's mechanisms for comparing and integrating these representations. History has not supported a literal interpretation of Fred Attneave's (1950: 516) claim, "The question 'What makes things seem alike or seem different?' is one so fundamental to psychology that very few psychologists have been naive enough to ask it" in that the topic has inspired considerable research, but this research has vindicated Attneave at a deeper level by testifying to the importance and complexity of similarity.

Simulation vs. Theory-Theory

The debate between the "simulation" theory and the "theory" theory, initiated in the late 1980s in philosophy of mind and developmental psychology, concerns the source of everyday human competence in predicting and explaining human behavior, including the capacity to ascribe mental states. Unlike earlier controversies concerning the role of empathetic understanding and historical reenactment in the human sciences, the current debate appeals to empirical findings, particularly experimental results concerning children's development of psychological competence.

Since the 1960s it has been widely assumed that the source of this competence is a body of implicit general knowledge or theory, commonly called FOLK PSYCHOLOGY by philosophers and THEORY OF MIND by psychologists, concerning the basic internal organization of the system that controls human behavior. The theory is either inherited as an innate module comparable to Noam Chomsky's language module (e.g., Jerry Fodor, Alan Leslie) or largely developed in childhood in a manner comparable to the development of scientific theories (e.g., Alison Gopnik, Josef Perner, and Henry Wellman). It is usually understood to consist in a body of lawlike generalizations, with PROPOSITIONAL ATTITUDES, especially beliefs and desires, thought to be the chief posits of the theory. Many but not all proponents of this view think that the theory must be measured against computational and/or neuroscientific accounts of the system that controls behavior. The chief disagreement among proponents of the theory theory is between those who think folk psychology likely to be largely vindicated by cognitive science and those who believe it has been or will be shown to be radically mistaken (see ELIMINATIVE MATERIALISM).

The simulation (or "mental simulation") theory, introduced in 1986 by Robert Gordon and Jane Heal and further developed by Alvin Goldman, Paul Harris, and others, is usually, though not always, taken to present a serious challenge to the very assumption that a theory underlies everyday psychological competence. According to this account, human beings are able to use the resources of their own minds to simulate the psychological etiology of the behavior of others, typically by making decisions within a "pretend" context. A common method is role-taking, or "putting oneself in the other's place." However, like the term *theory,* "simulation" has come to be used broadly and in a variety of ways. The term is often taken to cover reliance on a shared world of facts and emotive and motivational charges, where there is no need to put oneself in the other's place. (Gordon calls this the default mode of simulation.) Sometimes the term is taken to include automatic responses such as the subliminal mimicry of facial expressions and bodily movements. Stephen Stich and Shaun Nichols, whose critical papers have clarified the issues and helped refine the theory, urge that the term be dropped in favor of a finer-grained terminology.

Simulation is often conceived in cognitive-scientific terms: one's own behavior control system is employed as a manipulable model of other such systems. The system is first taken off-line, so that the output is not actual behavior but only predictions or anticipations of behavior, and inputs and system parameters are accordingly not limited to those that would regulate one's own behavior. Many proponents hold that, because one human behavior control system is being used to model others, general information about such systems is unnecessary. The simulation is thus said to be process-driven rather than theory-driven (Goldman 1993).

Important differences exist among simulation theorists on several topics. According to Goldman and (less clearly) Harris, to ascribe mental states to others by simulation, one must already be able to ascribe mental states to oneself, and thus must already possess the relevant mental state concepts. Gordon holds a contrary view suggested by Kant and Quine: Only those who can simulate can understand an ascription of, for instance, belief—that *to S* it is the case that *p.* Although no simulation theorist claims that all our everyday explanations and predictions of the actions of other people are based on role-taking, Heal in particular has been a moderating influence, arguing for a hybrid simulation-and-theory account that reserves simulation primarily for items with rationally linked content, such as beliefs, desires, and actions.

Three main areas of empirical investigation have been thought especially relevant to the debate.

False belief. Taking into account another's ignorance or false belief when predicting or explaining his or her behavior requires imaginative modifications of one's own beliefs, according to the simulation theory. Thus the theory offers an explanation of the results of numerous experiments showing that younger children fail to take such factors into account. It would also explain the correlation, in AUTISM, of failure to take into account ignorance or false belief and failure to engage in spontaneous pretend-play, particularly role-play. Although these results can also be explained by certain versions of theory theory (and were so interpreted by the experimenters themselves), the simulation theory offers a new interpretation.

Priority of self- or other-ascription. A second area of developmental research asks whether children ascribe mental states to themselves before they ascribe them to others. Versions of the simulation theory committed to the view that we recognize our own mental states as such and make analogical inferences to others' mental states seem to require an affirmative answer to this question; other versions of the theory seem to require a negative answer. Some experiments suggest a negative answer, but debate continues on this question.

Cognitive impenetrability. Stich and Nichols suppose simulation to be "cognitively impenetrable" in that it operates independently of any general knowledge the simulator may have about human psychology. Yet they point to results

suggesting that when subjects lack certain psychological information, they sometimes make incorrect predictions, and therefore must not be simulating. Because of problems of methodology and interpretation, as noted by a number of philosophers and psychologists, the cogency of this line of criticism is unclear.

The numerous other empirical questions of possible relevance to the debate include the following:

- Does brain imaging reveal that systems and processes employed in decision making are reemployed in the explanation and prediction of others' behavior?
- Does narrative (including film narrative) create emotional and motivational effects by the same processes that create them in real-life situations?

Some philosophers think the simulation theory may shed light on issues in traditional philosophy of mind and language concerning INTENTIONALITY, referential opacity (SENSE AND REFERENCE), broad and NARROW CONTENT, the nature of MENTAL CAUSATION, TWIN EARTH problems, the problem of other minds, and the peculiarities of SELF-KNOWLEDGE. Several philosophers have applied the theory to aesthetics, ethics, and philosophy of the social sciences. Success or failure of these efforts to answer philosophical problems may be considered empirical tests of the theory, in a suitably broad sense of "empirical."

Single-Neuron Recording

One of the most useful tools for the study of individual neurons in the nervous system is the microelectrode. A variety of specific techniques have evolved using this tool which enable investigators to determine how neurons act, how they communicate with each other, what kinds of NEUROTRANSMITTERS they use, what molecular mechanisms underlie their excitability, how they respond to sensory inputs, how they generate signals to activate muscles, and what the relationship is between their physiology and morphology.

In trying to understand the various uses to which microelectrodes have been put, the first distinction that needs to be made is between extracellular and intracellular recordings. In the case of extracellular recording, the tip of the microelectrode is not intended to enter the cell by penetrating its membrane; instead, electrical events are recorded in the immediate vicinity of each neuron. This method limits investigators mostly to the study of action potentials. A variety of electrode types have been developed for this kind of recording. These include fine-tipped glass pipettes filled with electrolytes and electrolytically sharpened metal wires coated with insulating material. Metal electrodes, especially those coated with a thin layer of molten glass except for the tip, are very strong and can penetrate without breaking even relatively tough tissue like dura. This makes it possible to record individual cells in alert animals, often for many hours, while they engage in various behavioral tasks. Using such methods, extensive sampling of neurons allows investigators to infer the functional characteristics of different brain structures. Such studies investigate how neurons respond to sensory inputs, how they discharge when various motor acts are executed, and even how higher-level mental events, such as ATTENTION, are represented at the neuronal level.

Intracellular recording methods enable investigators to study not only action potentials but also the graded potentials that reflect the excitatory and inhibitory inputs to the cell (excitatory and inhibitory postsynaptic potentials). Injection of current and pharmacological agents can provide information about the neurotransmitters and neuromodulators involved as well as the properties of the cell membrane at the molecular level.

Intracellular recording in the living organism is fraught with difficulties: the cells and axons are small and the movement artifact produced by heartbeat and breathing tends to dislodge the tip of the pipette from inside the cell. To combat this problem a variety of refinements have been made. Considerable improvement in recording stability can be realized in in vitro preparations: nerve tissue or individual cells are maintained outside of the body in an artificial medium, thereby eliminating movement due to heartbeat and breathing.

Three refinements in intracellular recording are noteworthy: *Voltage clamping* is a procedure that enables investigators to measure the flow of current across the membrane of single cells while the intracellular voltage is maintained at a constant value. This procedure has made a major contribution to our understanding of the mechanisms responsible for

the electrical excitability of neurons. *Patch clamping* is also a technique for studying the flow of current through cell membranes. As in the case of voltage clamping, voltage across the membrane is typically controlled and the resultant current flow is measured. Mild suction is applied to the microelectrode when the tip comes in apposition with the cell membrane, which thereby creates a very tight and reliable connection. A variant of this technique, called *whole-cell clamping,* involves applying enough suction to rupture the cell membrane within the small opening of the pipette tip. Whole-cell clamping has the benefit of ease of fluid exchange. In general, these last two methods, compared with other intracellular recording approaches, can provide a more detailed description of the characteristics of membrane channel proteins; the experimenter has better control of the experimental situation and can study smaller cells than with previous methods.

To establish the relationship between function and morphology, investigators have carried out intracellular recordings using dye-filled glass pipettes; first, the response characteristics of the cell are studied, after which the dye is injected into the cell. Some dyes, such as Lucifer yellow, diffuse through the entire dendritic network of the cell so that subsequently, using a variety of anatomical procedures, the morphology of the cell can be disclosed in detail. Such studies have succeeded in establishing the functional characteristics of the major cell types identified in the mammalian RETINA, in the CEREBELLUM, and in several other neural structures.

Lastly, microelectrodes can also be used to eclectically stimulate various brain regions. When areas involved in the execution of motor acts are stimulated in alert animals with brief trains of 60- to 500-Hz pulses, the responses elicited provide important clues about the role these structures play in the control of eye, head, limb, and body movement.

Situated Cognition and Learning

Situated cognition and learning is the study of cognition within its natural context. This perspective emphasizes that individual minds usually operate within environments that structure, direct, and support cognitive processes. "Context" can be defined as physical or task-based (including artifacts and external representations of information), environmental or ecological (such as workplace and marketplace), and social or interactional (as in educational instruction or clinical settings). This emphasis on the physical, environmental,

and social contexts for cognition was termed SITUATED-NESS/EMBEDDEDNESS by Lucy Suchman (1987).

As Roy Pea and John Seeley Brown (1987) note, "It may appear obvious that human minds develop in social situations, and that they use the tools and representational media that culture provides to support, extend, and reorganize mental functioning. But cognitive theories of knowledge representation and educational practice, in school and in the workplace, have not been sufficiently responsive to questions about these relationships." As evidence, Jean Lave (1988) cites laboratory studies of cognition that report extremely poor performance by adults on simple arithmetic problems. She argued that asking the same questions in the context of grocery shopping at a supermarket reveals people's competence, and the strategies (e.g., "get best price per unit") used to solve familiar problems. Ceci and Roazzi (1994) also demonstrate the importance of context by showing that child street vendors can solve sophisticated arithmetic problems only when posed as familiar vending decisions. But though related to the ECOLOGICAL PSYCHOLOGY movement, the situated perspective goes beyond arguing for realistic settings and problem content.

Instead, this situated cognition approach argues that the *nature* of cognitive processing is uniquely determined within its context, and that it cannot be studied in isolation without destroying its defining properties. Consider this example: Imagine the myriad devices and agents that play critical roles in cognition while flying a plane. Edwin Hutchins (1995a) conceptualizes this circumstance as a cognitive system extending beyond the physical boundary of the pilot's head, and *distributed* over the people and objects within the environment. The control panel on a 747 can be taken into a lab and studied; however, important features of its use by the pilot may only arise when she is functioning within a team of crew members, during a complete flight sequence, talking to flight controllers in her nonnative English, under darkness, in an airplane with a history of hydraulic indicator failures, for the second time. Hutchins (1995a) argues it is impossible to understand the cognition involved in flying a plane apart from this distributed system in which it is embedded.

Mind and environment interact not only in highly technical tasks, but also in everyday tasks where COGNITIVE ARTIFACTS represent needed information, support decisions, and potentially even interfere with performance (Norman 1987). For example, the mental artifact of the columnar format for arithmetic provides a structure to keep track of information when short-term memory would otherwise be overwhelmed. As Agre and Chapman (1987) suggest, the physical setting can greatly lighten the processing load of the thinker by providing external cues about what to do next and when goals are accomplished (such as giving feedback through elevator buttons that light up when activated). This relationship of cognition to environmental structure is also used in HUMAN-COMPUTER INTERACTION to design artifacts that can exploit cognitive processes while supporting difficult tasks (Winograd and Flores 1986).

The social environment also influences cognition through the presence of other minds to influence, assist, mislead, demonstrate, question, and raise other perspectives. The interactionist method (Cicourel 1987; Jordan and Henderson

1995) examines communication between participants as an externalized measure of cognition. The social context may also provide a method for LEARNING through the demonstration and assistance of others in a "socially constituted world" (Chaiklin and Lave 1993). For example, novices often learn through apprenticeships, where they spend many hours observing and interacting with more experienced team members as they learn to perform tasks on the job (Seifert and Hutchins 1992; Lave and Wenger 1991). Lev Semenovich VYGOTSKY's activity theory (c.f. Wertsch 1985) proposes that cognitive development even occurs through the witnessing of acts within a social context that are later internalized by the individual. For example, a child may first participate in a class where questions are asked and answered aloud during reading; later, the child may internalize these social interaction processes as the self-monitoring of comprehension during reading (Palincsar 1987).

This *social mediation* approach to the development of cognitive skills has had a tremendous impact on theories of learning and EDUCATION. For example, Tomasello, Kruger, and Ratner (1993) have theorized that underlying sociocognitive concepts and processes give rise to a developmental ordering of learning strategies, from imitative to instructed and finally to collaborative learning. Much recent work in education has focused on identifying the role of social interaction in classroom learning, and proposing ways of facilitating its effects (McDermott 1993; Brown 1989). The notion that a learner's progress can be understood only in the context of the social classroom directs educational interventions toward altering the social context (Cole 1991), rather than the individual. Many of these interventions are aimed at changing social context through new technology-based activities (Pea 1985; Tripp 1993; Wood 1995) that can expand the learning environment far beyond the time and space delimited by classroom walls.

The situated cognition perspective argues that our goal as cognitive scientists must be to understand the mind as it operates within a natural context. Our theories must account for "cognition in the wild" (Hutchins 1995b) because that is where cognition usually occurs, and where it demonstrates its true capabilities and limitations. The benefits of achieving this goal are not only theoretical, but may also provide many benefits for the structuring of cognition in our daily lives. As this example from Norman (1980) demonstrates, there is much at stake in this enterprise: "In March of 1977, two Boeing 747 airliners collided on a runway at Tenerife, in the Canary Islands, and the crash killed 582 people. What caused the accident? No single factor. The crash resulted from a complex interaction of events, including problems of attentional focus, the effects of expectation upon language understanding . . . a technically limited communication . . . the subtle effects of differences of social structure among the participants, the effects of stress, economic responsibilities and social and cultural factors upon decision making. All in all, it is a fascinating—if horrifying—story for Cognitive Science (pp. 4–5)."

Situatedness/Embeddedness

The situated movement—situated language, SITUATED COGNITION AND LEARNING, situated behavior—views intelligent human behavior as engaged, socially and materially embodied activity, arising within the specific concrete details of particular (natural) settings, rather than as an abstract, detached, general-purpose process of logical or formal ratiocination.

Situatedness arose in the 1980s as a reaction against the then-dominant classical view of mind. The classical approach, inherited from the logical and metamathematical traditions (dubbed "GOFAI" by Haugeland 1997, for "good old fashioned artificial intelligence"), views cognition as: *individual,* in the sense that the essential locus of intelligence is taken to be the solitary person; *rational,* in that deliberative, conceptual thought is viewed as the primary exemplar of cognition; *abstract,* in the sense that implementation and the nature of the physical environment are treated as of secondary importance (if relevant at all); *detached,* in the sense that thinking is treated separately from perception and action; and *general,* in the sense that cognitive science is taken to be a search for universal principles of general intellection, true of all individuals and applicable in all circumstances.

Situated approaches reject one or more of these assumptions, arguing instead that cognition (indeed all human activity) is: *social,* in the sense of being located in humanly constructed settings among human communities; *embodied,*

in that material aspects of agents' bodies are taken to be both pragmatically and theoretically significant; *concrete,* in the sense that physical constraints of realization and circumstance are viewed as of the utmost importance; *located,* implying that context-dependence is a central and enabling feature of all human endeavor; *engaged,* in that ongoing interaction with the surrounding environment is recognized as primary; and *specific,* in that what people do is seen as varying, dramatically, depending on contingent facts about their particular circumstances.

Within these broad outlines, situated approaches vary widely, from incremental proposals incorporating a degree of context-dependence within largely classical frameworks to more radical suggestions with substantial methodological and metaphysical commitments.

Closest to traditional models are "situated language" proposals for treating INDEXICALS, tense, and other context-dependent linguistic constructs (Barwise and Perry 1983). Terms such as *here*, *I*, and *now* are used on different occasions, by different individuals, to refer to different people and places, in ways that depend systematically on the circumstances of use. Formally, treating such context-dependence requires a two-stage SEMANTICS, distinguishing the MEANING of a word or sentence (the stable "rule" or pattern that the child learns, such as that "I" is used to refer to the speaker) from the *interpretation* of any particular utterance. Thus when two people shout "I'm right! You're wrong!" their utterances are said to coincide in meaning, but to differ in interpretation. Similarly, "4:00 p.m." can be assigned a single, constant meaning, mapping utterance situations onto times, depending on the date and time zone.

This general strategy of treating meaning as a function from context to interpretation (λ context . interpretation) has been applied to other forms of circumstantially determined interpretation, including anaphora and ambiguity (Gawron and Peters 1991). Methodologically, it requires a shift in focus from sentence types to individual utterances, and a generalization of inference from truth-preservation to reference-preservation (e.g., to understand why tomorrow we use "yesterday" to refer to what today we refer to with "today"). Nevertheless, such treatments remain largely compatible with classical views of cognition as individualistic, deductive, even relatively abstract (see INDIVIDUALISM).

Many, however, feel that situated intuitions run deeper. A further step, embodied in research on COGNITIVE ARTIFACTS, recognizes that an agent's embedding situation is not only a semantic resource for determining REFERENCE, but also a material resource for simplifying thought itself. Agents need not remember what remains in their visual fields, nor measure what they can directly compare. More generally, as captured in Brooks's (1997) slogan that "the world is its own best model," it is more efficient for an agent to let the world do the computing, and determine the result by inspection, than to attempt to shoulder the full load deductively. Moreover (see, e.g., Kirsh 1995), if the world happens not to provide exactly what one wants, one can sometimes rearrange it a bit so that it does. Lave, Murtaugh, and de la Rocha (1984) cite a near-mythic example of someone who, when asked to make 3/4 of a recipe that called for 2/3 of a cup of cottage cheese, measured out 2/3 of a cup,

smooshed it into a flattened circle, and cut away 1/4 of the resulting patty.

As these examples suggest, situated approaches tend to shift theoretical focus from abstract deduction onto concrete activity: cooking dinner, making one's way across a crowded subway platform, negotiating turn-taking in a conversation. Situated theorists take these activities not only to be nontrivial achievements, but also to be paradigmatic of human intelligence. With respect to action, furthermore, several writers advocate a shift in emphasis from (rational) advance planning to on-the-fly improvisation. Thus Brooks (1997), Agre and Chapman (1987), and Rosenschein (1995) argue that embodied agents can inventively exploit facts about their physical circumstances to avoid explicit representation and reasoning. Suchman (1987) claims that most human activity, rather than implementing preconceptualized plans, consists of incessant, creative, improvisational mobilization and appropriation of the vast array of resources that environments regularly make available. Not only do people rarely "figure it all out in advance," she argues, but their stories should be understood not as veridical reports of how activity comes to be, but as after-the-fact reconstructions whose role is to retrospectively render activity intelligible (and perhaps accountable).

These shifts in focus have substantial methodological implications. In part, they involve the rejection of long-standing Cartesian intuitions that although movement, sensation, and adaptive reaction to the physical world lie within the province of "mere brutes," high-level conceptualization is challenging and paradigmatic of what it is to be human. They also reflect a change in disciplinary affiliation, from LOGIC, mathematics, computer science, and (individual) psychology, toward sociology, anthropology, science studies, general epistemology, and philosophy of science. More concretely, they involve a shift in methods from *in vitro* toward *in vivo* studies, and from both statistical surveys and laboratory experiments toward "thick descriptions" of real people acting in real-life situations.

Such methodological and epistemological considerations lead to even more radical situated positions. In the situated language proposal discussed earlier, meanings were considered stable, but interpretation varied. But some writers argue that circumstance can affect *meaning,* too. Winograd (1985) argues that what *water* means in the question "Is there any water in the refrigerator?" depends on whether the questioner is thirsty, worried about humidity and condensation, or testing a child's understanding of the constitution of eggplants. Smith (1996: 328–329) considers a case where two friends, in late-night conversation, shape the meanings of their words (such as when describing a friend as "skewed"), rather in the way that blues players bend notes on a guitar. Such examples are theoretically challenging because they raise the ontological question of what properties such utterances designate. It is not obvious "bendable" predicates can be accommodated on the model of ambiguity, with contextual factors selecting from a fixed (pregiven) stock of external properties.

Pressed by such challenges, the strongest variants of situatedness bite the bullet and take ontology itself to be context-dependent. On such a view, not only is what we do, what we say, and how we get at the world viewed as depen-

dent on facts about our circumstances, but also *how the world is*—the very objects and properties in the world we therein talk about and live in and get at—are also taken to depend on (interpretive) context (Cussins 1992; Smith 1996). Taken to its logical extreme, that is, situatedness leads to a view of an ontologically plastic (though perhaps still highly constrained) world that, in contrast with the naive realism implicit in the classical picture, is at least partially socially constructed. Not surprisingly, such views reflect back onto our understanding of the nature of science itself (see, e.g., Haraway 1991). This is situatedness with a vengeance.

At the broadest level, the basic tenet of the situated movement has been accepted. That language, cognition, and activity are fundamentally context-dependent is by now a theoretical truism. What remains a matter of debate is how far this situated intuition should be taken. Everyone agrees that language is indexical, a smaller number are prepared to dethrone ratiocination as the hallmark of the mental, and those who are prepared to take context-dependence through to metaphysics remain a distinct minority. How the issues are resolved may depend on the extent to which the various communities advocating a situated approach—linguistics, cognitive science, AI, sociology, philosophy, feminism, science studies, and so on—collaborate in following out the consequences of this transformation to our traditional self-conception.

Situation Calculus

The situation calculus is a language of predicate logic for representing and reasoning about *action* and *change*. This KNOWLEDGE REPRESENTATION language was originally developed by John McCarthy (McCarthy 1963; McCarthy and Hayes 1969) and is commonly used in artificial intelligence for purposes such as predicting the effects of actions on a system's state, PLANNING actions to achieve given goals (Green 1969), diagnosing what events might explain some observations, and analyzing the operation of programs that perform such tasks. Other formalisms used for the same purposes include modal logics such as dynamic logic and various logics for TEMPORAL REASONING (Goldblatt 1987), as well as the event calculus (Kowalski and Sergot 1986).

In the situation calculus, the initial situation of the world or system under consideration is represented by the constant S_0; this is simply understood as a situation where no actions of interest have yet occurred. The situation that results from an action a being performed in a situation s is represented by the term $do(a,s)$. For example, $do(pickup(Rob,Package_1),S_0)$ might represent the situation where the robot *Rob* has performed the action of picking up the object $Package_1$ in the initial situation S_0; similarly, $do(goTo(Rob,MailRoom),do(pickup(Rob,Package_1),S_0))$ might represent the situation where *Rob* subsequently moved to the *MailRoom*. Thus, a situation is essentially a possible world history, viewed as a sequence of actions.

The situation calculus provides a way of specifying what the effects of an action are. For example, the axiom

$$\forall o \forall x \forall s (\neg Heavy(o, s) \\ \rightarrow Holding(x, o, do(pickup(x, o), s)))$$

could be used to state that an agent x will be holding an object o in the situation that results from x performing the action of picking up o in situation s provided that o is not heavy. Note that relations whose truth value depends on the situation, such as *Heavy* and *Holding*, take a situation argument; such relations are called *fluents*. From the above axiom and the assumption $\neg Heavy(Package_1,S_0)$, that is, that $Package_1$ is not heavy initially, one could conclude that $Holding(Rob,Package_1,do(pickup(Rob,Package_1),S_0))$, that is, that *Rob* would be holding $Package_1$ after picking it up in the initial situation. One can also use the situation calculus to represent the preconditions of actions, that is, the conditions under which it is possible to perform the action. Note that a situation calculus model of a system is just a theory in classical first-order logic and thus an ordinary theorem proving system can be used to infer consequences from it. This may be an advantage over the alternative modal logic formalisms.

Some of the most problematic features of commonsense reasoning manifest themselves in reasoning about action. For instance, although it seems reasonable that a model of a system should include an effect axiom for every action affecting a fluent (actions typically affect very few fluents), one should not have to include an axiom for every fluent that remains unchanged by an action (e.g., that going to a location does not change the color of objects). Yet this is just what is required by a straightforward application of logic to such reasoning. Dealing with the resulting mass of axioms is error-prone and computationally costly. This problem of representing succinctly and computing effectively with the "invariants" of actions has been called the FRAME PROBLEM by McCarthy and Hayes (1969) and has been the subject of much recent research (Elkan 1992; Hanks and McDermott 1986; Pylyshyn 1987; Reiter 1991; Sandewall 1994; Shanahan 1997). It has been one of the major motivations for research on nonmonotonic logics where a conclusion may be invalidated by additional assumptions (Reiter 1987). A nonmonotonic logic might attempt to solve the frame problem by representing the "persistence" assumption that says that fluents remain unaffected by actions unless it is known to be otherwise.

Note that some approaches to reasoning about action or processes such as STRIPS-based planning (Fikes and Nilsson 1971) and most work in process control and software

verification may use simple state database update techniques and avoid the frame problem because they assume that one always has complete information about the world state and the effects of actions. But this assumption is rarely justified for intelligent agents (e.g., a robot must acquire information about its environment through its sensors as it operates). This is where a logical approach, with its ability to represent incomplete information, becomes essential.

Another problem viewed as fundamental in the area is called the *ramification problem;* this concerns the effects of actions and how they could be represented so as to avoid having to explicitly mention all indirect effects (e.g., the robot going somewhere changes the location of the packages it is carrying). Finally, there is also the *qualification problem* (McCarthy 1977), that is, how to represent the preconditions of actions when there is in fact a very large number of things that could prevent an action from happening (e.g., the robot's being unable to pick up a package because it is glued to the floor).

The situation calculus continues to be at the center of much knowledge representation research. In recent years, it has been extended to model time and concurrent processes (Gelfond, Lifschitz, and Rabinov 1991; Pinto 1994; Reiter 1996), complex actions (Levesque et al. 1997; De Giacomo, Lespérance, and Levesque 1997), knowledge (Moore 1985), and other mental states. It is also at the core of a recently proposed framework for modeling and programming intelligent agents (Lespérance, Levesque, and Reiter 1999).

Sleep

Sleep is a behavioral adaptation of vertebrate animals with much to teach the cognitive scientist about the relationship of mind to brain. In no other behavioral state are the differences from waking psychology so profound or so clearly tied to the underlying changes in neurophysiology. It is this psychophysiological concomitance that will be emphasized in the account given here of the natural history and neurobiology of sleep.

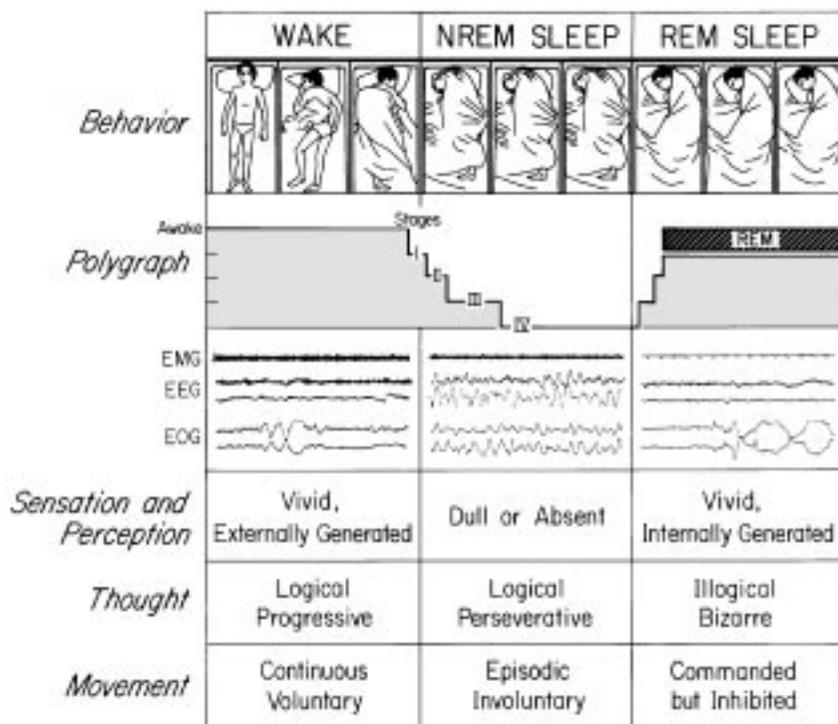
As a behavior, sleep is characterized by (1) a recumbent posture with varying degrees of relaxation of the skeletal musculature; (2) an increase in the threshold of response to sensory stimuli; and (3) a characteristic set of electrographic signs. From an evolutionary point of view sleep is clearly a strategy for energy conservation and for protection from predators since all animals sleep at times and in places that confer a benefit in one or both of these domains. Sleep is distinguished from simple rest, from torpor, and from anesthetic or traumatic unresponsiveness by its active and distinctive brain mechanisms of induction and maintenance, as well as by its ready reversibility.


Figure 1. Sleep cycle schematic. The states of waking, NREM, and REM sleep have behavioral, polygraphic, and psychological manifestations that are depicted here. In the behavioral channel, posture shifts—detectable by time-lapse photography or video—can be seen to occur during waking and in concert with phase changes of the sleep cycle. Two different mechanisms account for sleep immobility: disfacilitation (during stages I–IV of NREM sleep) and inhibition (during REM sleep). In dreams, we imagine that we move, but we do not. The sequence of these stages is schematically represented in the polygraph channel and sample tracings are also shown. Three variables are used to distinguish these states: the electromyogram (EMG), which is highest in waking, intermediate in NREM sleep, and lowest in REM sleep; and the electroencephalogram (EEG) and electrooculogram (EOG), which are both activated in waking and REM sleep, and inactivated in NREM sleep. Each sample record is about 20 sec long. Other subjective and objective state variables are described in the three lower channels. (From J. A. Hobson and M. Steriade (1986), Neuronal basis of behavioral state control. In V. Mountcastle and F. E. Bloom, Eds., *Handbook of Physiology: The Nervous System.* Vol. 4, pp. 701–823.)

As a function of the circadian rhythm generated by the suprachiasmatic nucleus of the hypothalamus, all vertebrate animals show prominent rest-activity cycles with an endogenous period of about one day. Corresponding to the increased complexity of the supervening thalamocortical brain and the greater sophistication of their thermoregulatory capacity, the vertebrate mammals link active sleep control mechanisms in the lower brain stem to the circadian cycle. The result is a stereotyped sequence of events that is coordinated throughout the brain so as to alter every aspect of cognition in a dramatic and sometimes paradoxical fashion. The most surprising aspect of this automatic sequence of events is the regular recurrence of periods of brain activation and rapid eye movement (REM) in sleep that is associated in humans with hallucinoid DREAMING.

Waking, with all of its cognitive components, is an actively maintained brain state in which the thalamocortical circuitry is kept open and receptive to information from within and without by the depolarization of reticular thalamic neurons by cholinergic and aminergic modulatory elements of the brain stem. This activation, together with its specific neuromodulatory effects, renders the forebrain capable of sensation, perception, ATTENTION, orientation, emotion, and stimulus evaluation in terms of past experience, and deliberate action. Whenever the brain stem neuromodulatory influence declines to a critical level, the thalamocortical system tends to oscillate, producing its own endogenous rhythm of electroencephalographic (EEG) spindles and slow waves which are incompatible with waking conscious experience because the inputs to and outputs from the cortex are blocked and intracortical communication is preempted. Cognitive function is thus progressively obtunded as this progressive brain deactivation proceeds in nocturnal sleep. This is reflected by the shift from stage I to stage IV of so-called non-REM (NREM) sleep from the depths of which human subjects are very difficult to rouse. Even when verbally responsive they may then show marked sleep inertia with persistent slow waves in the EEG and an inability to perform even trivially simple cognitive tasks such as serial seven subtraction. This sleep inertia process is greatest in the first two NREM cycles of the night and is intensified in postdeprivation recovery sleep.

Recent POSITRON EMISSION TOMOGRAPHY (PET) studies of human NREM sleep have revealed decreased blood flow in the brain stem reticular formation, the subthalamus, and in frontal cortical regions denoting the massive deactivation of these structures in NREM sleep. Animal studies further confirm this deactivation process at the level of individual neurons, many of which decrease their rate of firing by as much as 50 percent. There is also a 50 percent decline in the output of the wake state neuromodulatory chemicals acetylcholine, norepinephrine, and serotonin. It is for all these reasons that the NREM sleeping brain is such a poor cognitive instrument and it is the carryover of these effects into subsequent waking that so severely impairs problem-solving behavior upon arousal from deep NREM sleep. That this cognitive impairment may nonetheless be beneficial is suggested by the finding that complex DECISION MAKING is more efficient during waking that follows nights with uninterrupted NREM sleep.

After sixty to seventy minutes of deep NREM sleep subjects show a reversal of these oscillatory EEG patterns and the brain spontaneously reactivates. Together with the EEG desynchronization is an activation of the upper brain's

motor systems signaled by flurries of rapid saccadic movements of the eyes (the so-called REMs). However, the output of most of these signals in behavior is blocked by strong inhibition of final common path motor neurons. Postural tone is obliterated and signaled by the complete obliteration of electromyographic activity. Awakening subjects from REM sleep is much easier, they perform most tasks better, and they commonly give longer, more detailed dream reports than following NREM awakenings. Recent PET studies of human REM sleep indicate increased activation (compared even to waking) of the pontine brain stem, the basolateral forebrain, and especially the limbic subcortical and paralimbic cortical structures, while the more dorso-frontal cortical areas remain inactivated. This finding has a strong bearing on the strongly emotional character and the bizarreness of human dreaming because it indicates a bottom-up activation of the limbic brain with the release of emotions and related memories which must be integrated in conscious experience without the benefit of executive cortical guidance. Cellular-level studies in animals confirm the activation inferences of human PET studies for the pontine brain stem and other subcortical areas. In addition they describe a dissociation between cholinergic neuromodulation (which equals or exceeds that of waking) and noradrenergic and serotonergic neuromodulation which falls to near-zero levels.

These paradoxical findings show that the brain activation patterns of waking and REM sleep are actually quite different even though they are indistinguishable from an EEG point of view. They also shed light on the differences in cognition, especially the disorientation, the defective reasoning and judgment, and the poor memory during and after dreaming.

Subjects who are deprived of either NREM or REM sleep (or both) show progressively impaired cognitive capacities which may progress to psychotic disorganization if they can be kept awake despite the marked increase in their intrinsic drive to sleep. This finding indicates that sleep confers critical benefits to the brain and to cognitive capability. These benefits are yet to be fully elucidated but may relate to the dramatic alterations in neuromodulatory balance alluded to above. From a commonsense point of view, the hypothesis crying out for critical test is that sleep benefits cognition not only by cerebral energy conservation but also by a more specific and profound rest of the very chemical systems most critical to wake state cognition.

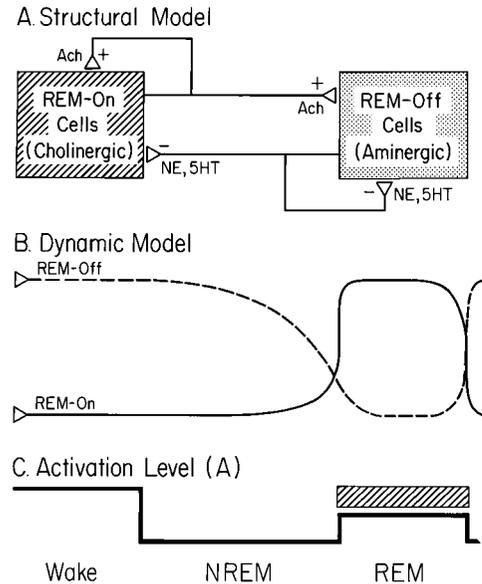
One of the most attractive hypotheses regarding the cognitive benefit of sleep is that it enhances LEARNING and MEMORY. Many experiments have shown increases in sleep to be associated with the mastery of learning tasks in both animal models and human subjects. Some of these increases are immediate while others are delayed. While most of these studies have emphasized REM sleep, others have presented evidence for a two-stage process with NREM sleep serving to iterate recently learned material followed by its consolidation in REM. This theory is congruent with the differential subjective experience of the two states of sleep: during NREM mental activity tends to be a perseverative and nonprogressive rumination regard-


Figure 2. Reciprocal Interaction. (*A*) Structural model. REM-on cells of the pontine reticular formation are cholinoceptively excited and/or cholinergically excitatory (ACH+) at their synaptic endings (open boxes). Pontine REM-off cells are noradrenergically (NE) or serotonergically (5HT) inhibitory (−) at their synapses (filled boxes). (*B*) Dynamic model. During waking the pontine aminergic (filled box) system is tonically activated and inhibits the pontine cholinergic (open box) system. During NREM sleep aminergic inhibition gradually wanes and cholinergic excitation reciprocally waxes. At REM sleep onset aminergic inhibition is shut off and cholinergic excitation reaches its high point. (*C*) Activation level (A). As a consequence of the interplay of the neuronal systems shown in A and B, the net activation level of the brain (A) is at equally high levels in waking and REM sleep and at about half this peak level in NREM sleep.

ing recent events; in contrast, REM sleep mentation melds both recent and remote memories in bizarre scenarios that are often associated with strong, usually unpleasant, emotion, suggesting the possibility that emotional salience is a feature of the consolidation process. The specification of these hypotheses in cellular and molecular terms presents cognitive neuroscience with one of its central challenges. Because so much is known about the neuromodulatory underpinnings of the waking and NREM and REM sleeping states, a unique opportunity exists to unite neurobiological sleep research with classic experimental psychology, solving a central problem of both fields simultaneously.

That the cognitive and more general energetic benefits of sleep may have a unitary underlying mechanism is suggested by animal experiments which have consistently demonstrated reciprocal impairment (by deprivation) and enhancement (by normal or recovery sleep) of both thermoregulatory and cognitive functions. So critical is sleep to the life of the mind and the body that its loss is at first deleterious and later ultimately fatal to both.

Smell

The olfactory system is a phylogenetically ancient sensory system capable of detecting and discriminating among a vast number of different odorants. Olfaction is critical to the survival of a variety of lower animals ranging from insects to mammals, while in humans it has been considered less important than the other senses. Understanding how the olfactory system encodes and decodes information is not an easy task, given the lack of a clear physical energy continuum to characterize and control stimulus presentation, like wavelength for COLOR VISION (see VISUAL ANATOMY AND PHYSIOLOGY) or frequency for auditory pitch (see AUDITION and AUDITORY PHYSIOLOGY). The situation is made even more complex by the findings that similar chemical substances can sometimes have quite different odors and some substances with altogether different chemical formulas can smell alike.

The olfactory organ of vertebrates is a complex structure designed to collect odorant molecules and direct them to the sensory neurons. Although the chemoreceptive endings and neural projections of the olfactory nerve are primary to the sense of smell, other cranial nerves are involved, namely, the trigeminal, glossopharyngeal, and vagus. These accessory cranial nerves possess at least some chemoreceptive endings which line the nose, pharynx, and larynx, giving rise to the pungent or irritating quality often experienced as part of an odor sensation.

For much of the animal kingdom olfaction is basic to the maintenance of life, regulating reproductive physiology, food intake, and social behavior. In fact, the essence of ANIMAL COMMUNICATION is chemical, relying on odors produced by body glands, feces, and urine. For example, the male silk moth uses olfactory cues to find his mate, as does the adult salmon to return to the place where it was spawned. Many mammalian species, ranging from deer to cats and dogs, mark their territory with urine or other secretions. These chemical messages provide the animal sampling the scent mark with information regarding whether it came from a conspecific, if the depositor was male or female, dominant or submissive, and even its reproductive status.

There is also a dependency of reproductive and sexual behavior on olfactory cues. Introducing the odor of a male mouse or his urine can induce and accelerate the estrus cycle of a female. Moreover, appropriate odor cues from a female are important in attracting the male's interest during estrus and promoting copulation. In some species sexual dysfunction and even retarded development of the sex organs results when olfaction is compromised.

In humans, the sense of smell is considered less critical to survival than the other special senses, although the detection of stimuli such as smoke, gas, or decaying food prevents bodily harm. Instead, civilized society appears to emphasize the importance of olfaction on the quality of life. People attempt to modify attractiveness by adding perfumes to their bodies and incense to their homes. Consider the plethora of commercial products for use against "bad" odors. One instance in which smell plays a major role is in flavor perception and the recognition of tastes. Much of what people think they TASTE they actually smell and a large percentage of people coming to chemosensory clinics complaining of taste problems actually have smell dysfunction (consider what happens to food appreciation when a cold strikes). In fact, disorders of the sense of smell can often be profoundly distressing, as well as harbingers of more general disease states.

Although not as extensively documented as in animals, a relationship between olfaction and sex seems likely in humans. Olfactory acuity in women seems better at ovulation than during menstruation and there is evidence that olfactory cues (i.e., human pheromones) among women can synchronize the menstrual cycle and that odors serve as attractants to the opposite sex.

In vertebrates, olfactory receptor neurons (ORNs) differ in the number and profile of odorants to which they respond (see NEURON). For example, one electrophysiological study of single ORN responses to twenty different stimuli demonstrated that individual neurons responded to as few as two of the odorants within the panel. Furthermore, despite sampling over fifty neurons, each had a distinct odorant response profile. Thus, ORN responses define the range of odorants that can elicit a response in a given cell (termed its molecular receptive range [MRR], analogous to the spatial receptive field in the visual system). Emerging evidence further suggests that a cell's MRR may reflect interactions with particular ligand determinants (compounds with similar

organization of carbon atoms or functional groups). Accordingly, if ORNs are to be classified as to type on the basis of their response to the odorant universe, then the number of such types must likely exceed fifty.

Recently, a large olfactory-specific gene family (numbering 500 to 1000 genes in humans) has been identified. The proteins encoded by these genes are expressed in ORNs and are considered to be putative odorant receptors (PORs) based on their structural and sequence homology with other known G protein–activating receptors (and G protein cascades have been implicated in the transduction of olfactory stimuli). At present, these PORs remain functionally anonymous. Nonetheless, the extremely large size of the gene family is considered strong evidence that these are odorant receptors, fulfilling the criterion of diversity to interact with an immense number of different odorants.

In other sensory systems (i.e., audition, vision, and somesthesis; see HAPTIC PERCEPTION), receptor cells encode specificity about the sensory stimulus by virtue of their exact placement in the receptor sheet. In contrast, the receptor sheet in olfaction does not form a spatial map about the environment. Instead, as previously noted, the responsivity of an ORN may result from the affinity of its receptor for a particular odorant ligand. So how is this molecular information mapped into the nervous system? Studies of the ensemble properties of the olfactory epithelium suggest that odorant quality information is encoded in large-scale spatial patterns of neural activity. That is, direct presentation of odorants to the exposed olfactory epithelium reveal intrinsic spatial differences in the sensitivity to different odorants across this neural tissue. The biological basis for these intrinsic patterns likely stems from the differential distribution of POR expression across the epithelium. Neurons expressing a particular POR are segregated to one of four broad nonoverlapping zones. Within a zone some PORs are dispersed throughout the anterior-posterior extent of the epithelium, while others are clustered in more limited areas.

Despite the fact that the vertebrate olfactory system does not process information about odors by virtue of a single type of ORN's placement in the receptor sheet, a degree of rhinotopy (analogous to retinotopy in the visual system) does exist in the organization of the central projection. The foundation for this rhinotopy lies in the topographical organization of bulbar glomeruli (neuropil structures comprised of ORN axon terminals and the distal dendrites of mitral, tufted, and periglomerular cells) in relation to the expression of POR type. An entire subset of ORNs expressing a particular POR send their axons to converge on a single glomerulus in the olfactory bulb. As a result, the odorant information contained in the large-scale differential activation of subsets of ORNs can be encoded by producing differential spatial patterns of activity across the glomerular layer of the olfactory bulb. This activity is further sharpened in the relay neurons of the bulb via complicated local circuits that act both locally and laterally on the signals impinging on the bulb.

Exactly how the aforementioned parameters of neural excitation lead to perception is unknown. However, recent work combining animal PSYCHOPHYSICS with neurophysio-logical techniques suggest a predictive relationship between the large-scale spatial patterning of neural excitation and odorant quality perception.

Social Cognition

About the time that experimental psychology was trying to solve the problem of rat behavior, social psychology was trying to solve the problem of mind, and for several decades it stood virtually alone in its attempt to develop an experimental science of mental phenomena such as belief, judgment, inference, attitude, affect, and MOTIVATION (e.g., Allport 1954; Asch 1952; Heider 1958; Lewin 1951). Defined broadly, *social cognition* refers to those aspects of mental life that enable and are shaped by social experience, and in this sense, social cognition is among social psychology's perdurable concerns.

Although social psychology has been a cognitive science for the better part of a century, it was nonetheless profoundly influenced by the "cognitive revolution" that took place in its neighbor discipline during the 1960s and 1970s. Defined narrowly, *social cognition* refers to an intellectual movement (circa 1975) that borrowed the techniques, theories, and metaphors of the new cognitive psychology and brought them to bear on traditional social psychological problems, such as attitude structure and change (see COGNITIVE DISSONANCE), causal attribution (see ATTRIBUTION THEORY; CAUSAL REASONING), social inference (see JUDGMENT HEURISTICS), CATEGORIZATION and STEREOTYPING, SELF-KNOWLEDGE and self-deception (see SELF), and the like. The social cognition movement was characterized by (a) its allegiance to the information processing metaphor, which suggested that mental phenomena are properly explained by describing a sequence of hypothetical operations and structures that might produce them; (b) its emphasis on MENTAL REPRESENTATION with an attendant lack of emphasis on motivation, emotion, behavior, and social interaction; (c) its conviction that social cognition was a special case of cognition, and that theories of the former should thus be grounded in theories of the latter; and (d) its penchant for highly controlled experimental methods that maximized internal validity rather than ECOLOGICAL VALIDITY.

The movement was enormously influential, and in just a few years it came to dominate social psychology's intellectual landscape, giving rise to new journals, new societies, new graduate training programs, and new textbooks. Suddenly, social psychologists were theorizing about activation and inhibition, arguing about schemas and exemplars, manipulating cognitive load and search set size, and measuring interference effects and reaction times. The social cognition movement brought social psychology into the experimental mainstream, and for a while it looked as though other approaches within social psychology might soon be obsolete. But as enthusiasms often do, this one exceeded its warrant in at least two ways. First, the new experimental techniques did indeed provide more precise answers than social psychologists were used to receiving, but to smaller questions than social psychologists were used to asking. Cognitive psychology was able to set aside the problems of motivation, emotion, and action while concentrating on more tractable issues, but these problems were among social psychology's core concerns. To ignore them was to let the method pose the question rather than deliver the answer, and to many social psychologists, that seemed to be putting things back end first. Second, the social cognition movement was predicated on the assumption that social and nonsocial cognition are only superficially distinct, and that a single theory could thus explain both instances quite nicely. Alas, it is becoming increasingly clear that although

all cognitive processes do share some basic, defining features, the mind is not an all-purpose information processing device that understands social objects in the same way that it understands tomatoes, giraffes, and nonsense syllables. Rather, it seems to be a family of highly specialized modules, many of which are dedicated explicitly to social tasks (see DOMAIN SPECIFICITY and MODULARITY OF MIND). The human brain is the evolutionary adaptation of an organism whose survival is largely dependent on its relations with others, and thus it is not surprising that special functions should develop to parse, understand, and remember the social world (see EVOLUTIONARY PSYCHOLOGY and MACHIAVELLIAN INTELLIGENCE HYPOTHESIS). In some ways, then, the social cognition movement's attempt to reduce social cognition to more general information-processing principles was a step in the wrong direction.

Like most intellectual movements, the social cognition movement's early excesses have been forgotten as its considerable wisdom has been incorporated into the mainstream. Indeed, the phrase *social cognition* no longer has much discriminating power because virtually all social psychologists are comfortable with the information-processing metaphor, fluent in its languages, and familiar with its techniques. The wall between social and cognitive psychology has never been thinner, and the two disciplines are distinguished more by topical emphasis and aesthetic sensibility than by theoretical orientation. Nonetheless, their separate histories allow each to play an important role for the other. Social psychology has always been driven by intellectual problems rather than by methodological innovations, which means that social psychologists have often had to look to their neighbors for new scientific tools and new conceptual metaphors. Cognitive psychologists have given both in abundance. On the other hand, social psychology's problem-focus has allowed it to maintain a steady orbit around a core set of issues and resist the faddish forces that remade experimental psychology several times in a single century. Social psychology is slow to respond to the zeitgeist and quick to retreat when the paradigm de jour threatens to ignore, set aside, or define away the problems that animate the discipline. As such, it serves as cognitive psychology's conscience, emphasizing the rich social context in which cognition evolved and occurs, keeping issues such as emotion and motivation on the table despite the daunting complexities they present, and insisting that cognition be thought of as a prelude to action and interaction rather than as an end unto itself.

Fiske and Taylor (1991) provide an excellent primer on social cognition; Higgins and Bargh (1987) and Fiske (1993) provide timely reviews of the field; Ostrom (1984) and Landman and Manis (1983) provide early analyses of the social cognition movement; and Devine, Hamilton, and Ostrom (1997) provide a useful retrospective. Extended treatments of most topics in social cognition can be found in Gilbert, Fiske, and Lindzey (1998).

Social Cognition in Animals

Individuals in many animal species do not interact at random but have qualitatively different social relationships with different members of their group. The most stable, long-term bonds are typically found among matrilineal kin (paternity is generally unknown) and have their genesis in the close relationships formed between a mother and her offspring (Kummer 1971). For example, immature female African elephants interact at high rates with their mother and, through their mother, with their matrilineal aunts, siblings, and cousins. Matrilineal kin remain together throughout their lives, tolerating one another's proximity and cooperating to defend feeding areas against other matrilines (Moss 1988).

Old World monkeys, like the macaques of Asia or the baboons and vervet monkeys of Africa, are organized along similar lines but differ in the size of their social units. Groups of baboons may contain over one hundred individuals. Each group contains several matrilineal families. Immature animals acquire dominance ranks immediately below those of their mothers, and families are arranged in a linear rank order so that all members of family A rank above the members of family B, who rank above the members of family C, and so on. As in a Jane Austen novel, social interactions follow two general patterns. Most cooperative behavior (grooming, play, tolerance at feeding sites, and the formation of alliances) occurs among close kin, but cooperative behavior between the members of different matrilines can arise when a middle- or low-ranking individual attempts to groom, play, or form an alliance with the member of a higher-ranking family (for reviews, see Smuts et al. 1987).

The study of social cognition in animals attempts to identify the mechanisms that underlie these interactions. It is now clear that individuals in many species know a great deal about their own social relations. They recognize others as individuals, remember who has cooperated with them in the past, and adjust their future behavior accordingly. This is not surprising, given what is known about the learning and memory of animals in the laboratory, where they have been tested with objects. Social cognition in animals is most striking, however, when we consider what individuals know about the social relations of others in their group.

One hypothesis, derived from traditional learning theory, holds that animals develop their own social relationships and learn about the relationships of others through classical and operant CONDITIONING. Individuals recognize and respond differently to one another because of past experience, or because they have formed specific associations between particular individuals. A second view holds that social relationships in many species—particularly long-lived animals like elephants, parrots, dolphins, and primates—cannot be explained unless we assume that individuals differentiate among classes of relationships and make use of mental representations similar to our concepts of "kinship," "closely bonded," or "linear dominance hierarchy." These hypotheses have been tested most often on monkeys and apes.

In order to understand a dominance hierarchy or predict which individuals are likely to form alliances with each other, a monkey must step outside its own sphere of interactions and recognize the relationships that exist among others. Such knowledge can be obtained only by observing interactions in which one is not involved and making the appropriate inferences. There is, in fact, growing evidence that monkeys do possess knowledge of other animals' social relationships and that such knowledge affects their behavior. For example, in a test of individual recognition a juvenile vervet monkey's scream was played from a concealed loudspeaker to three adult females, one of whom was the juvenile's mother. As expected, the mother responded most strongly; however, even before this occurred the control females looked at the mother. Apparently, control females associated a particular scream with a particular juvenile and this juvenile with a particular adult female. They acted as if they recognized the kin relations that exist among others (Cheney and Seyfarth 1990).

Following aggression, a monkey may "reconcile" by engaging in friendly behavior with its former opponent. A fight may also cause a victim to "redirect" aggression and threaten a third, previously uninvolved individual. In both cases, individuals act as if they recognize their opponent's close kin. When animals reconcile they do so either with their former opponent or with one of their opponent's close matrilineal relatives; when they redirect aggression they do so most often against a close relative of their prior opponent (reviewed in Cheney and Seyfarth 1990; de Waal 1996).

Monkeys can also recognize the dominance ranks of others. When female vervet monkeys compete for grooming partners, competition is greatest for the highest-ranking female, next for the second-ranking female, and so on. When a high-ranking female approaches two lower-ranking individuals and interrupts their grooming, it is the lower-

ranking of the two who is much more likely to move away (Cheney and Seyfarth 1990).

It is widely accepted, then, that nonhuman primates—and very likely many other animals—classify others according to their patterns of association and recognize the friendships and enmities that exist among individuals other than themselves. Humans, however, go further and classify different types of relationships into more abstract, superordinate categories like "friends," "family," and "enemies" that are independent of the particular individuals involved. Do social concepts of this sort exist in any animal species?

Dasser (1988) studied social knowledge in longtailed macaques that were members of a group of forty individuals living in a large outdoor enclosure. She trained three adult females to leave the group temporarily, enter a test room, and view slides of other group members. When shown two slides, one of a mother and her offspring and the other of two unrelated group members, subjects were rewarded for pressing a button below the mother-offspring slide. After training with five different slides of the same mother and her juvenile daughter, subjects were tested using fourteen novel slides of different mothers and offspring paired with fourteen novel unrelated alternatives. Mother-offspring pairs varied widely in their physical characteristics: they included mothers with infant daughters, mothers with juvenile sons, and mothers with adult daughters. Nonetheless, in all fourteen tests the subjects correctly selected the mother-offspring pair. They behaved as if they recognized a concept of "mother and offspring" that was independent of the particular individuals involved.

We have, as yet, no idea how monkeys might represent social relationships in their mind. They may use physical resemblance as a cue, because members of the same matriline often (but not always) look alike, or they may use rates of interaction. The latter seems unlikely, however, because kin do not always interact at higher rates than non-kin. Mothers and infants, for example, interact at high rates whereas mothers and older sons do not. Both were classified by Dasser's subjects as falling within the same category. Similarly, although bonds within matrilineal kin groups can be extremely variable (depending, for example, on the ages and sex of family members), monkeys nevertheless treat competitive interactions as pitting one family against another (Cheney and Seyfarth 1990).

In sum, monkeys seem to use a metric to classify social relationships that cannot be explained simply in terms of physical features or the number and type of interactions. To do this, they must compare relationships according to an underlying relation that has been abstracted from a series of interactions over time. Monkeys take note of the elements that make up a relationship (grooming, alliances, etc.), then make judgments of similarity or difference not by comparing specific elements but by comparing the different relationships that these elements instantiate. By this view, conditioning and the formation of mental representations are not *alternative* mechanisms underlying social cognition; instead, they interact, with the former helping to give rise to the latter (see also PRIMATE COGNITION).

The hypothesis that monkeys classify relationships into relatively abstract categories receives additional support

from experiments indicating that vervet and diana monkeys classify vocalizations into categories according to their meaning. When asked to compare two vocalizations, vervets judge them to be similar or different not according to their acoustic properties, which are measurable and concrete, but according to their referents, which are more abstract (Seyfarth and Cheney 1992). Female diana monkeys give their characteristic leopard alarm when they hear either a leopard's growl, a male diana monkey's leopard alarm, which is acoustically different from their own, or the shriek of a duiker, a small antelope that is often hunted by leopards (Zuberbuhler, Noe, and Seyfarth 1997). These results suggest that, in the mind of a female diana monkey, some sort of MENTAL REPRESENTATION of a leopard serves as an intervening variable between hearing one type of call and producing another (see also ANIMAL COMMUNICATION).

It has been suggested that natural selection has acted with particular force in the domain of social interaction (Jolly 1966; Humphrey 1976), and that, as a result, the cognitive mechanisms that underlie social interactions are different from those that underlie, for example, foraging or ANIMAL NAVIGATION. The processing of knowledge about social relationships, it is argued, constitutes a mental module, much like the processing of language or music (Fodor 1983; Jackendoff 1987; Cheney and Seyfarth 1990; see also EVOLUTIONARY PSYCHOLOGY). Despite great theoretical interest, however (e.g., Byrne and Whiten 1988), this view is largely untested.

Social Play Behavior

Recently, the scientific study of play behavior has undergone many significant changes. New data are forcing people to give up old ideas and set ways of thinking about this phenomenon. Most researchers recognize the importance of rigorous interdisciplinary collaboration in play research (Pelligrini 1995; Bekoff and Byers 1998; Burghardt 1999), and the interactions among those studying humans and nonhumans are producing exciting new results. Currently, workers in many areas are conducting detailed theoretical, observational, and experimental analyses of play in mammals (including humans) and birds. (Using criteria that are employed to characterize play in mammals and birds, it appears that some reptiles might also play [Burghardt 1999].) They are concerned with such topics as evolution, ecology, development, social communication, individual well-being, neurobiology, LEARNING, and cognition (for references see Bekoff and Byers 1981, 1998; Fagen 1981; Smith 1982 and commentaries, 1984; Martin and Caro 1985; Burghardt 1999; Bekoff and Allen 1992, 1998; Allen and Bekoff 1994, 1997; Brown 1998; Pelligrini 1995; Sutton-Smith 1998).

Because social play (hereafter play) is a widespread phenomenon, especially among mammals, it offers the opportunity for comparative work on animal cognition, including such areas as intentionality, communication, and information sharing (Bateson 1956; Bekoff 1998; Bekoff and Allen 1992; Allen and Bekoff 1994, 1997). Through difficult to define and to study, play is generally recognized as a distinctive category of behavior. Difficulties with functional definitions led Bekoff and Byers (1981: 300–301; see also Martin and Caro 1985) to offer the following definition: "*Play* is all motor activity performed postnatally that *appears* [my emphasis] to be purposeless, in which motor patterns from other contexts may often be used in modified forms and altered temporal sequencing. If the activity is

directed toward another living being it is called *social play*." This definition centers on the structure of play sequences—what individuals do when they play—and not on possible functions of play.

Why engage in social play? Despite physical risks (and perhaps other costs) associated with play, many individuals persistently seek it out. A major question centers on why play has evolved and what benefits outweigh the energy and risk costs of play. Play may serve a number of functions simultaneously (for example, socialization, exercise, practice, or cognitive development) and there are species, age, and sex differences. Functional (evolutionary) accounts are often tied to analyses of what individuals do when they play. Although many agree that play seems to have something to do with motor development, or with the development of cognitive skills that support motor performance, hard evidence is scant and opinions are divided. One important theme stemming from recent comparative research is that functional accounts of play resist being pigeonholed into simple and misleading summary statements. In the past, for example, play-fighting was considered important in learning fighting skills that would be used in adulthood or for physical training. Although in some species play may be important for the development of certain skills, in others this might not be the case. For example, play-fighting does not seem to be important in the development of motor training for fighting skills in some rats (Pellis and Pellis 1998), but others (Biben 1998; Heinrich and Smolker 1998; Miller and Byers 1998; Thompson 1998; Watson 1998) have shown that play may be important in the development of motor training, cognitive/motor training, or in the development of other social skills (social competence) in birds and mammals, including humans.

Questions dealing with the immediate causes and benefits of play also need more attention. Research on the neurobiology of play also centers on possible causes (Byers 1998). For example, it appears that dopamine, serotonin, and norepinephrine are important in the regulation of play, and that a lot of the brain is active during play (Siviy 1998). Based on these data, some have suggested that play may facilitate coping with environmental stressors and be important in coordinating an organism's response to stress. These data also provide the basis for more informed discussions of the role of play in learning and promoting creativity. Neurobiological data are also essential for assessing hypotheses about whether play is a pleasurable activity for nonhumans as it seems to be for humans, and there is some neurochemical evidence that suggests that it is. In light of these neurobiological data, scientists who study play might be less resistant to explanations that appeal to enjoyment as a motivator for the activity.

Communicative and cognitive aspects of play also are receiving attention. When individuals play they typically use action patterns that are also used in other contexts, such as predatory behavior, antipredatory behavior, and mating. These action patterns may not be intrinsically different across different contexts, or they may be hard to discriminate even for the participants. To solve the problems that might be caused by confusing play with mating or fighting, many species have evolved signals that function to establish and to maintain a play "mood." In most species in which play has been described, individuals have to communicate that "this is play, not fighting, mating, or preying," and there are data that show that certain signals are used to communicate "what follows is play" or "let's keep playing no matter what I just did or plan to do." For example, in infant coyotes, wolves, and domestic dogs, a behavior pattern called the "play bow" is not performed randomly, but rather immediately precedes or immediately follows behavior patterns that can be misinterpreted (for example, biting accompanied by vigorous side-to-side shaking of the head; Bekoff 1995). Suffice it to say, in most species in which play has been described, play-soliciting signals (or play markers) appear to foster some sort of cooperation between players so that each responds to the other in a way consistent with play and different from the responses the same actions would elicit in other contexts. There is little evidence that play signals are used to deceive others.

Bekoff and Allen (1998) point out that the strongly cooperative nature of much social play makes it a useful model for study of the communication of intention. For example, when two individuals engage in play-fighting, there is a risk of injury to each, especially if one switches from play-fighting to real fighting. Somehow, the playful and cooperative nature of the interaction is maintained, even though the motor acts themselves may closely resemble aggression. How do individuals "read" play intention in a conspecific? Cooperative social play may involve rapid exchange of information on intentions, desires, and beliefs. Discussions of self-handicapping (individuals do not bite or hit others as hard as they can) and role-reversals (dominant individuals allow subordinate individuals to dominate them) in play by individuals of many taxa can also inform cognitive inquiries. We can also ask what are the consequences of failure to play for individuals of species in which cooperative social play is a form a social cognitive training. By reviewing the lives of homicidal and antisocial personalities and the influence of diseases on early human behavior, Brown (1998) presents a set of interesting correlations showing that play in childhood is required for the social integration of humans. Data on nonhumans also support this idea.

The flexibility and versatility of play make it a good candidate for comparative and evolutionary cognitive studies. These data may provide important insights into what might be going on in an individual's mind.

Sociobiology

The term *sociobiology* (*behavioral ecology* and *evolutionary ecology* are synonyms) refers broadly to the application of the principles of Darwinian evolutionary theory to the study of behavior. It grew out of the integration of classical ethology (the naturalistic study of animal and human behavior), population ecology, and population genetics during the 1960s and early 1970s.

The fundamental breakthrough at the heart of sociobiology was provided by a solution to the problem of ALTRUISM. Ever since DARWIN, it had been recognized that altruistic behavior (such as alarm-calling) whereby an individual incurs a potentially life-threatening cost while others benefit creates an anomaly for Darwinian thinking. Any gene for such behavior would soon be eradicated from the population because its carriers would die prematurely, leaving few descendants, while "cheats" who exploited the behavior of the altruist would survive and leave many descendants. W. D. Hamilton provided the solution to this problem in a pair of seminal papers published in 1964. He realized that the anomaly evaporates when the unit of evolutionary accounting is the gene and not the individual: relatives share a proportion of their genes in common by virtue of the fact that they inherit them from the same common ancestor. A gene for altruism can thus evolve whenever the benefit to the altruist via its relatives is greater than the cost it bears through lost personal reproduction, even if the altruist dies in the process.

This observation is the basis of *kin selection theory* and provides the single most important theorem in sociobiology, known as *Hamilton's rule.* This in effect points out that the genetic fitness of a gene (loosely, the effectiveness with which it replicates itself in future generations) is made up of two components: the number of copies transmitted to the next generation through an individual carrier's own reproduction, and the number of copies of the same gene transmitted to the next generation through the additional reproduction achieved by his or her relatives as a direct result of that individual's actions. This combined measure is referred to as *inclusive fitness.*

The crucial assumption underlying this new perspective is that natural selection favors those behaviors that allow genetic fitness to be maximized (the so-called *selfish gene* perspective). However, the Darwinian formula for natural selection does not contain within it any explicit reference to DNA or genes (neither of which were known in the mid-nineteenth century). Rather, the modern theory of neo-Darwinism is built on the integration of Darwin's theory of natural selection with Mendel's theory of inheritance. Because Mendel's theory is concerned with the heritability of characters (or phenotypes) and not genes as such, it follows that anything that can faithfully copy itself is in principle a Darwinian entity and will evolve subject to the laws of natural selection. Learning and the transmission of cultural rules by imitation thus come under the remit of sociobiology as bona fide Darwinian processes.

It is important to appreciate that sociobiology makes no presuppositions about the genetic bases of behavior. The sociobiological perspective is concerned with functional explanations of behavior and centers on the question of whether an organism's behavior (or traits) are designed to maximize inclusive fitness. Although an intrinsically interesting question in itself, the issue of whether the mechanism of inheritance is genetic or learning is irrelevant to the sociobiological approach. Evolutionary theory assumes that organisms are locked into a perpetual scramble for representation in the next generation, but an important distinction thus has to be drawn between the processes involved at the level of the "gene" (the notional unit on which natural selection acts) and the behavioral mechanisms that implement these processes at the level of the individual. One of the central principles of evolutionary biology is that the "selfishness of genes" (the gene's imperative to replicate itself) may be expressed as cooperativeness at the level of the individual.

This important distinction lies at the root of many of the controversies that were generated by the emergence of sociobiology. Many critics assumed, for example, that sociobiology assumes that all behavior is genetically determined. However, such a view would be both biologically unrealistic and would miss the very insight that lies at the heart of Darwinian evolutionary theory. Nonetheless, the adoption of evolutionary ideas in disciplines outside of biology has sometimes resulted in views that approach a form of strict genetic determinism more strongly than is either justified or necessary.

These controversies aside, the extent to which evolutionary thinking revolutionized the understanding of animal behavior during the 1970s justifiably led to its being referred to as the *sociobiological revolution.* The explanatory power of its theories explained many previously puzzling phenomena, and their predictive power generated many new research programs in both the field and the laboratory. The sociobiological approach has widely been acknowledged as being especially successful in explaining foraging behavior, conflict resolution, mate choice patterns, and parental investment decisions in animals, as well as many aspects of communication and signaling.

The early success of the application of these ideas to the study of animal behavior inevitably raised the possibility of their being applied to human behavior. The early sociobiological discussions of human behavior were based on very limited empirical evidence, and were much criticized for their naivety as a result. However, since the mid-1980s, there has been a dramatic growth in the number of empirical studies. These included studies of both traditional societies, contemporary postindustrial Western societies, and historical societies, with the main focus being on mate choice, reproductive decisions, inheritance patterns, foraging strategies, and cultural evolution mechanisms (see Betzig, Mulder, and Turke 1988; Smith and Winterhalder 1992).

More recently, a second dimension has developed out of human sociobiology that focuses more on the cognitive mechanisms that underpin behavior. Because the sociobiological perspective was concerned exclusively with functional explanations of behavior (the purpose that behavior serves in the life history of the individual organism), little attention was given to the cognitive mechanisms underpinning these behavioral processes. A growing interest in these

issues, informed by an evolutionary perspective, now makes it possible to distinguish two subdisciplines, at least in the context of research on humans: evolutionary anthropology (which focuses on the adaptiveness of individuals' behavioral decisions) and EVOLUTIONARY PSYCHOLOGY (which focuses on the cognitive mechanisms involved in the making of such decisions). The two subdisciplines are divided by the issue of whether contemporary human behavior is ever functionally adapted.

Evolutionary psychologists argue that because the cognitive mechanisms that guide behavior evolved during the Pleistocene and have been overtaken by rapid changes in culture and technology, the behavior they generate will commonly be nonadaptive: in effect, we operate with Stone Age minds in a Space Age environment. Instead, evolutionary psychologists typically focus on the design features of human cognition that give rise to universal patterns of behavior that are true of all humans (for some examples, see Barkow, Cosmides, and Tooby 1992). In contrast, evolutionary anthropologists argue that many aspects of behavior are still functionally adaptive, and most of their research is directed to empirical tests of the functional consequences of behavioral decisions. They focus on the adaptive flexibility of behavior at the level of the individual (for examples, see Betzig, Mulder, and Turke 1988; Smith and Winterhalder 1992).

Although it is no doubt true that cognition constrains behavior, it is a purely empirical question as to whether or not our cognitive mechanisms are sufficiently flexible to operate effectively in the modern world. The wealth of studies demonstrating that human and animal behavior is functionally adaptive despite radically changed environments undermines the strong version of the evolutionary psychologist's position, though there must surely be some aspects of behavior that are now maladaptive in this sense.

Spatial Perception

As we move through the world, new visual, auditory, vestibular, and somatosensory inputs are continuously presented to the brain. Given such constantly changing input, it is remarkable how easily we are able to keep track of where things are. We can reach for an object, or look at it, or even kick it without making a conscious effort to assess its location in space. Spatial perception is the faculty that allows us to do so. Sensory and motor information are used together to construct an internal representation of the space we perceive. The nature of this representation and the neural mechanisms underlying it have become a topic of great interest in cognitive neuroscience (Stein 1992; Milner and Goodale 1995). Both neuropsychological studies in humans and neurophysiological studies in nonhuman primates have yielded important insights into how the brain builds spatial representations (Colby 1998).

The dramatic impairments of spatial perception that result from damage to the parietal lobe indicate that this part of cortex plays a critical role in spatial functioning. The most striking of these deficits is the tendency to ignore or neglect objects in particular regions of space. A patient with hemineglect as a result of a right parietal lobe lesion may fail to notice objects on the left, including food on the left side of a plate or words on the left side of a page. Two aspects of neglect are particularly interesting with respect to spatial perception and representation.

First, neglect occurs in all sensory modalities (Bisiach and Vallar 1988). The multimodal nature of neglect indicates that what has been damaged is not simply a set of sensory maps but a high-level, supramodal representation of space. Second, neglect occurs with respect to a variety of spatial reference frames. A patient with right parietal damage is typically unaware of objects on the left side of space but left may be defined with respect to the body, or with respect to the line of sight, or with respect to the object to which the patient is attending. Moreover, these spatial impairments are dynamic, changing from moment to moment in accord with changes in body posture (Moscovitch and Behrmann 1994) and task demands (Behrmann and Tipper 1994). (See VISUAL NEGLECT and MODELING NEUROPSYCHOLOGICAL DEFICITS.)

The variety of deficits observed following parietal lobe damage in humans suggests that parietal cortex contains more than one kind of spatial representation. To understand more precisely how parietal cortex contributes to spatial perception and action, several groups of investigators have recorded from single neurons in alert monkeys trained to perform spatial tasks. Physiologists have sought to specify the sensory and motor conditions under that parietal neurons are activated, using tasks that typically require a hand or eye movement toward a visual target. This work in monkeys has provided direct evidence that parietal cortex contains multiple representations of space (Colby and Duhamel 1991, 1996). Parietal areas differ in their inputs, in the modalities and stimulus features represented, and in their outputs, projecting to separate regions of frontal cortex and subcortical structures, such as the superior colliculus. Of particular interest are parietal areas that contain bimodal somatosensory and visual neurons. These are obvious candidates for integrating information from different modalities into unified representations of space. The specific response properties in these areas and their projections to premotor cortex suggest that one function of parietal cortex is to perform the sensory-to-motor-coordinate transformations required for generating action. Parietal projections to posterior cingulate and parahippocampal cortex may also provide the sensory information essential to the construction of allocentric spatial maps in the HIPPOCAMPUS (O'Keefe and Nadel 1978). The emerging consensus is that neurons in separate areas within parietal cortex encode object location relative to a variety of reference frames (Arbib 1991; Colby and Duhamel 1991, 1996; Jeannerod et al. 1995; Rizzolatti, Fogassi, and Gallese 1997; Gross and Graziano 1995; Olson and Gettner 1995). (See MULTISENSORY INTEGRATION and VISUAL PROCESSING STREAMS.)

Contrasting types of spatial representations exist in two adjacent areas in monkey parietal cortex, the ventral intraparietal area (VIP) and the lateral intraparietal area (LIP). Area VIP, in the fundus of the sulcus, is distinguished from neighboring parietal areas by a preponderance of direction-selective visual neurons (Colby, Duhamel, and Goldberg 1993). In this respect, VIP neurons resemble those in other dorsal stream visual areas that process stimulus motion, especially areas MT and MST (see MOTION, PERCEPTION OF). An unexpected finding in VIP is that the majority of these visual neurons also respond to somatosensory stimuli, such as light touch (Colby and Duhamel 1991; Duhamel, Colby, and Goldberg 1998). These neurons are truly bimodal, in the sense that they can be driven equally well by either a visual or a somatosensory stimulus. Most VIP neurons have somatosensory receptive fields restricted to the head and face. The somatosensory and visual receptive fields of individual neurons match in location, in size, and even in their preferred direction of motion.

The observation of matching visual and somatosensory receptive fields raises the question of what happens to the relative locations of these fields in a single cell when the eyes move. If the visual receptive field were simply retinotopic, it would move when the eyes do. And if the somatosensory receptive field were purely somatotopic, it would be unchanged by eye position. There could not be a consistent correspondence in location if both receptive fields were defined solely with respect to the receptor surfaces. The answer is that some VIP visual receptive fields shift their location on the retina when the eyes move (Colby et al. 1993; Duhamel et al. 1997). A neuron that responds best to a visual stimulus approaching the mouth, and that has a somatosensory receptive field around the mouth, responds best to a stimulus moving on a trajectory toward the mouth regardless of where the monkey is fixating. This indicates that both the visual and somatosensory receptive fields are defined with respect to the skin surface. The receptive fields of these VIP neurons are head-centered: they respond to a certain portion of the skin surface and to the visual stimulus aligned with it, no matter what part of the retina is activated. In sum, these neurons encode bimodal sensory information in a head-centered representation of space. Similar neurons are found in the specific region of premotor cortex to which area VIP projects (Fogassi et al. 1992).

In contrast to area VIP, area LIP contains an eye-centered (oculocentric) representation of space. Neurons in area LIP have retinotopic receptive fields and are activated by sensory, motor, and cognitive events related to the receptive field (Andersen et al. 1990; Goldberg, Colby, and Duhamel 1990; Robinson, Goldberg, and Stanton 1978). Activity in LIP cannot be characterized as reflecting a simple sensory or motor signal. Rather, LIP neurons encode salient spatial locations; activity reflects the degree to which spatial attention has been allocated to the location of the receptive field (Colby, Duhamel, and Golberg 1995; Colby and Duhamel 1996).

Neural representations of space are maintained over time and the brain must solve the problem of updating them when a receptor surface is moved. Every time we move our eyes, each object in our surroundings activates a new set of retinal neurons. Despite this constant change, we experience the world as stable. This perceptual stability has long been understood to reflect the fact that what we perceive is not a direct impression of the external world but a construction, or internal representation, of it. It is this internal representation that is updated in conjunction with eye movements. Neurons in area LIP contribute to updating the internal image (Duhamel, Colby, and Goldberg 1992a). The experiment illustrated shows that an LIP neuron is activated when the monkey makes an eye movement that brings the receptive field to a screen location that previously contained a stimulus. The neuron's response is to the memory trace of the earlier stimulus: no stimulus was ever physically present in the receptive field, either before or after the saccade. The explanation for this surprising response is that the memory trace of the stimulus was updated, or remapped, at the time of the saccade. Nearly all LIP neurons show evidence of remapping the memory trace of a stimulus from the coordinates of the initial eye position to the coordinates of the final eye position.

The significance of this result is in what it tells us about spatial representation in area LIP. It shows that the internal image is dynamic and is always centered on the current position of the fovea. Instead of creating a spatial representation in purely retinotopic coordinates, tied solely to the specific neurons initially activated by the stimulus, area LIP

Stimulus in receptive field
No saccade

Saccade brings receptive
field onto stimulus

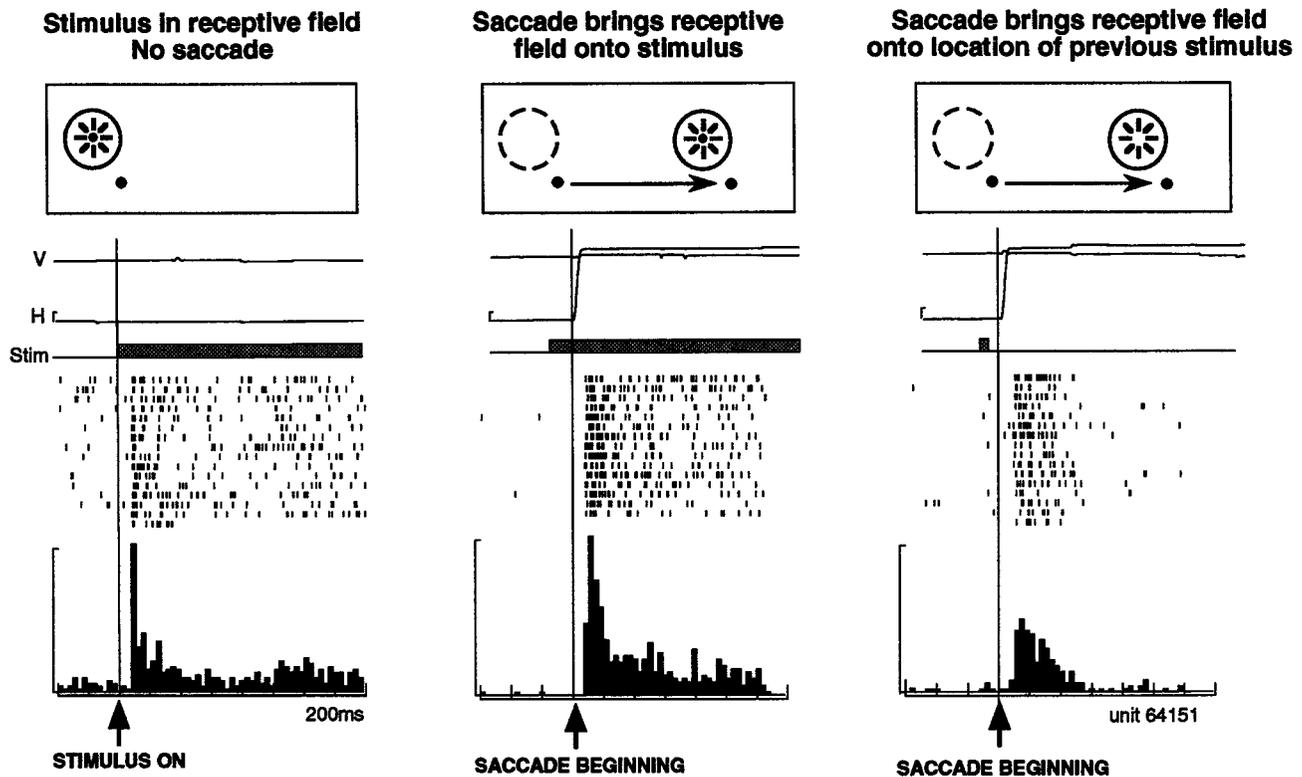
Saccade brings receptive field
onto location of previous stimulus


Figure 1. Remapping of memory trace activity in area LIP. Responses of one LIP neuron in three conditions. *Left:* during fixation, the neuron responds to the onset of a stimulus in the receptive field. *Center:* response following a saccade that moves the receptive field onto a stimulus. *Right:* response following a saccade that moves the receptive field onto a previously stimulated location. The stimulus is presented for only 50 msec and is extinguished before the saccade begins so that no stimulus is ever physically present in the receptive field. The response is to a memory trace that has been remapped from the coordinates of the initial eye position to those of the final eye position. (Modified from Duhamel et al. 1992a.)

constructs a representation in eye-centered coordinates. The distinction is a subtle one but very important for generating accurate spatial behavior. Maintaining visual information in eye-centered coordinates tells the monkey not just where the stimulus was on the retina when it first appeared but where it would be now, in relation to the current position of the fovea, if it were still visible. The result is that the monkey always has accurate spatial information with which it could program an eye movement toward a real or remembered target. Compared to a head-centered or world-centered representation, an eye-centered representation has the advantage that it is already in the coordinates of an effector system that could be used to acquire the target visually. Studies of patients indicate that the process of remapping and the construction of an eye-centered representation is selectively impaired by parietal lobe damage (Duhamel et al. 1992b; Heide et al. 1995). (See OCULOMOTOR CONTROL and AFFORDANCES.)

Our current understanding of the neural basis of spatial perception can be summarized as follows. First, parietal cortex contains multiple representations of space. These are instantiated in several discrete areas that have been defined on the basis of anatomical connections and neuronal response properties. Second, parietal neurons in each of these areas have complex response profiles, with sensitivity to multiple stimulus dimensions and, often, multiple stimu-

lus modalities. Single neurons exhibit motor and cognitive activity in addition to sensory responses. Third, the spatial representation in each area can best be understood in terms of the effector system to which it is related: area VIP is most strongly connected to premotor regions controlling head movements, while area LIP projects to oculomotor structures. Finally, spatial representations in parietal cortex are dynamically updated in conjunction with self-generated movements. The primary insight gained from neuropsychological and neurophysiological studies of parietal cortex is that our unitary experience of space emerges from a diversity of spatial representations.

Speech Perception

The ability to comprehend spoken language derives from the operation of a highly complex set of perceptual, cognitive, and linguistic processes that permit the listener to recover the meaning of an utterance when listening to speech. The domain of speech perception concerns the earliest stages of this processing, during which the listener maps the time-varying acoustic signal of speech onto a set of discrete linguistic representations. These representations are typically (though not universally) construed in terms of sequences of phonetic segments—consonants and vowels —that form the words of the language. For example, the word *keep* is composed of three phonetic segments: an initial consonant (in phonetic notation, symbolized as /k/), a medial vowel (/i/), and a final consonant (/p/). Each phonetic segment can itself be described in terms of values on a small set of DISTINCTIVE FEATURES that recombine to form the set of segments in any given language. For example, at a

featural level, the segment /k/ can be described as a voiceless stop consonant with a velar place of articulation; this segment contrasts minimally with /p/, which is also a voiceless stop consonant but has a labial place of articulation. Within this framework, the central issue in speech perception is how listeners are able to recover the phonetic structure—the sequences of featurally defined phonetic segments—when listening to speech, so that they can recognize the individual words that were produced and, ultimately, comprehend the meaning of the spoken utterance.

Mirroring the interdisciplinary nature of cognitive science itself, the study of speech perception has a long tradition of drawing from many diverse fields, most notably experimental psychology, linguistics, speech and hearing science, acoustics, and engineering. More than five decades of research from these disciplines have yielded a vast amount of information on the nature of the speech signal and the way in which listeners process it to derive the phonetic structure of the utterance.

One of the fundamental discoveries of this research is that there is not a simple one-to-one mapping between the phonetically relevant acoustic properties of speech and the phonetic structure of an utterance (though see Stevens and Blumstein 1981 for an alternative view). Many factors contribute to this complexity in mapping. One of the primary factors, called coarticulation, derives from the fact that when speakers talk, they do not produce the phonetic segments of a given word (such as *keep*) sequentially, one at a time (e.g., /k/, then /i/, then /p/; Liberman et al. 1967). Rather, phonetic segments are coarticulated, with the articulatory gestures for given segments overlapping in time; for example, the gestures for /i/ and even /p/ are in the process of being implemented during the ARTICULATION of /k/. Coarticulation allows speakers to produce sequences of segments rapidly, but it results in two major complications in the mapping between acoustic signal and phonetic structure. The first complication, called the *segmentation problem*, is that any given stretch of the acoustic signal contains, in parallel, information for more than one phonetic segment. Thus it is not possible to divide the acoustic signal into discrete "chunks" that correspond to individual phonetic segments. The second complication, called the *lack of invariance problem*, is that the precise form of a given acoustic property important for specifying a phonetic segment itself changes as a function of phonetic context (i.e., as a function of which segments precede and follow the target segment). So, for example, the form of critical acoustic information for /k/ is different when /k/ is followed by /i/ as in *keep* compared to when it is followed by /u/ as in *cool*. To complicate matters further, many factors other than coarticulation also alter the precise form of the acoustic properties specifying phonetic segments; among the most prominent of these are changes in speaker (Nearey 1989) and speaking rate (Miller 1981). Moreover, given the nature of the articulatory process, it is nearly always the case that phonetic contrasts are specified not by a single property of the acoustic signal but by multiple acoustic properties (Lisker 1986).

Given this considerable (though, importantly, highly systematic) complexity in the mapping between acoustic signal and phonetic structure, the listener must have some means of "unpacking" the highly encoded, context-dependent speech signal. Indeed, there is now considerable evidence that listeners are exquisitely sensitive to such factors as acoustic-phonetic context, speaker, and speaking rate, and that they take into account the acoustic consequences of variation due to these factors when mapping the acoustic signal onto phonetic structure (for review, see Nygaard and Pisoni 1995). Just how this is accomplished, however, remains unknown, and current theoretical approaches are quite diverse (for review, see Remez 1994). One long-standing debate, for example, focuses on whether phonetic perception is accomplished by a modular, specialized, speech-specific mechanism that computes the intended phonetic gestures of the speaker and thereby recovers the phonetic structure of the utterance (Liberman and Mattingly 1985) or whether some form of general perceptual and/or cognitive processing is sufficient to accomplish the mapping from acoustic signal to phonetic structure, even given the complexity involved (Diehl and Kluender 1989; Pastore 1987; see also Fowler 1986).

Research on speech perception has not only revealed that the mapping between acoustic and phonetic levels is complex, but it has also shown that phonetic perception is itself influenced by input from higher-order linguistic levels, most notably information from the LEXICON. A classic example of this lexical influence is the finding that potentially ambiguous phonetic segments are typically identified so as to create real words of the language rather than nonwords (Ganong 1980). For example, a stimulus with acoustic information that is potentially ambiguous for stimulus-initial /b/ versus /p/ will be identified (under certain conditions) as /b/ in the context of *-eef* and as /p/ in the context of *-eace*, thus creating the real word *beef* (as opposed to *peef*) and the real word *peace* (as opposed to *beace*). Results such as these underscore the close tie between the processes underlying phonetic perception and those responsible for SPOKEN WORD RECOGNITION (lexical access). However, although the influence of lexical information on phonetic perception is well established, there is currently considerable controversy over the nature of this influence. One major alternative, in line with autonomous, modular models of perception, is that lexical factors operate independently of the initial acoustic-phonetic analysis to influence the final percept (e.g., Cutler et al. 1987). Another major alternative, in line with interactive approaches, is that lexical information plays a direct role in the initial acoustic-phonetic mapping per se (e.g., McClelland and Elman 1986). As in other domains of cognitive science, providing clear-cut empirical support for modular versus interactive models has proven to be extremely difficult (see Miller and Eimas 1995).

Finally, yet another major finding of research on speech perception is that the ability to map the acoustic signal onto linguistic representations has its origins in the perceptual processing of early infancy (see PHONOLOGY, ACQUISITION OF). It is now known that infants come to the task of speech perception with highly sophisticated abilities to process the speech signal (for review, see Jusczyk 1995). This includes the ability to distinguish nearly all (if not all) of the phonetic contrasts used in the world's languages and the ability to cat-

egorize variants of speech sounds in a linguistically relevant manner (Eimas et al. 1971). For example, young infants will spontaneously group together instances of a given vowel (e.g., /i/) that are produced by different speakers and hence are quite distinctive acoustically (Kuhl 1979). These initial abilities of the infant to perceive speech become tuned in accord with the sound structure of the native language over the course of development, such that infants gradually change from "language-general" to "language-specific" perceivers of speech. This attunement process begins very early—for example, within days of birth, infants show a preference for their native language (Mehler et al. 1988). It continues to unfold in a complex manner over the course of development, with major changes occurring during the first year of life (Best 1994; Jusczyk 1993; Kuhl 1993; Werker and Pegg 1992). Understanding the nature of the earliest abilities of infants to perceive speech, the way in which these abilities become tuned in the course of learning a particular language, and the role of this attunement process in the overall course of LANGUAGE ACQUISITION, remains a major challenge in the study of spoken-language processing.

Speech Recognition in Machines

Over the past several decades, a need has arisen to enable humans to communicate with machines in order to control their actions or to obtain information. Initial attempts at providing human-machine communications led to the development of the keyboard, the mouse, the trackball, the touch-screen, and the joystick. However none of these communication devices provides the richness or the ease of use of speech, which has been the most natural form of communication between humans for tens of centuries. Hence a need has arisen to provide a voice interface between humans and machines. This need has been met, to a limited extent, by speech-processing systems that enable a machine to speak (speech synthesis systems) and that enable a machine to understand (speech recognition systems) human speech. We concentrate on speech recognition systems in this section.

Speech recognition by machine refers to the capability of a machine to convert human speech to a textual form, providing a transcription or interpretation of everything the human speaks while the machine is listening. This capability is required for tasks in which the human is controlling the actions of the machine using only limited speaking capability, such as while speaking simple commands or sequences of words from a limited vocabulary (e.g., digit sequences for a telephone number). In the more general case, usually referred to as *speech understanding,* the machine need only reliably recognize a limited subset of the user input speech—namely, the parts of the speech that specify enough about the action requested so that the machine can either respond appropriately or initiate some action in response to what was understood.

Speech recognition systems have been deployed in applications ranging from control of desktop computers, to telecommunication services, to business services.

The earliest approaches to speech recognition were based on finding speech sounds and providing appropriate labels to these sounds. This is the basis of the *acoustic-phonetic* approach (Hemdal and Hughes 1967), which postulates that there exist finite, distinctive phonetic units (phonemes) in spoken language and that these units are broadly characterized by a set of acoustic properties that are manifest in the speech signal over time. Even though the acoustic properties of phonetic units are highly variable, both with speakers and with neighboring sounds (the so-called coarticulation effect), it is assumed in the acoustic-phonetic approach that the rules governing the variability are straightforward and can be readily learned (by a machine).

The first step in the acoustic-phonetic approach is a spectral analysis of the speech combined with a feature detection that converts the spectral measurements to a set of features that describe the broad acoustic properties of the different phonetic units.

The next step is a segmentation and labeling phase in which the speech signal is segmented into stable acoustic regions, followed by attaching one or more phonetic labels to each segmented region, resulting in a phoneme lattice characterization of the speech. The last step in this approach attempts to determine a valid word (or string of words) from the phonetic label sequences produced by the segmentation to labeling. In the validation process, linguistic constraints on the task (i.e., the vocabulary, the syntax, and other semantic rules) are invoked in order to access the lexicon for word decoding based on the phoneme lattice. The acoustic-phonetic approach has not been widely used in most commercial applications.

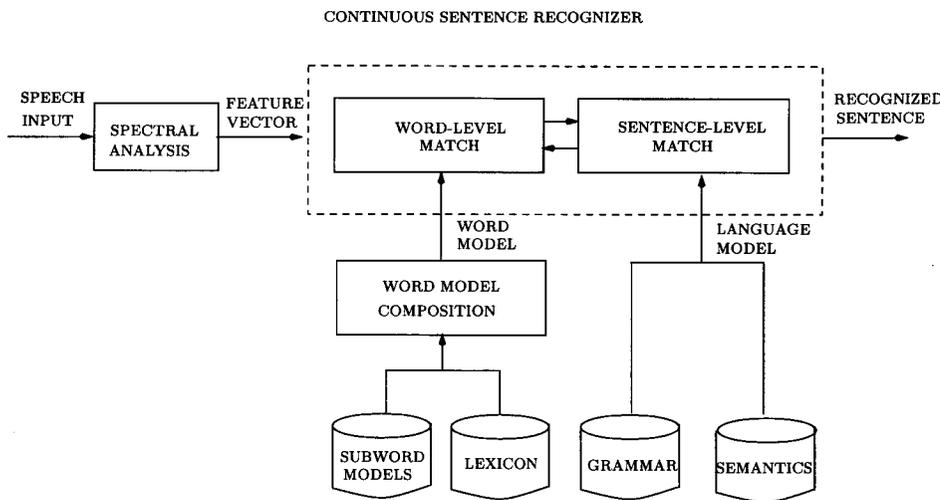
The *pattern-matching approach* (Itakura 1975; Rabiner 1989; Rabiner and Juang 1993) involves two essential steps—namely, pattern training and pattern comparison. The essential feature of this approach is that it uses a well-formulated mathematical framework and establishes con-sistent speech-pattern representations, for reliable pattern comparison, from a set of labeled training samples via a formal training algorithm. A speech-pattern representation can be in the form of a speech template or a statistical model (e.g., a HIDDEN MARKOV MODEL or HMM) and can be applied to a sound (smaller than a word), a word, or a phrase. In the pattern-comparison stage


Figure 1. Overall block diagram of subwork unit-based continuous-speech recognizer.

of the approach, a direct comparison is made between the unknown speech (the speech to be recognized) with each possible pattern learned in the training stage in order to determine the identity of the unknown according to the goodness of match of the patterns. The pattern-matching approach has become the predominant method of speech recognition in the last decade.

The *artificial intelligence approach* (Lesser et al. 1975; Lippmann 1987) attempts to mechanize the recognition procedure according to the way a person applies intelligence in visualizing, analyzing, and characterizing speech based on a set of measured acoustic features. Among the techniques used within this class of methods are use of an expert system (e.g., a neural network) that integrates phonemic, lexical, syntactic, semantic, and even pragmatic knowledge for segmentation and labeling, and uses tools such as artificial NEURAL NETWORKS for learning the relationships among phonetic events. The focus in this approach has been mostly in the representation of knowledge and integration of knowledge sources. This method has not been used widely in commercial systems.

A block diagram of a complete system for *large vocabulary speech recognition* (Lee, Rabiner, and Pieraccini 1992; Jelinek 1985; Baker 1990) based on the pattern-matching approach is shown in Figure 1. The first step in the processing is spectral analysis to derive the feature vector used to characterize the spectral properties of the speech input. The second step in the recognizer is a combined word-level/sentence-level matching procedure. The way this is accomplished is as follows. Using a set of subword models (phoneme-like units) along with a word lexicon, a set of word models is created by concatenating each of the subword models as specified by the word lexicon. The word-level match procedure provides scores for individual words as specified by the sentence-level match procedure (which uses a word grammar—the syntax of the system) and the semantics (which specifies valid sentences in the task language). The final result is the sentence that provides the best match to the speech input according to the word vocabulary, task syntax, and task grammar.

Table 1 illustrates current capabilities in continuous speech recognition for three distinct and rather simple tasks—namely, database access (Resource Management), natural language queries (ATIS) for air-travel reservations, and read text from a set of business publications (NAB). The task syntax is the system grammar (or language model) and is realized as one of a finite-state word-pair grammar, a word-trigram grammar, or a five-gram word grammar. The systems all run in a speaker independent (SI) mode with either fluently read speech or naturally spoken dialogue.

It can be seen from Table 1 that for tasks with medium size vocabularies (1000–2500 words) and with language perplexities (average word-branching factors) significantly below that of natural language speech (perplexity of 100–200), word-error rates below 5 are easily obtainable with modern technology. Such systems could actually be utilized in limited (controlled) user environments and could be designed to work rather well. On the other hand, for more complex tasks like NAB with a 60,000-word vocabulary and perplexity comparable to that of natural-language speech, word-error rates exceed 10, thereby making these systems almost unusable in practical environments.

Table 1. Performance of continuous-speech recognition systems

Task	Syntax	Mode	Vocabulary	Word Error Rate
Resource Management (DARPA)	Finite State Grammar (Perplexity = 60)	SI Fluent Read Input	1000 Words	4.4%
Air Travel Information System (ATIS-DARPA)	Backoff Trigram (Perplexity = 18)	SI Natural Language	2500 Words	3.6%
North American Business (NAB) (DARPA)	Backoff 5-gram (Perplexity = 173)	SI Fluent Read Input	60000 Words	10.8%

Speech recognition has been successfully applied in a range of systems. We categorize these applications into five broad classes.

1. *Office or business system*   Typical applications include data entry onto forms, database management and control, keyboard enhancement, and dictation. Examples of voice-activated dictation machines include the IBM Via Voice system and the Dragon Dictate system.
2. *Manufacturing*   ASR is used to provide "eyes-free, hands-free" monitoring of manufacturing processes (e.g., parts inspection) for quality control.
3. *Telephone or telecommunications*   Applications include automation of operator-assisted services (the Voice Recognition Call Processing system by AT&T to automate operator service routing according to call types), inbound and outbound telemarketing, information services (the ANSER system by NTT for limited home-banking services, the stock-price quotation system by Bell Northern Research, Universal Card services by Conversant/AT&T for account information retrieval), voice dialing by name/number (AT&T VoiceLine, 800 Voice Calling services, Conversant FlexWord, etc.), directory-assistance call completion, catalog ordering, and telephone calling feature enhancements (AT&T VIP—Voice Interactive Phone for easy activation of advanced calling features such as call waiting, call forwarding, and so on by voice rather than by keying in the code sequences).
4. *Medical*   The application is primarily in voice creation and editing of specialized medical reports (e.g., Kurzweil's system).
5. *Other*   This category includes voice-controlled and -operated toys and games, aids for the handicapped, and voice control of nonessential functions in moving vehicles (such as climate control and the audio system).

For the most part, machines have been successful in recognizing carefully articulated and read speech. Spontaneous human conversation has proven to be much more difficult a task. Recent performance evaluations using speech recorded off a radio station, as well as from monitoring speech of family members talking over conventional telephone lines, shows word-error rates of from 27 to upwards of 50. These high word-error rates are an indication of how much more must be learned before machines are truly capable of recognizing human conversational speech.

Speech Synthesis

The history of "speaking machines" goes back at least to the work of Wolfgang von Kempelen in 1791, but until the advent of the digital computer all such devices required a human operator to "play" them, rather like a musical instrument. Perhaps the best known machine of this sort was Homer Dudley's VODER, which was demonstrated at the 1939 World's Fair.

Modern speech synthesis programs, of course, can produce speechlike output on the basis of symbolic input, with no further intervention. When the symbolic input to such a program is ordinary text, the program is often called a text-to-speech (TTS) system. Most TTS systems can be viewed as having two fairly distinct halves: a first stage that analyzes the text and transforms it into some form of annotated phonetic transcription, and a second stage, which is often thought of as synthesis proper, which produces a sound wave from the phonetic transcription.

Programs that generate their own sentences, for example, automated information systems, can produce synthesizer input directly and avoid the difficulties of textual analysis. There is, at the beginning of 1998, no standard format for synthesizer input, and most systems have their own ad hoc notations. There is a move toward the development of standardized speech markup languages, on the model of text markup languages like LaTex and HTML, but considerable work remains to be done.

Text analysis in TTS systems serves two primary purposes: (1) specifying the pronunciations of individual words and (2) gathering information to guide phrasing and placement of pitch accents (see PROSODY AND INTONATION).

Word pronunciations can be looked up in dictionaries, generated by spelling-to-sound rules, or produced through a combination of the two. The feasibility of relying on spelling-to-sound rules varies from language to language. Any language will need at least a small dictionary of exceptions. English spelling is sufficiently problematic that current practice is to have a dictionary with tens of thousands—or even hundreds of thousands—of entries, and to use rules only for words that do not occur in the dictionary and cannot be formed by regular

morphological processes from words that do occur. Systems vary in the extent to which they use morphology. Some systems attempt to store all forms of all words that they may be called on to pronounce. The MITalk system had a dictionary of orthographic word fragments called "morphs" and applied rules to specify the ways in which their pronunciations were affected when they were combined into words.

The parsing and morphological analysis (see NATURAL LANGUAGE PROCESSING and MORPHOLOGY) techniques used in text processing for text-to-speech are similar to those used elsewhere in computational linguistics. One reason for parsing text in text-to-speech is that the part of speech assignment performed in the course of parsing can disambiguate homographs—forms like the verb *to lead* and the noun *lead,* or the present and past tenses of the verb *to read,* which are spelled the same but pronounced differently. The other main reason is that it is possible to formulate default rules for placement of pitch accents and phrase boundaries on the basis of syntax. On the basis of such rules, markers can be placed in the annotated phonetic output of the text analysis stage that instruct the synthesis component to vary vocal pitch and introduce correlates of phrasing, such as pauses and lengthening of sounds at the ends of phrases. Such default rules tend to yield the rather unnatural and mechanical effect generally associated with synthetic speech, and improving the quality of synthetic prosody is one of the major items on the research agenda for speech synthesis.

Synthesis proper can itself be broken into two stages, the first of which produces a numerical/physical description of a sound wave, and the second of which converts the description to sound. In some cases, the sound is stored in the computer as a digitized wave form, to be played out through a general purpose digital to analog converter, whereas in other cases, the numerical/physical description is fed to special purpose hardware, which plays the sound directly without storing a waveform.

Synthesizers can be distinguished in two primary ways according to the nature of the numerical/physical description they employ, and the manner in which they construct it. These distinctions are *acoustic vs. articulatory* and *stored unit vs. target interpolation.* The two distinctions are largely independent and any of the four possibilities they offer is in principle possible, but in practice articulatory synthesizers use target interpolation.

The acoustic vs. articulatory distinction depends on whether numerical/physical descriptions describe sounds or vocal tract shapes. In the acoustic case, converting the description to sound essentially means creating a sound that fits the description, and there are usually efficient algorithms to do the job. In the second case, the computation involves simulating the propagation of sound through a vocal tract of the given description. This requires a great deal more computation. Articulatory synthesis remains a research activity and is not used in practical applications. Formant synthesis, linear prediction synthesis, sinewave synthesis, and waveform concatenation are common forms of acoustic synthesis. The acoustic vs. articulatory distinction is to some extent blurred by systems such as YorkTalk that arrive at a (formant based) acoustic description by way of an intermediate articulatory feature level.

In target interpolation, descriptions of complete utterances are built up by establishing target values to be achieved during phonetic units (see PHONETICS) and then, as the term suggests, interpolating between the targets. The first synthesizers capable of producing intelligible renditions of a wide range of sentences, such as the JSRU synthesizer of John Holmes, Ignatius Mattingly, and John Shearme, and KlattTalk, were of this type, with formant values as targets.

The transitions between relatively stable regions of sound in natural speech are in fact very complex and difficult to model through interpolation. An alternative is to store the descriptions of whole stretches of speech, including the difficult transitions. This is the basis of *stored unit synthesis.* One popular unit is the diphone, which is essentially the transition between one stable region and the next. Many of the present generation of good quality commercial synthesizers use diphones. Other units in current use are demi syllables, syllables plus affixes, and units of varying length chosen on the spot from a large speech database to build a particular utterance.

Nearly all systems adopt the simplifying assumption that the aspects of speech dependent on the activity of the larynx —vocal pitch and much of what is often considered voice quality—can be modeled independently from the aspects dependent on mouth shape, which determine what phonemes, and hence what words are produced. In articulatory synthesis, this comes naturally in the form of separate modeling of separate articulators. In acoustic synthesis it is often done using Gunnar Fant's source-filter model of speech production, where the speech is modeled as the result of passing a sound corresponding to the larynx contribution through a filter corresponding to the mouth shape. Formant synthesis and linear prediction are based on the source filter model, but the more recently developed PSOLA and sinewave methods are not.

Sperry, Roger Wolcott

Roger Wolcott Sperry (1913–1994), who received the Nobel Prize in Physiology and Medicine in 1981, made pathfinding contributions to the sciences of brain and mind through half a century. His experiments on nerve regeneration, on cortical mechanisms of perception and learning in split-brain cats and monkeys, and on hemispheric modes of consciousness in commissurotomy patients, display outstanding creativity and skill. The intrinsic factors of nerve net patterning and in psychological action and awareness that Sperry discovered are fundamental to cognitive science.

Mastery of his scientific vocation came quickly for Roger Sperry. While an english literature major at Oberlin, he chose a masters project with R. H. Stetson, an expert on timing in speech and music. Sperry's first paper on this myographic analysis of arm movements appeared in 1939. He proved that each time the subject repeated the same circle in space, electrical activity appeared in different muscles. The constancy of movement implied an internal image of the circular act. That year, with Paul Weiss at Chicago, Sperry published his Ph.D. abstract on the behavioral effects of surgical transposition of hindlimb muscles in rats. Within three years he had tested motor nerve regeneration in rats and monkeys, noting important species differences in motor plasticity. He also began experiments with newts that brought international renown, on growth of eye-to-brain connections after surgical rotations of the eyes (Evarts 1990). Results proved that chemical markers, previously envisaged by developmental studies of Ramon y CAJAL, Harrison, and Langley, were guiding prefunctional visual projections, even when rearranged eye-to-body relations produced totally nonfunctional reactions to stimuli (Hunt and Cowan 1990). This radically qualified prevailing theories of the construction of functional brain circuits by learning.

Experiments with optic nerve regeneration in fish after eye rotation uncovered a central patterning of movements that Sperry (1950) named "corollary discharge from efference." Independently, von Holst and Mittelstaedt in Germany had seen the same phenomenon, labeling it the "reafference principle." This proved a neural basis for the psychological fact that formulation of a motor purpose transforms processing of perceptual information. Sperry and the German scientists fully appreciated its importance in explaining the perceptual constancies, and the stability of the world seen by a moving eye. Current motor imagery theory identifies intrinsic processes defining the space-time frame for experience (Jeannerod 1994). Sperry's motor theory of perception made the same point.

In an influential paper, "Neurology and the Mind-Brain Problem," Sperry took the position that preoccupation with input to perception and cognition, disregarding constraints imposed by prewired motives or prospective MOTOR CONTROL, often leads psychology into arcane and unprofitable theorizing (Sperry 1952). His concept of biological determination of functional perceptual-motor systems met with resistance from the behaviorist psychology of his day. How he overcame this, and the strength of his evidence for chemical guidance of regenerating nerve fibers, has been reviewed recently (Evarts 1990; Levi-Montalcini 1990; Hunt and Cowan 1990). Now Sperry's principle of "chemo-affinity" as a constraining factor mapping both nerve cell interactions in the embryo and nerve tract regeneration in lower vertebrates (Sperry 1963) is beyond contention, despite powerful abstract theories developed to model order emerging in complex nonlinear dynamic systems of nerve cells, axonal and dendritic branches, and synapses, and evidence for selective retention of these elements under the validation of environmental input. Emergent order and selection create new functions, but these carry the imprint of the constraints of cell-to-cell communication set up prefunctionally in the embryo.

Surgical skills that he developed in operating on small fish enabled Sperry to attempt direct interference with corticocortical circuits in the cat by delicate subpial slicing of white matter to test various "field" theories of form perception. He proved that high-acuity vision of form must involve fiber loops leaving and returning to the cortex. Then, his interest in intrinsic whole-brain function in awareness led, by elegant logic, to division of the corpus callosum, the major axonal bridge between cortical circuits in the two cerebral hemispheres that mediate ideation and conscious guidance of purposes. Split-brain studies of cats and monkeys demonstrated that awareness and learning could be surgically bisected. They also showed that the aim of attention and voluntary responses around the subject's body, and their evolution in time, invoked a great array of structures, including undivided brain stem mechanisms (Sperry 1961).

Later, with the clinical application of commissurotomy to treat multifocal epilepsy, the split-brain approach was extended to human patients, opening the way to tests of active rational consciousnesses in left and right hemispheres, their convergent influence over acts and ideas of the whole person, and the role of language (Sperry, Gazzaniga, and Bogen 1969; Levy 1990). This research brought dramatic scientific confirmation of Sperry's theory of the causal potency of conscious ideas and beliefs. Commissurotomy research at CalTech boosted neuropsychological analysis of hemispheric differences, and, by clarifying the special modes of processing in isolated cortical territories, prompted the "cognitive revolution" of the 1960s (Sperry 1993).

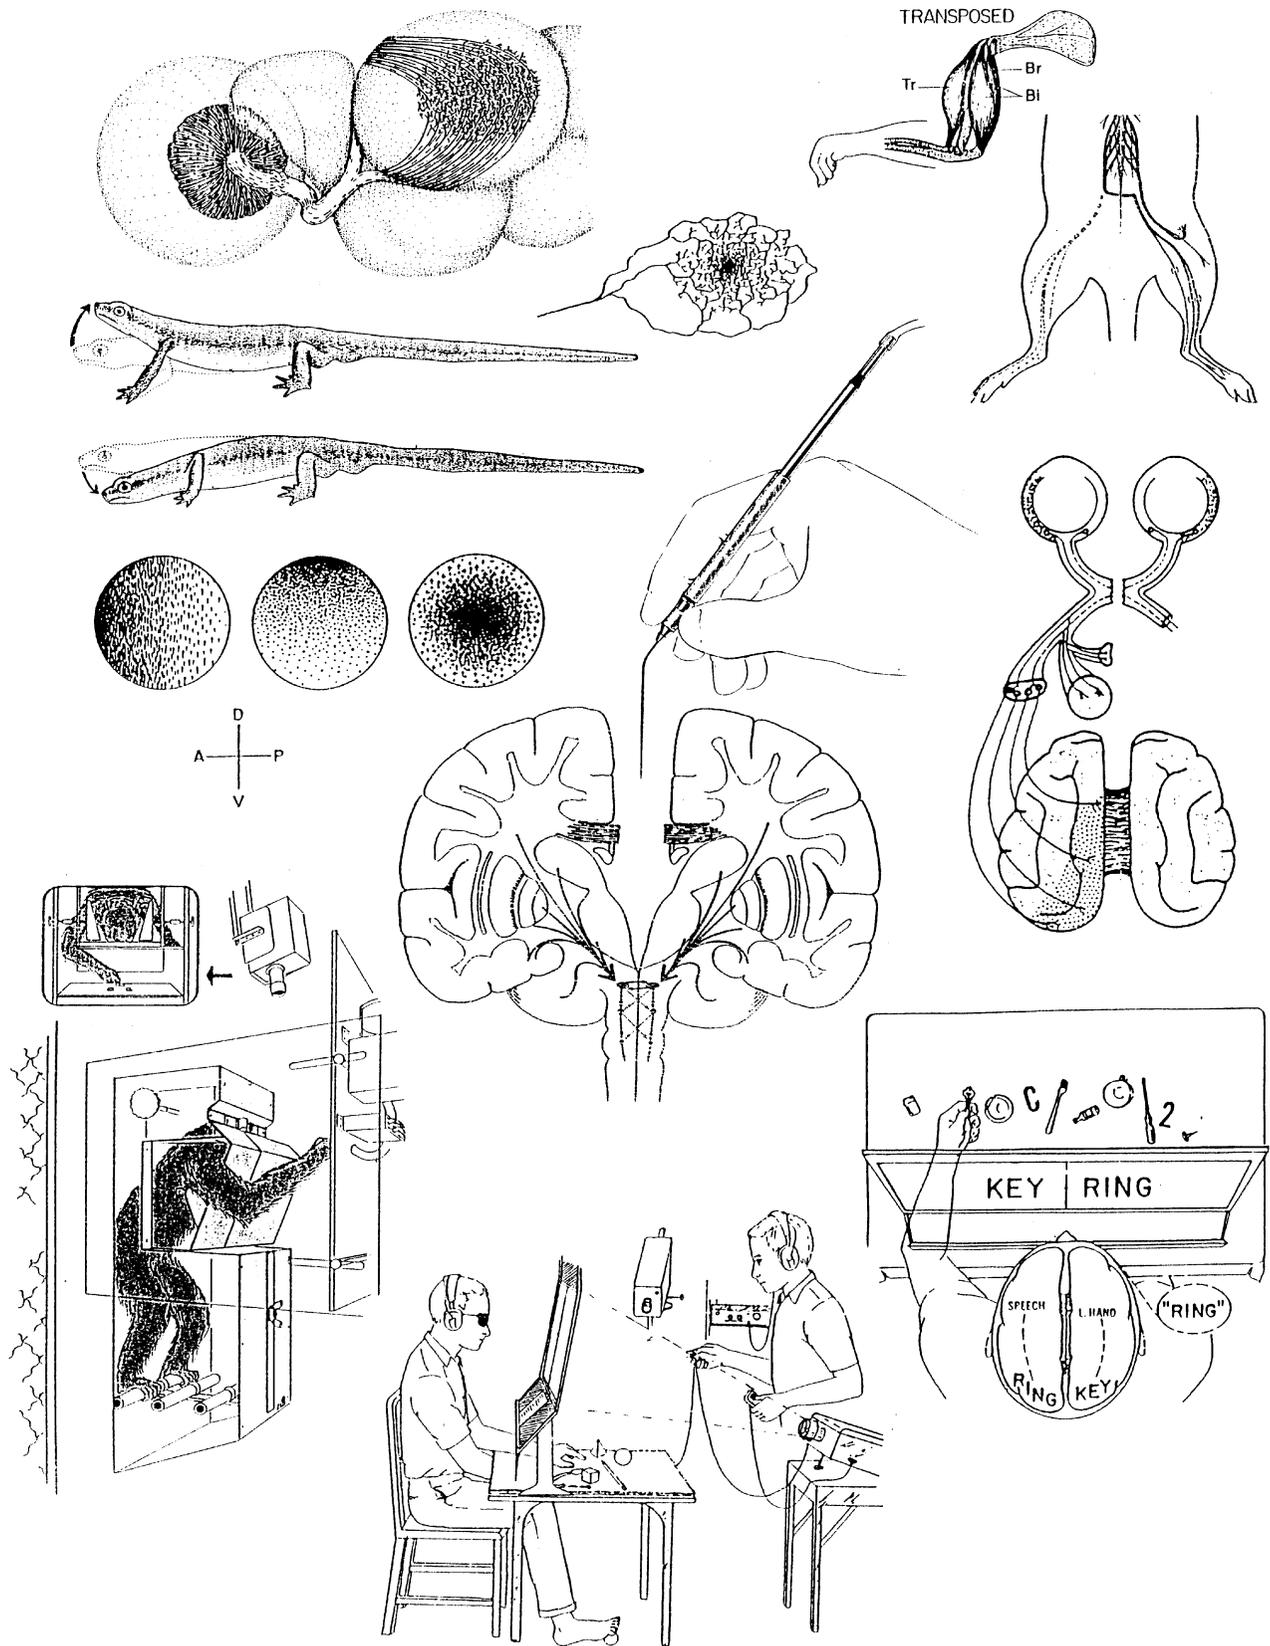
In his scientific work Sperry had an idealist impulse that led him beyond searching for motive principles in awareness. In the 1960s, he formulated a philosophy of natural humanistic values, and enunciated ethical principles that recognize the innate causal power of human consciousness, for both good and ill (Sperry 1965, 1983). In the last ten years, 95 percent of his publications were on these more philosophical matters. Sperry claimed that his theory of "downward causation" or "macro-determinism" gave a new


Figure 1. Selected drawings from articles by Roger Sperry, illustrating phases of his scientific career.

paradigm for resolving tensions between science and religion. At first, scientific colleagues thought he strayed from objectivity, but now it is clear that he foresaw the need for a larger perspective on brain activities at their highest level of organization, in human purposes, ideas, and beliefs. The foray into ethics and issues of values in policy and practice now seems prophetic. It is now far from strange to insist that a science of values is necessary.

Sperry's achievements depended on skills he showed in his earliest research—incisive anatomical logic, imagination for the inner dynamics of psychological action, and a gift for clear writing. Sperry's psychobiology was perfectly balanced between the hard anatomical and physiological facts of the brain in communication with the freely moving body, and an imaginative, creative psychology of the mind, with all of its ethical implications. This balance he described as a "monist" position, mind and matter as inseparable parts of natural psychological processes, and he worked tirelessly to explain his view of the continuity between everyday phenomena of consciousness and the matter of the brain that scientists observe.

Spoken-Word Recognition

Listening to speech is a recognition process: SPEECH PERCEPTION identifies phonetic structure in the incoming speech signal, allowing the signal to be mapped onto representations of known words in the listener's LEXICON. Several facts

about spoken-word recognition make it a challenging research area of PSYCHOLINGUISTICS. First, the process takes place in time—words are not heard all at once but from beginning to end. Second, words are rarely heard in isolation but rather within longer utterances, and there is no reliable equivalent in speech of the helpful white spaces that demarcate individual words in a printed text such as this article. Thus the process entails an operation of segmentation whereby continuous speech is effectively divided into the portions that correspond to individual words. Third, spoken words are not highly distinctive; language vocabularies of tens of thousands of words are constructed from a repertoire of on average only 30 to 40 phonemes (Maddieson 1984; see PHONOLOGY for further detail). As a consequence, words tend to resemble other words, and may have other words embedded within them (thus *steak* contains possible pronunciations of *stay* and *take* and *ache,* it resembles *state* and *snake* and *stack,* it occurs embedded within possible pronunciations of *mistake* or *first acre,* and so on). How do listeners know when to recognize *steak* and when not?

Methods for the laboratory study of spoken-word recognition are comprehensively reviewed by Grosjean and Frauenfelder (1996). This field of study is very active, but it began in earnest only in the 1970s; before then, models of word recognition such as Morton's (1969) *logogen* model were not specifically designed to deal with the characteristics of speech. Now, spoken-word recognition research is heavily model-driven, and the models differ, inter alia, as to which of the above challenges they primarily address. The first model specifically in this area was Marslen-Wilson and Welsh's (1978) *cohort* model; it focused on the temporal nature of spoken-word recognition and proposed that the initial portion of an incoming word would activate all known words beginning in that way, with this "cohort" of activated word candidates gradually being reduced as candidates incompatible with later-arriving portions of the word drop out. Thus /s/ could activate *sad, psychology, steak,* and so on; if the next phoneme were /t/, only words beginning with /st/ (*stay, steak, stupid,* etc.) would remain activated; and so on until only one word remained in the cohort. This could occur before the end of the word—thus *staple* could be identified by the /p/ because no other English words would remain in the cohort.

The *neighborhood activation model* (Luce, Pisoni, and Goldinger 1990) concentrates on similarities between words in the vocabulary and proposes that the probability of a word being recognized is a function of the word's frequency of occurrence (see VISUAL WORD RECOGNITION for more extensive discussion of this factor) and the number and frequency of similar words in the language; high-frequency words with few, low-frequency neighbors will be most easily recognized.

The currently most explicit models are TRACE (McClelland and Elman 1986) and SHORTLIST (Norris 1994), both implemented as connectionist networks (see COMPUTATIONAL PSYCHOLINGUISTICS; also Frauenfelder 1996). They both propose that the incoming signal activates potential candidate words that actively compete with one another by a process of interactive activation in which the more active a candidate word is, the more it may inhibit activation of its

competitors. Activated and competing words need not be aligned with one another, and thus the competition process offers a potential solution to the segmentation problem; so although the recognition of *first acre* may involve competition from *stay, steak,* and *take,* this will eventually be overcome by joint inhibition from *first* and *acre.*

TRACE and SHORTLIST differ primarily in one other feature that is an important characteristic of most psycholinguistic processing models—namely, whether or not they allow unidirectional or bidirectional flow of information between levels of processing. TRACE is highly interactive. That is, it allows information to pass in both directions between the lexicon and prelexical (and in principle post lexical) processing levels. SHORTLIST allows information to flow from prelexical processing of the signal to the lexicon but not vice versa. In contrast to TRACE, SHORTLIST also has a two-stage architecture, in which initial word candidates are generated on the basis of bottom-up information alone, and competition occurs only between the members of this "shortlist." TRACE allows competition in principle within the entire vocabulary, which renders it less computationally tractable, whereas SHORTLIST's structure has the practical advantage of allowing simulations with a realistic vocabulary of tens of thousands of words.

All theoretical issues separating the models are still unresolved. There is abundant experimental evidence confirming the subjective impression that spoken-word recognition is extremely rapid and highly efficient (Marslen-Wilson 1987). Concurrent activation of candidate words is supported by a wide range of experimental findings from different experimental paradigms, and active competition between such simultaneously activated words—such that concurrent activation can produce inhibition—is also supported (McQueen et al. 1995). Many findings have been interpreted in terms of interaction between levels of processing (e.g., Pitt 1995; Samuel 1997; Tabossi 1988) but noninteractive models in general can account for these findings as well (Cutler et al. 1987; Massaro and Oden 1995). In some cases, apparent demonstrations of top-down information flow have proven to be spurious, arising instead from independent bottom-up processing (for example, Elman and McClelland 1988 reported an apparent effect of lexically determined compensation for coarticulation, but Pitt and McQueen 1998 showed that the finding was actually due to transitional probability effects and hence could be accounted for without postulating top-down lexical influences on prelexical processing).

Orthogonal to these principal questions of model architecture are further issues such as the nature of the primary prelexical unit of representation (Mehler, Dupoux, and Segui 1990; Pisoni and Luce 1987); the relative contribution to word activation of matching versus mismatching phonetic information (Connine et al. 1997); the phonological explicitness of lexical representations (Frauenfelder and Lahiri 1989); the processing of contextually induced phonological transformations such as *sweek girl* for *sweet girl* (Gaskell and Marslen-Wilson 1996); the role of prosodic structure in recognition (Cutler et al. 1997); and the role of word-internal morphological structure in recognition (Marslen-Wilson et al. 1994).

Statistical Learning Theory

Statistical learning theory addresses a key question that arises when constructing predictive models from data—how to decide whether a particular model is adequate or whether a different model would produce better predictions. Whereas classical statistics typically assumes that the form of the correct model is known and the objective is to estimate the model parameters, statistical learning theory presumes that the correct form is completely unknown and the goal is to identify the best possible model from a set of competing models. The models need not have the same mathematical form and none of them need be correct. The theory provides a sound statistical basis for assessing model adequacy under these circumstances, which are precisely the circumstances encountered in MACHINE LEARNING, PATTERN RECOGNITION, and exploratory data analysis.

Estimating the performance of competing models is the central issue in statistical learning theory. Performance is measured through the use of *loss functions.* The loss $Q(\mathbf{z},\alpha)$ between a data vector $\mathbf{z}$ and a specific model α (one with values assigned to all parameters) is a score that indicates how well α performs on $\mathbf{z}$, with lower scores indicating better performance. The squared-error function for regression models, the 0/1 loss function for classification models, and the negative log likelihood for other more general statistical models are all examples of loss functions. The choice of loss function depends on the nature of the modeling problem.

From the point of view of UTILITY THEORY, α is a decision variable, $\mathbf{z}$ is an outcome, and $Q(\mathbf{z},\alpha)$ is the negative

utility of the outcome given the decision. Hence, if the statistical properties of the data were already known, the optimum model would be the α that minimizes the expected loss $R(\alpha)$:

$$R(\alpha) = \underset{\mathbf{z}}{E}\left[Q(\mathbf{z}, \alpha)\right] = \int Q(\mathbf{z}, \alpha)dF(\mathbf{z}),$$

where $F(\mathbf{z})$ is the probability measure that defines the true statistical properties of the data. $R(\alpha)$ is also referred to as the *risk* of α. In learning situations, however, $F(\mathbf{z})$ is unknown and one must choose a model based on a set of observed data vectors $\mathbf{z}_i$, $i = 1, \ldots, l$, that are assumed to be random samples of $F(\mathbf{z})$. The average loss $R_{emp}(\alpha, l)$ on the observed data is used as an empirical estimate of the expected loss, where

$$R_{emp}(\alpha, l) = \frac{1}{l}\sum_{i=1}^{l}Q(\mathbf{z}_i, \alpha).$$

$R_{emp}(\alpha, l)$ is also referred to as the *empirical risk* of α.

The fundamental question in statistical learning theory is the following: under what conditions does minimizing $R_{emp}(\alpha, l)$ yield models that also minimize $R(\alpha)$, inasmuch as the latter is what we actually want to accomplish? This question is answered by considering the accuracy of the empirical loss estimate.

As in classical statistics, accuracy is expressed in terms of confidence regions; that is, how far can $R_{emp}(\alpha, l)$ be expected to deviate from $R(\alpha)$, and with what probability? One of the fundamental theorems of statistical learning theory shows that the size of the confidence region is governed by the maximum difference between the two losses over all models being considered:

$$\sup_{\alpha \in \Lambda}\left|R(\alpha) - R_{emp}(\alpha, l)\right|,$$

where Λ is a set of competing models. The maximum difference dominates because of the phenomenon of overfitting.

Overfitting occurs when the best model relative to the training data tends to perform significantly worse when applied to new data. This mathematically corresponds to a situation in which the average loss $R_{emp}(\alpha, l)$ substantially underestimates the expected loss $R(\alpha)$. Although there is always some probability that underestimation will occur for a fixed model α, both the probability and the degree of underestimation are increased by the fact that we explicitly search for the α that minimizes $R_{emp}(\alpha, l)$. This search biases the difference between $R(\alpha)$ and $R_{emp}(\alpha, l)$ toward the maximum difference among competing models. If the maximum difference does not converge to zero as the number of data vectors increases, then overfitting will occur with probability one.

The core results in statistical learning theory are a series of probability bounds developed by Vapnik and Chervonenkis (1971, 1981, 1991) that define small-sample confidence regions for the maximum difference between $R(\alpha)$ and $R_{emp}(\alpha, l)$. The confidence regions differ from those

obtained in classical statistics in three respects. First, they do not assume that the models are correct. Second, they are based on small-sample statistics and are not asymptotic approximations. Third, a uniform method is used to take into account the degree to which overfitting can occur for a given set of competing models. This method is based on a measurement known as the Vapnik-Chervonenkis (VC) dimension.

Conceptually speaking, the VC dimension of a set of models is the maximum number of data vectors for which overfitting is virtually guaranteed in the sense that one can always find a specific model that fits the data exactly. For example, the VC dimension of the family of linear discriminant functions with n parametric terms is n, because n linear terms can be used to discriminate exactly n points in general position for any two-class labeling of the points. This conceptual definition of VC dimension accurately reflects the formal definition in the case of 0/1 loss functions, wherein $Q(\mathbf{z}, \alpha) = 0$ if α correctly predicts $\mathbf{z}$ and $Q(\mathbf{z}, \alpha) = 1$ otherwise. However, the formal definition is more general in that it considers arbitrary loss functions and does not require exact fits.

In the probability bounds obtained by Vapnik and Chervonenkis, the size of the confidence region is largely determined by the ratio of the VC dimension h to the number of data vectors l. For example, if $Q(\mathbf{z}, \alpha)$ is the 0/1 loss function used for classification models, then with probability at least $1 - \eta$,

$$R_{emp}(\alpha, l) - \frac{\sqrt{\varepsilon}}{2} \leq R(\alpha)$$

$$\leq R_{emp}(\alpha, l) + \frac{\varepsilon}{2}\left(1 + \sqrt{1 + \frac{4R_{emp}(\alpha, l)}{\varepsilon}}\right)$$

where

$$\varepsilon = \frac{4h}{l}\left(\ln\frac{2l}{h} + 1\right) - \frac{4}{l}\left(\ln\frac{\eta}{4}\right)$$

Note that the ratio of h over l is the dominant term in the definition of ε and, hence, in the size of the confidence region for $R(\alpha)$.

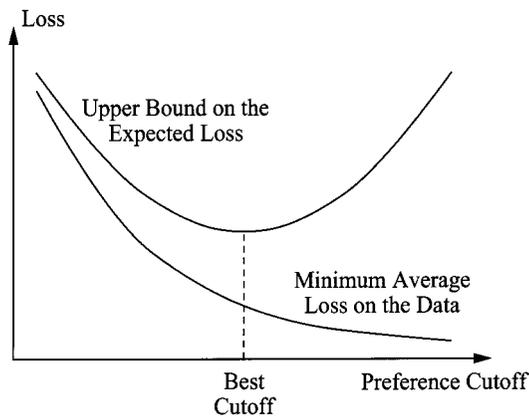
V. N. Vapnik (1982, 1995, 1998) has reported probability bounds for other families of loss functions that yield analogous confidence regions based on VC dimension. Bounds also exist for the special case in which the set of competing models is finite (continuous parameters typically imply an infinite number of specific models). These bounds avoid explicit calculation of VC dimension and are useful in validation-set methods. A remarkable property shared by all of the bounds is that they either make no assumptions at all or very weak assumptions about underlying probability distribution $F(\mathbf{z})$. In addition, they are valid for small sample sizes and they depend only on the VC dimension of the set of competing models Λ, or on its size, and on the properties of the loss function $Q(\mathbf{z}, \alpha)$. All bounds are independent of the mathematical forms of the models—the VC dimension and/or the number of specific models summarizes all relevant information. Thus, the bounds are equally


Figure 1. For each cutoff point in the model preference ordering, one selects the model that minimizes the average loss on the data from among those that occur before the cutoff. The most suitable model for the data is then the one with the smallest upper bound on the expected loss.

applicable to both nonlinear and nonparametric models, and to combinations of dissimilar model families. This includes NEURAL NETWORKS, DECISION TREES and rules, regression trees and rules, radial basis functions, BAYESIAN NETWORKS, and so on.

When using statistical learning theory to identify the best model from a set of competing models, the models must first be ordered according to preference. The most preferable model that best explains the data is then selected. The preference order corresponds to the notion of learning bias found in machine learning. No restrictions are placed on the order other than it must be fixed prior to model selection. The ordering itself is referred to as a *structure* and the process of selecting models is called *structural risk minimization.*

Structural risk minimization has two components: one is to determine a cutoff point in the preference ordering, the other is to select the best model from among those that occur before the cutoff. As the cutoff point is advanced through the ordering, both the subset of models that appear before the cutoff and the VC dimension of this subset steadily increase. With more models to choose from, the minimum average loss $R_{emp}(\alpha, l)$ for all models α before the cutoff tends to decrease. However, the size of the confidence region for $R(\alpha)$ tends to increase because the size is governed by the VC dimension. The cutoff point is selected by minimizing the upper bound on the confidence region for $R(\alpha)$, with the corresponding α chosen as the most suitable model given the available data. For example, for classification problems one would choose the cutoff and the associated model α so as to minimize the right hand side of the inequality presented above for a desired setting of the confidence parameter η.

The overall approach is illustrated by the graph in figure 1. The process balances the ability to find increasingly better fits to the data against the danger of overfitting and thereby selecting a poor model. The preference order provides the necessary structure in which to compare competing models. Judicious choice of the model order enables

one to avoid overfitting even in high-dimensional spaces. For example, Vapnik and others (Cortes and Vapnik 1995; Vapnik 1995, 1998) order models within parametric families according to the magnitudes of the parameters. Each preference cutoff then limits the parameter magnitudes, which in turn limits the VC dimension of the corresponding subset of models. Reliable models can thus be obtained using structural risk minimization even when the number of data samples is orders of magnitude less than the number of parameters.

Statistical Techniques in Natural Language Processing

Statistical natural language processing is concerned with the creation of computer programs that can perform language-processing tasks by virtue of information gathered from (typically large) corpora. Usually this information is in the form of statistics, but it may be distilled into other forms, such as DECISION TREES, dictionary entries, or various kinds of rules (see also NATURAL LANGUAGE PROCESSING). The techniques have been applied to (or have correlates in) areas as diverse as lexicography and document retrieval (Church and Mercer 1993). Here, however, we concentrate on subareas closer to cognitive science.

Most statistical language programs sacrifice depth or accuracy to breadth of coverage. That is, statistical NLP programs typically work on most everything one throws at them, but they do not provide very deep analyses and/or may make occasional mistakes. This has the salutary effect of making it easier to compare competing techniques since they will work on the same body of data (i.e., "everything"). They work as well as they do because one can get a great deal of leverage from relatively weak (and easily collected) pieces of information—combined with the fact that, at least at the shallower linguistic depths, computers seem better at collecting linguistic phenomena than people are at thinking them up.

Historically, the push behind statistical techniques came primarily from the speech community that discovered in the early 1970s that programs automatically trained from corpora worked better than their hand-tooled versions. These programs exploited the training properties of HIDDEN MARKOV MODELS (HMMs; Levinson, Rabiner, and Sondhi 1983). These models can be thought of as finite state machines in which the transitions between states have probabilities. There are well-understood mathematical techniques for training them—adjusting the probabilities to better fit the observed data. The "hidden" in their name comes from the fact that in such models one cannot know the sequence of states that produced the output (or, equivalently, accepted the input), but there are linear-time techniques for finding the most probable of such state sequences. The trick is then to identify states with the properties one wishes to infer (e.g., the word uttered).

These speech programs also typically incorporate language models, assignments of probabilities to all sequences of words in the language. The most popular such model is the simple but remarkably accurate trigram model (Jelenik 1985) in which the probability of the next word is conditioned on just the two previous words. The language model enables the speech recognizer to pick the best word in con-

text when the speech signal analysis by itself is insufficient (Church and Mercer 1993).

An early successful application of HMM technology to language tasks was the HMM "taggers," programs that try to assign the correct part of speech to each word in a text. For example, in *the can will rust* the program should identify *can* as a noun (not a modal verb) and *will* as a modal verb (not a noun). In these programs, the states of the HMM correspond to the parts of speech, so that finding the most probable sequence of states when the HMM is driven by the input gives us the desired tagging (Church 1988). Other schemes compile the statistics into rules (Brill 1995). Moderately well-crafted programs achieve about 96 percent accuracy. For comparison, human taggers are consistent with one another at a 98 percent level.

Moving up the linguistic food chain, statistical techniques are now being applied to wide-coverage syntactic parsing—determining the syntactic structure of a sentence. Such parsers are able to come up with at least a semi-reasonable structure for, say, every sentence on the front page of today's *New York Times*. In this area, statistical parsers rule the roost. One simple idea here is the probabilistic context-free grammar (PCFG; Charniak 1993). PCFGs are context-free grammars in which each rule is assigned a probability. Alternatively, they can be thought of as the context-free generalization of HMMs. PCFGs can be parsed using the standard techniques applied to their nonprobabilistic brethren, and the most probable parse for a sentence can be found in n-cubed time, where n is the length of the sentence.

Statistical parsing researchers have greatly benefited from moderate-size corpora of hand-parsed sentences, the most notable being the one-million-word Penn tree-bank (Marcus, Santorini, and Marcinkiewicz 1993). For example, one very simple technique for "learning" a PCFG grammar is to read it directly off the parse trees in the corpus. One estimates the rule probabilities by counting how often each rule is used and dividing this by the counts of productions for the same part of speech (Charniak 1996). Programs using this technique, or others using similar sources of information, parse at about a 75 percent level of accuracy. That is, 75 percent of the constituents produced are correct, where correct means that the constituent starts at the correct place, ends at the correct place, and has the right "label" (e.g., "noun phrase"). Researchers are exploring techniques that exploit more of the information in the hand-parsed corpora. One popular idea involves keeping track of the "head" of a constituent, the constituent's most important lexical item (e.g., the main noun in a noun phrase), and then conditioning probabilities on this head. These techniques are now achieving an 87 percent accuracy level (Charniak 1997; Collins 1997).

Statistical word-sense disambiguation is yet another thriving area. Here we can exploit the fact that very different senses of a word (e.g., river *bank* vs. savings *bank*) typically occur in texts concerning quite different topics, and this in turn is signaled by the occurrence of different content words in the surrounding text. So if we see "leaf" and "water" near "bank," *river bank* is a good guess. Thus, to a first approximation, statistical word-sense disambiguation programs work by taking a window of, say, the 100 words

on either side of the ambiguous word and determining the probability of seeing these words if we assume that the ambiguous word is in one sense versus the other. Thus, to restate formally what we said informally about "bank," if the words in the window include "leaf" and "water" but do not include, say, "money" or "loan," then the probability of the words is higher under the *river bank* interpretation. The hard part in all of this is collecting the statistics needed without access to a large corpus in which the words are marked with their senses. Researchers have solved this in a variety of interesting ways: using extra sources of information such as bilingual corpora (Gale, Church, and Yarowsky 1992), looking for clusters in probability space that indicate an identifiable sense (Schütze 1992), or using dictionary definitions as key words to start the process (Yarowsky 1995).

One potential application of these ideas is MACHINE TRANSLATION. In preparation for such work, there is now an active research community looking at "parallel corpora"—articles and their translations side by side. One problem here is bringing the alignment down from the article level to the sentence level (Brown, Lai, and Mercer 1991) and another is creating bilingual lexica (Brown et al. 1993). Statistical techniques in both these areas (frequently done in parallel) are quite accurate.

Stereo and Motion Perception

Given several views of a scene, how does one recover its structure and, possibly, the pose of the cameras that have acquired the views? In the case of two views, this is known as the stereo problem; when there are more than two views, it is the discrete structure from motion (DSFM) problem. These are two of the subjects of COMPUTATIONAL VISION. Many applications of DSFM are found in robotics in general and in MOBILE ROBOTS in particular, as well as in VISUAL OBJECT RECOGNITION.

A general solution to the DSFM problem requires the availability of correspondences, based, for example, on TEXTURE, between some of the views. How to obtain those cor-

respondences is itself a formidable problem that completely determines the solution to the DSFM problem.

Why is this a formidable task? Suppose that there are M views and the number of pixels per view is N. A correspondence is an M-tuple of features and there are N^M such tuples. If we take $N = 1$ million, $M = 10$, the number of possible tuples is 10^{60}!

To reduce this number, we must exploit the geometrical constraints that are induced by the fact that a camera is a projective engine. Projective geometry is a rich source of constraints on the number of possible correspondences and, as we will show, is a fundamental tool for determining the sort of geometrical structure that can be recovered from the views. DFSM can be thought of as a combination of a HEURISTIC SEARCH and CONSTRAINT SATISFACTION problem.

A camera is a projective engine because it can usually be accurately modeled as a pinhole camera. In the pinhole camera, an image is formed on the retinal plane by perspective projection with respect to the optical center (Faugeras 1993). Since this is a projective construction, it implies that the tools of projective geometry (Semple and Kneebone 1952) can immediately be brought to bear on the DSFM problem. In particular, projective geometry allows us to represent a camera by a matrix, called the perspective projection matrix.

Projective geometry is a rich source of constraints for the DSFM problem because M image points are the images of a single 3-D point, if and only if their image coordinates satisfy a number of polynomial constraints. The coefficients of those polynomials are functions of the (unknown) coefficients of the perspective projection matrices.

The simplest example occurs in the case of two views, that is, stereo, where the coordinates of two corresponding points satisfy a quadratic polynomial. This polynomial arises from the beautiful epipolar geometry of two views that is routinely used in common stereo programs (Grimson 1985).

The next example is the case of three views ($M = 3$), which offers an even richer geometry and algebra. The coordinates of three corresponding points satisfy four algebraically independent polynomials of degree 3, the trilinear constraints (Hartley 1997; Shashua 1995).

When does this process stop? There are two phenomena that take place. First, when $M = 4$ the constraints of degree 4 are algebraically dependent on the polynomials of degrees 2 and 3 obtained from subsets of 2 and 3 views of the M views (Faugeras and Mourrain 1995). Second, the case $M > 4$ does not bring in any new constraints. Since, moreover, the constraints of degree 3 imply all constraints of degree 2 (Heyden 1995), the geometrical constraints between $M > 3$ views are completely described by the trilinear constraints between all triples of views among the M.

In order to use the constraints to eliminate wrong correspondences or to reconstruct the scene, their coefficients have to be estimated. This can only be achieved if "correct" correspondences can be obtained. This sounds like a chicken-and-egg problem since correct correspondences are needed to estimate the constraints that will then be used to extract correct correspondences. RANSACK-like techniques (Fischler and Bolles 1981) can be used successfully to break that vicious circle and produce reliable estimates of the constraints (Zhang et al. 1995; Torr and Zissermann 1997).

The geometry of the M views being represented by the trilinear constraints, can we recover the perspective projection matrices of the cameras from them? There is no unique solution to this problem in the absence of further information; given all the trilinear constraints (in practice only a small subset of those are necessary), a four parameter family of perspective projection matrices of the M cameras can be computed. The four parameters correspond to the global scale of the scene and to the choice of a plane of reference (Luong and Viéville 1994).

Any element of this family of perspective projection matrices allows us to recover the projective structure of the scene (Faugeras 1992; Hartley and Gupta 1993). By projective structure we mean that the 3-D coordinates of the reconstructed points are defined up to an arbitrary projective transformation of the 3-D space, that is, up to fifteen parameters.

How can the Euclidean coordinates of the points be obtained? It is in general possible, even without any a priori information on the scene, thanks to the use of group invariance theory. The information contained in the perspective projection matrix of a camera can be decomposed into two parts, one that encodes the internal parameters of the camera, for instance its focal length, and the other that encodes its pose. In order to access the Euclidean coordinates of the scene it is only necessary to recover the internal parameters since the camera poses can be computed from them.

The internal parameters of the cameras can be recovered from feature correspondences in at least two cases: first, if the images were acquired by the same camera (Maybank and Faugeras 1992) with the same internal parameters; and second, if the internal parameters are different but satisfy some constraints which are true for most cameras (Heyden and Åström 1997). In both cases, a simple mathematical entity called the absolute conic, or umbilic, plays the role of a calibration grid. The difference between this conic and the usual calibration grids is that the umbilic is located in the plane at infinity, a plane that defines the affine geometry of three-space (it is invariant to affine transformations), and has only complex points. The umbilic defines the Euclidean geometry of three-space (it is invariant to Euclidean transformations). The process can be thought of as first recovering the projective, then affine, and finally Euclidean structure of the scene (Faugeras 1995). The scene is then defined up to an arbitrary rigid transformation and scaling of the 3-D space, that is, up to six parameters.

It is worth noting that this stratified way of solving the DSFM problem is a faint echo of the Erlangen program put forward by the two German mathematicians, Felix Klein and Herman Weyl, in 1872 in which they suggested the study of geometry from the viewpoint of invariance of geometrical figures to the action of groups of transformations (Mundy and Zisserman 1992).

Stereotyping

Stereotyping is the process by which people use social categories (e.g., race, sex) in acquiring, processing, and recalling information about others. Stereotypes are the traits and roles associated with certain groups and may relate to the belief component of attitudes. By most historical accounts, Walter Lippmann introduced the term "stereotype" to behavioral scientists in 1922 to represent the typical picture that comes to mind when thinking about a particular social group.

Three general conceptual approaches have been applied historically to understand stereotyping (Ashmore and Del-Boca 1981). The *psychodynamic approach,* which has its origins in Freudian psychology, emphasizes the functions of stereotyping in satisfying personal needs (such as for esteem and status) and in operating as a defense mechanism (involving displacement and projection of negative feelings and characteristics). The *sociocultural approach* views stereotyping as an aspect of social learning in which stereotypes are acquired and transmitted along with other types of social "knowledge." At the societal level, stereotypes may help to rationalize and justify differential treatment of various social groups (such as limiting their rights). The *cognitive approach* describes stereotypes as mental representations and stereotyping in terms of information processing. This approach is derivative of the more general SOCIAL COGNITION framework. From this perspective, stereotyping is rooted in people's needs to simplify and organize social information. Although psychodynamic, sociocultural, and cognitive approaches are complementary rather than competing perspectives, the cognitive approach is the prevailing one in contemporary social psychology.

All of these perspectives view stereotyping as functional (Dovidio et al. 1996). Early accounts of stereotyping, influenced substantially by the psychodynamic approach, generally represented this process as functional but flawed. On the one hand, stereotyping was assumed to help manage the complexity of one's environment by simplifying the social world (see JUDGMENT HEURISTICS). On the other hand, stereotyping was considered a faulty process because (1) it was a rigid form of thinking that was highly resistant to change, and (2) it produced overgeneralizations that unfairly emphasized the influence of inborn and unalterable psychological characteristics relative to social or environmental influences. In line with the cognitive orientation that has characterized recent research on stereotyping, many current theorists have stressed the information-processing (e.g., simplification) function of stereotypes while deemphasizing any necessary objectionable aspects.

Needs to understand, to predict, and potentially to control one's environment lead to the development of social stereotypes (Mackie et al. 1996). Because of the complexity of the social environment and people's limited cognitive resources, people tend to categorize others into social groups. These categories are often based on readily apparent, salient similarities, such as physical characteristics associated with sex or race. However, the social context significantly influences which characteristics are the most relevant bases of categorization (Oakes, Haslam, and Turner 1994), even with minimal physical distinctiveness (e.g., first-year students vs. upper-class students). Once categorization occurs, members of the group are viewed as more similar to one another (the outgroup homogeneity effect)

and as having common characteristics. Personal traits (dispositional attributions; see ATTRIBUTION THEORY) are often overemphasized in stereotypes because they offer more stable explanations for the group's behavior (which enhance feelings of predictability) than do situational or environmental attributions. Although not necessarily so, stereotypic characterizations of other groups also tend to be relatively negative. Perceiving members of other groups as possessing less favorable characteristics can increase personal feelings of regard as well as esteem for the group with which one identifies. Categorizing people into ingroups and outgroups typically initiates a process in which people attend to dimensions on which their group is superior and the other group is inferior (Tajfel 1981).

Once established, stereotypes operate as cognitive structures that influence how others are perceived and how information about others is stored and retrieved. These stereotyping processes operate in unconscious and unintentional ways, as well as consciously (Greenwald and Banaji 1995). Consistent with general principles of AUTOMATIC- ITY, repetition during socialization or personal experience may make some social stereotypes so overlearned that they will automatically become activated when people are presented with a representative or symbol of that group. There are individual differences in attitudes that can influence the likelihood and strength of this effect (Lepore and Brown 1997), but often this effect occurs generally for people sharing common socialization experiences (Devine 1989). What distinguishes high and low prejudiced people is their difference in the likelihood of automatically activating stereotypes and their motivation to suppress these stereotypes when they are automatically activated. Nevertheless, attempts at suppressing automatically activated stereotypic thoughts, particularly for those who do not normally do so, can result in rebound effects in which stereotypical thoughts are even more prevalent than normally so (Macrae et al. 1994).

When stereotypes are activated, people are judged in terms of the group's standards. For example, an aggressive woman may be judged as more aggressive than an objectively comparable aggressive man because women are stereotyped as being less aggressive than men in general. Furthermore, behaviors that are consistent with a stereotype are assumed to reflect dispositional characteristics and traits, and are described in that way, more than those that are inconsistent. In addition, ambiguous behaviors by group members are interpreted in stereotype-consistent ways.

People not only tend to interpret the behaviors of others in ways consistent with stereotypes, but also, once interpreted in that way, people show a bias in the way that information is subsequently recalled. Stereotype-consistent information has a recall advantage: People recall information better and more readily when it is consistent with a pre-existing stereotype than when it is inconsistent (Bodenhausen 1988). This recall advantage for consistent over inconsistent information may reflect how stereotypes facilitate retrieval of information rather than differences in how well the information is represented in MEMORY. Thus, this effect can be reversed or eliminated when recognition rather than recall measures are used (Stangor and McMillan 1992).

People also develop expectations about others substantially on the basis of their group membership and the associated stereotypes, although this effect may be undermined by providing information about the unique characteristics of a person (Fiske 1998). Stereotypes are particularly likely to influence expectations, inferences, and impressions when people are not motivated to attend to individuating information or are limited in their capacity to process information due to other demands on their attention and thoughts. Because stereotypes shape interpretations, influence how information is recalled, and guide expectations and inferences in systematic ways, they tend to be self-perpetuating. They also can produce self-fulfilling prophecies in social interaction, in which the stereotypes of the perceiver influence the interaction in ways that conform to stereotypical expectations (Jussim 1991). Stereotypes can also directly influence members of stereotyped groups. Under conditions that make stereotypes salient, such as aptitude testing situations or situations in which the group member has solo or token status, the performance of members of the stereotyped group may be adversely affected even though they do not personally endorse the stereotype (Steele and Aronson 1995).

Perhaps because of the functional properties of stereotyping, stereotypes are difficult to change or eliminate. Cognitive strategies focus on providing counterstereotypic or nonstereotypic information about group members to undermine or dilute stereotypic associations. This approach is more effective when stereotype-disconfirming information is dispersed among a broad range of group members rather than concentrated in one person or in a small number of group members (Weber and Crocker 1983). In the latter case, people are likely to maintain their overall stereotype of the group while subtyping, with a different stereotype, the set of group members who disconfirm the general group stereotype (e.g., black athletes; Hewstone 1994). Intergroup approaches to changing stereotypes focus on changing the social category representations on which the stereotypes are based (Gaertner et al. 1993). Decategorization approaches attempt to degrade group boundaries by drawing attention to the individualized or personalized characteristics of people originally perceived in terms of their group membership. Recategorization strategies involve redefining group boundaries either (1) to change the representations from separate groups to one group which reflects a common identity; or (2) to maintain the original group categories but simultaneously to emphasize connection to a larger entity through common goals and mutual interdependence (Hewstone and Brown 1986). Whereas the former approach may be more effective at changing attitudes and stereotypes of people immediately present in the situation, the latter approach may produce more generalized stereotype change because it maintains the associative links to group members not present in a contact situation. Producing significant and enduring stereotype change typically requires direct, sustained, and personal intergroup contact.

Stress

Stress may be defined as a threat, real or implied, to the psychological or physiological integrity of an individual. Although stress can be assessed as subjective experience, it is the behavioral and physiological responses to stress that are the most closely linked to measurable health outcomes.

Stress involves a stressor and a stress response. Stressors include trauma or injury, physical exertion at the limit of the body's capacity, and environmental factors like noise, overcrowding, and excessive heat or cold. Major life events are stressful, as are daily hassles in the family and workplace. Social isolation is stressful, and supportive social contact reduces the physiological stress response.

Stress responses may be both behavioral and physiological. Behavioral responses to stress may avoid trouble, but they may also exacerbate the consequences of stress: for instance, confrontational behaviors that exacerbate the stress, as well as self-damaging behaviors like smoking, drinking, and driving an automobile recklessly. Physiological stress responses involve the activation of the autonomic nervous system and the hypothalamo-pituitary-adrenal (HPA) axis.

The brain and behavior play an important role in determining what is stressful. The brain interprets what is stressful on the basis of past experience of the individual, and then determines the behavioral response; and the brain regulates the physiological stress response. The brain is also a target of stress, which increases activity of systems that subserve fear (the AMYGDALA) and impairs systems that subserve declarative, episodic, spatial, and contextual MEMORY (the HIPPOCAMPUS; see also NEUROENDOCRINOLOGY).

Hans Selye described the "general adaptation syndrome" in response to stressors, which consists of the outpouring of catecholamines and cortisol as a common response to many noxious situations. There are two impor-

tant features of the physiological stress response: (1) turning it on in amounts that are adequate to the challenge, and (2) turning it off when it is no longer needed. The physiological mediators of the stress response, namely, the catecholamines of the sympathetic nervous system and the glucocorticoids from the adrenal cortex, initiate cellular events that promote adaptive changes in cells and tissues throughout the body, which in turn protect the organism and promote survival.

The physiological systems that react to stress are important protectors of the body in the short run but cause damage and accelerate disease over long periods of time. Thus "good stress" involves the adaptive response to acute stress, and "bad stress" involves chronic stress, with sustained physiological responses that produce wear and tear on the body and brain over months and years. Stressful experiences can often be exhilarating to some individuals, whereas prolonged stress is generally not beneficial. "Bad stress" occurs when the stress response is stimulated frequently or when it does not shut off when not needed. The price of adapation, involving wear and tear on the body, has been called "allostatic load." *Allostasis,* meaning "achieving stability through change," describes the process of physiological adaptation, and *allostatic load* refers to a gradual process of wear and tear on the body. Examples of allostatic load include the exacerbation of atherosclerosis by psychosocial stress; stress-induced acceleration of abdominal obesity; hypertension and coronary heart disease resulting from job strain; bone calcium loss in depressive illness and as a result of intensive athletic training; and atrophy and damage to nerve cells in the hippocampus with accompanying memory impairment.

The vulnerability of many systems of the body to stress is influenced by experiences early in life. In animal models, unpredictable prenatal stress causes increased emotionality and increased reactivity of the HPA axis and autonomic nervous system, and these effects last throughout the lifespan. Postnatal handling in rats, a mild stress involving brief daily separation from the mother, counteracts the effects of prenatal stress and results in reduced emotionality and reduced reactivity of the HPA axis and autonomic nervous system, and these effects also last throughout the lifespan. The vulnerability of the hippocampus to age-related loss of function parallels these effects—prenatal stress increasing and postnatal handling decreasing the rate of brain aging.

Stress and stress-related disorders represent one of the most common complaints that physicians encounter, and these are estimated to cause a loss of $300 billion annually in lost productivity and medical expenses. Some examples show what stress means for health. Social conflict and the formation of hierarchies of dominance produce measurable effects in the body and brain: for example, changes in brain structure and function, and acceleration of coronary artery atherosclerosis. Stressful experiences and lack of social support have been reported to increase susceptibility to the common cold, and social support is a protective factor.

In Russia, there has been an increase of almost 40 percent in the mortality rate among men since the fall of communism. Less dramatic but still very meaningful are the gradients of health across socioeconomic status, as exemplified by the British civil service system. The lowest employ-

ment grades have increased overall mortality and increased rates of cardiovascular disease and abdominal obesity.

One of the most important aspects of stress related to disease is the sense of control. Learned helplessness is a condition that has been described in animals and humans and represents one type of coping mechanism. Less extreme, the lack of control on the job has been shown to have adverse health consequences, affecting rates of cardiovascular disease. Interventions that have increased the sense of control and reduced time pressures have increased physical and mental health.

Stress is a highly individualized experience: events that are stressful for one individual may not be stressful for others; and stress may be exhilarating and even beneficial in the short run. Individual differences in stress responses are traceable to life experiences during development and adult life, as well as to individual differences in physiological vulnerability based on genetic background and physical and mental health. Most individuals cope with stressful situations and adapt, as long as the stress does not continue for long periods. Nevertheless, prolonged stressful experiences and more subtle aspects of stress physiology captured under the term *allostatic load* do produce a gradual wear and tear on the body and brain that can accelerate the onset and severity of diseases.

Stress, Linguistic

In pronouncing the word à*utobìog* *ráphic,* English speakers make the odd-numbered vowels more prominent than the even-numbered, with greatest prominence going on the last odd-numbered vowel. In the traditional terminology of phonetics, the odd-numbered vowels are said to be *stressed* and the even-numbered, *unstressed.* Stress is commonly—though not universally—implemented phonetically by an increase in the *pitch* (fundamental voice frequency) of the vowel. (For details of English stress, see Pierrehumbert 1980.)

In many languages, word stress is predictable. The principles and rules that make this possible are somewhat separate from the rest of the PHONOLOGY. This quasi-independence of the stress rules is reflected in the fact that when adding to its vocabulary a word from another language, the borrowing language often preserves the phonemes (sounds) of the original word but modifies its stress contour. For example, the Russian borrowing *babúshka* is stressed in English on the second syllable, whereas in Russian this word has initial stress (i.e., *bábushka*). Except for the stress, the sounds of the Russian word are (quite) faithfully reproduced in English. As there has been no concerted effort by the schools or media to instill a particular stress pattern, the most plausible explanation for the *babúshka* stress is that English speakers assign stress to this new word by analogy with such English words as *Aláska, fiásco.* Implicit in this explanation is the assumption that English speakers have knowledge of the English stress rules and make active use of this knowledge. Although little is known at present about how this knowledge is used by speakers in the production of utterances, a great deal has been learned in the last quarter century about the nature of this knowledge.

The fundamental insight into the nature of stress is due to Liberman 1975. It was he who suggested that stress reflects the grouping (chunking) of the vowels of the word—more exactly, of its stressable sounds—into subsequences called *feet.* Research since 1975 has shown that the construction of feet—and hence stress assignment—is governed by a small number of rules belonging to a few schemata that differ with respect to a handful of binary parameters. Because this perspective on stress is not widely known and may well fly in the face of common-sense views, the rest of this article presents a detailed illustration of how feet are employed to compute the stress of words. The discussion here adopts the formalism of Idsardi (1992), because it reflects most clearly the role of feet in the computation of stress. (For discussion of alternative approaches, see Halle and Vergnaud 1987; Idsardi 1992; Kenstowicz 1993; and Hayes 1995.)

We begin with the very simple stress system of colloquial Czech. In Czech, odd-numbered vowels are stressed, and main stress falls on the vowel of the word-initial syllable, as for example in *prábabìčkamì* in 'greatgrandmothers' (instrumental case) (Jakobson 1962). In most languages, vowels are stressable, but consonants are not. To reflect formally this difference between sounds that are and are not stressable, the Idsardi theory posits that metrical structure is computed on a separate plane onto which are projected all and only the stressable phonemes (usually the vowels) of the word. This is illustrated in (1) with the Czech word cited above.

         | | | | |
       prábabìčkamì

In (1) each vowel projects an asterisk and the sequence of asterisks so generated is labeled *line 0.* Additional lines of asterisks are generated by devices explained below. The set of asterisk lines associated with a given word is its *metrical grid.*

The grouping of stressable elements into feet is notated here by means of parentheses: a left parenthesis groups into a foot the stressable elements on its right, whereas a right parenthesis groups the elements on its left (cf. below). The parentheses themselves are inserted by three types of rules.

The first of these is *iterative foot construction* (IFC) rules. An IFC rule inserts left or right parentheses into a sequence of asterisks beginning at either its left or its right edge and proceeding toward the opposite edge of the string, subject to the constraint that except for the initial parenthesis a substring of two or three asterisks must separate an inserted parenthesis from the nearest parenthesis on its left, where insertion is from left to right, and on its right, where insertion is from right to left. The Czech IFC rule is given in (2) and its effects are illustrated in (3).

(2) On line 0 insert left parentheses starting from the left edge at an interval of two asterisks

(3)   (* *(*   * (* line 0
        | | | | |
        prábabìčkamì

What differentiates various IFC rules is the replacement of one or more of the three variables by its alternative (i.e., left by right or 2 by 3). The theory of metrical structure admits therefore exactly eight different IFC rules, of which a given language characteristically uses one. (For illustrations, see References.)

The second type are *head-marking* rules. In each foot, one of the elements—called the *head*—is specially marked (stressed). The head of a foot is either its left-most or its right-most element, and the head element of each foot is projected onto the next higher line in the grid, thereby signaling its marked (stressed) status. In Czech, line 0 feet are left-headed. This is illustrated in (4).

(4)   *   *   * line 1
       (* *(* *(* line 0
        | | | | |
        prábabìckamì

The third category are *edge-marking* rules. As noted above, the main stress in Czech words falls on the vowel of the initial syllable. In order to mark this vowel, the theory makes use of a second type of parenthesis insertion rule, Edge Marking, which in Czech has the form in (5).

(5) Insert a left parenthesis to the left of the left-most asterisk on line 1.

Like the IFC rule (2), the Edge Marking rule (5) has three binary variables. There exist therefore eight Edge Marking rules for languages to choose from.

The Edge Marking rule (5) creates a foot that includes all asterisks on line 1. Like all feet, those constructed by (5) have a head, which in Czech must evidently be the left-most asterisk. This is illustrated in (6).

(6)   *   line 2
       (*   *   * line 1
       (* *(* *(* line 0
        | | | | |
        prábabìčkamì

It is worth noting that in (6) the height of the asterisk columns reflects the relative degree of prominence of the different vowels in the word.

The stress rules of Czech are summarized in (7).

(7) Line 0:   i. IFC (2): Insert left parentheses starting from the left edge at an interval of 2 asterisks
              ii. Heads: left
    Line 1: iii. Edge Marking (5): Insert a left parenthesis to the left of the left-most asterisk on line 1
              iv. Heads: left
               v. Assign High pitch to vowel with line 1 asterisk

With one major addition detailed below, the machinery introduced above accounts correctly for the stress patterns of words of most (all?) languages. Two further examples are reviewed below.

Pintupi, an Australian language, differs from Czech in that the Pintupi IFC rule inserts Right rather than Left parentheses. The Pintupi word, like that of Czech, therefore has main stress on the initial vowel and secondary stresses on other odd-numbered vowels; Pintupi differs from Czech in that the word-final vowel is never stressed. This is illustrated in (8). (Capital letters represent retroflex consonants. For some additional discussion of Pintupi, see Kenstowicz 1994.)

(8)   *   line 2
       (*   *   *   line 1
)* *)* *)*   *)* line 0
        | | | | | | |
        TiLiriŋulampatʲu
        'the fire for our benefit flared up'

To deal with our final example, that of Selkup, a language of Siberia, a third type of parenthesis insertion rule is needed. This rule inserts a left/right parenthesis to the left/right of asterisks projecting vowels of special syllables—for example, syllables with long vowels. In Selkup, stress falls on the last long vowel of the word, but in words without a long vowel, stress is on the initial vowel. This migration of the stress toward opposite ends of the word is accounted for by the rules in (9).

(9) Line 0: i. Long Syllable Marking: Insert left parenthesis to left of asterisks projecting long vowel
            ii. Edge Marking: Insert right parenthesis to the right of the right-most asterisk
           iii. Heads: left
    Line 1: iv. Edge Marking: Insert right parenthesis to the right of the right-most asterisk
             v. Heads: right
            vi. Assign High pitch to vowel with line 2 asterisk

As illustrated in (10a), these rules assign stress to the last long vowel, and, as shown in (10b), in words without a long vowel the rules assign stress to the word-initial syllable. In view of (9iv) and (vi), there is but one stress per word in Selkup.

(10) a.   *   line 2
              *   *) line 1
           * (* *(*) line 0
           | | | |
            qumooqlilii
           'your two friends'

     b. *   line 2
         *)   line 1
         * * * *)   line 0
         | | | |
          qol'cɪmpatɪ
          'found'

Although Selkup stress is vastly different from that of both Czech and Pintupi, it is the result of the same rules

(rule schemata) with different settings of the parameters. To explain this similarity, we hypothesize that the schemata are part of the innate cognitive capacities that normal children bring to the task of learning the language of their milieu. Because the rule schemata are part of the innate cognitive equipment of learners, the task of a child learning a language reduces to figuring out the setting of a dozen or so binary parameters. This hypothesis accounts for the speed and accuracy with which children normally accomplish this task. Finally, by positing that knowledge of rule schemata is part of the genetic endowment of humans, but not of other species, we explain also why language is a uniquely human trait.

Structure from Visual Information Sources

Looking about, it is obvious to us that the surrounding world has many objects in it, each object with a particular identity and location in the environment. The primate nervous system effortlessly determines both the object structure and its location from multiple visual sources. The motion of the object, its reflectance and obscuring of light, and the fact that we view the object with two eyes are all combined to form its internal representation in our brain. These sources of visual information have been under intense scrutiny for more than a century beginning with the work of the physicist and physiologist HELMHOLTZ (Helmholtz 1962). However, it is only a relatively recent realization that there are substantial differences in how information from these sources is encoded by the primate brain to derive the shapes of objects. This development was driven by psychophysical, physiological, and anatomical determination of two VISUAL PROCESSING STREAMS in VISUAL CORTEX, one specialized for object shape and one for SPATIAL PERCEPTION. In the analysis of spatial environment, large portions

of the visual field are typically analyzed through neurons leading to the parietal lobe. In contrast, the analysis of object shape requires fine details of each object integrated over space and time and occurs in the temporal cortex.

There are three major cues for the analysis of object shape. The most thoroughly studied is derived from motion. Fifteen years before any scientific publications, Ginger Rogers and Fred Astaire exploited the illusion of depth from motion in the black-and-white film *The Gay Divorcee* (1939). The shadow from a cardboard cutout of dancers rotating on a phonograph turntable fooled a gigolo into thinking the young couple was pirouetting behind closed doors. A number of papers by the gestalt psychologists (see GESTALT PERCEPTION) thoroughly explored the ability to extract 3-D shape-from-motion, typified by the work of Gibson (1966) and Wallach and O'Connell (1953). Subjects were only able to reconstruct the 3-D shape of a bent wire from its shadow when the wire was rotated. Further studies identified that 3-D structural cues such as length and angles between segments could be used to extract the 3-D shape, as reviewed by Ullman (1979). These studies provided a number of different explanations for the extraction of structure-from-motion, pitting purely motion cues against varying recognizable form cues. This bottom-up vs. top-down controversy was further examined using computer-generated displays in which the motion of each element could be individually controlled (Ullman 1979). These studies have shown that pure motion is sufficient to extract form information in both human and nonhuman primates (Siegel and Andersen 1988), although they do not explicitly exclude the possibility that form cues may supplement motion.

Another source of visual information arises from the horizontal separation between the two eyes (figure 1). The binocular depth effect is seen with old-style Wheatstone stereoscopes in which the scene leaps into depth when viewed with both eyes (Wade and Ono 1985). Sufficient information exists in the disparity of the two images on the RETINA to provide depth profiles. As in the study of structure-from-motion, the issue arises as to whether recognizable details are needed to extract structure-from-disparity. Julesz (1995) generated computer displays in which all the visual cues were removed except for disparity using stimuli that appeared to each eye as random visual noise. The fusion of the random dot stereograms demonstrated that depth could unambiguously be derived from the disparity of the retinal images.

The third major source of information about the shape of an object arises from the reflectance of light from its surface (see figure 1). Different surface characteristics provide shape information. Specular (shiny) highlights arise from shiny surfaces and may accentuate regions of high curvature while color may also help in determining object shape. A well-studied luminance cue is shape-from-shading in which light passes over an object and part of the object is illuminated while part remains in shadow. Unlike structure-from-motion and structure-from-disparity, a top-down assumption that the light source is above the object is needed to explain much of the psychophysical data.

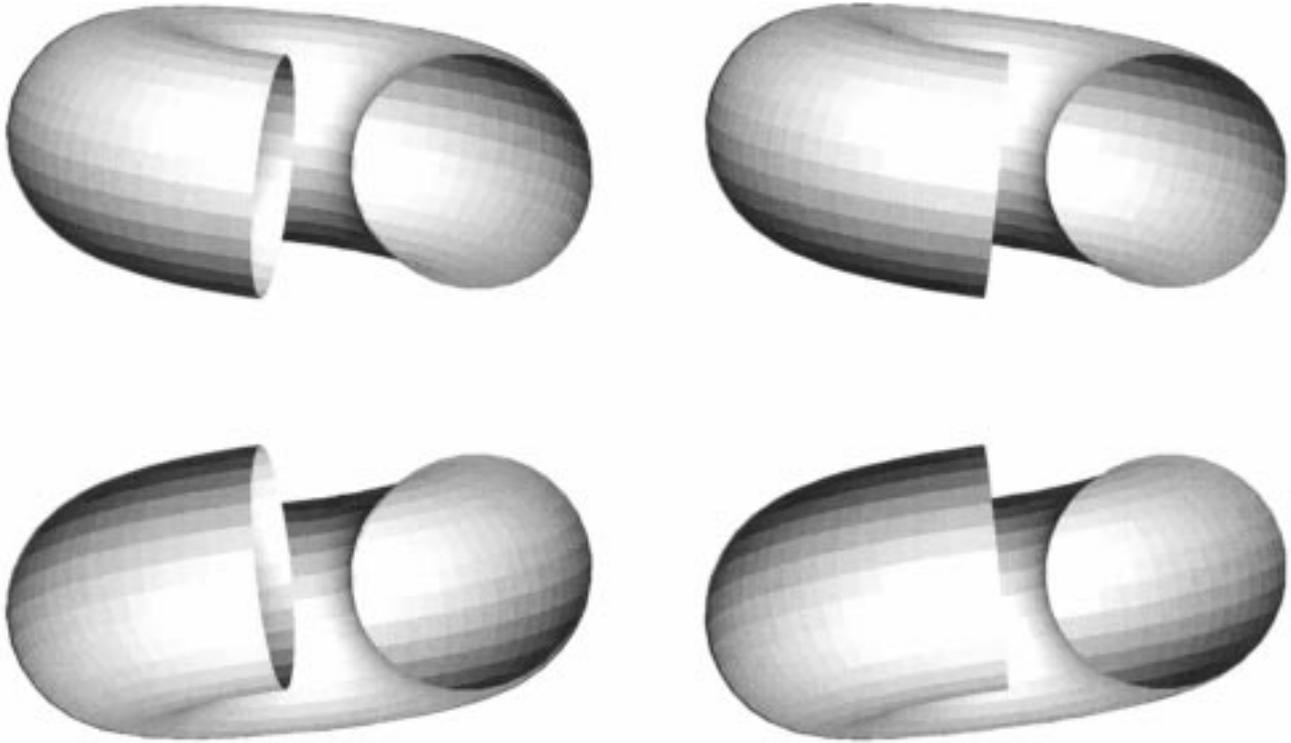
An assumption, such as the invocation of a highly elevated light source in structure-from-shading, is called a constraint by those in COMPUTATIONAL NEUROSCIENCE.


Figure 1. In both pairs of figures, the shape is easily determined from the shading cues, although the lower figure incorrectly appears to have a ball at one end. This is due to the expectation that all light sources are above. The pairs of figures may be fused by using a stereoviewer or free-fusing to provide unambiguous depth cues. In the upper pair, where the stereo and shape-from-shading cues agree, the right end of the tube is correctly seen as an opening. In the lower pair of figures, the disparity cues and the shape-from-shading cues are in opposition. Even with the presumably unambiguous disparity cues, the ball remains at the end of the tube. The shape-from-shading cues are dominant, suggesting that it is processed prior to disparity. Studies in which one type of shape cue is pitted against another are often used in psychophysical studies, with the actual physiological measurements lagging behind.

Constraints are often invoked in shape analysis because the raw measurements of motion, disparity, or luminance are insufficient to define objects in the world (MARR 1982; Poggio and Koch 1985). It arises because there are too many objects that can give rise to the measured motion, disparity, or shaded images. The constraints may be explicit or implicit in the theories, algorithms, or implementations (Marr 1982) that solve problems of shape recognition. For example, given a black-and-white photograph of an egg, most persons assume that the egg is lit from above and thus the egg's surface is perceived as convex. In fact, if the photograph is simply turned over, most observers will describe the surface as convex, their perception seemingly fixed on the idea that the light source is overhead (Ramachandran 1988). The rigidity of an object is often assumed in the analysis of structure-from-motion (Ullman 1979; Bennett and Hoffman 1985). It is still unknown how constraints are expressed in the brain and whether they are innate or develop through experience.

These assumptions combined with a geometrical description of the problem have led to a number of theorems that demonstrate the feasibility of obtaining information from the visual input. As a test of these theorems, algorithms are implemented on digital computers. These have been successful to some extent in that certain problems in MACHINE VISION, such as automobile part recognition, may be per-formed. However, the question as to whether the primate brain implements mathematically based approaches remains open.

Anatomical and physiological studies of the CEREBRAL CORTEX have been able to determine some of the actual processes and brain regions that are involved in shape recognition. Both hierarchical and parallel processes are involved in the representation of shape. The best-understood recognition process is the motion pathway that passes through striate cortex, to the middle temporal motion area (MT/V5). In MT/V5 there is a representation of the velocity of the image for different parts of the visual field (Albright, Desimone, and Gross 1984). This motion representation is further developed in the medial superior temporal area (MST) in which neurons are found that respond to environmental optic flow for spatial vision (Tanaka et al. 1986; Duffy and Wurtz 1991). Beyond MST, the motion signal passes to the parietal cortex (area 7a; Siegel and Read 1997) in which optic flow signals are further processed and combined with eye position information. Both 7a and MST project to the anterior polysensory temporal area (STPa) which has neurons that represent both flow and apparently 3-D shape (Bruce, Desimone, and Gross 1981; Anderson and Siegel submitted).

Running roughly in parallel to the processing of visual motion is the analysis of disparity cues. At each step from

striate to MT/V5 to MST to 7a, neurons are found that are tuned to disparity (Poggio and Poggio 1984; Roy, Komatsu, and Wurtz 1992; Gnadt and Mays 1995). Little is known as to how binocular cues are used for shape representation.

A more temporal cortical stream represents shape using luminance and color cues. Neurons have been described that represent all sorts of luminance cues, such as orientation (Hubel and Wiesel 1977) and borders (von der Heydt, Peterhans, and Baumgartner 1984). Geometrical figures (Tanaka 1993), as well as shapes as complex as faces (Gross 1973), may be represented by temporal cortical neurons. Color analysis surely is used in object identification, although little formal work has been done. Surprisingly, the dependence of these neurons upon parameters of motion (Perrett et al. 1985) and disparity are as yet little explored. Such studies are crucial, as the psychophysical ability to describe shape (a putative temporal stream analysand) does not deteriorate when motion or disparity (a putative dorsal stream analysand) is the underlying representation.

In summary, the visual perception of 3-D structure utilizes motion, disparity, and luminance. Psychophysical studies have defined the limits of our ability, while computational studies have developed a formal framework to describe the perceptual process as well as to test hypotheses. Anatomical and physiological results have provided essential cues from functional systems.

Superstition

See MAGIC AND SUPERSTITION; RELIGIOUS IDEAS AND PRACTICES

Supervenience

Supervenience is a determination relation, often thought to hold between physical characteristics and mental characteristics. In philosophy of mind, the concept of supervenience is sometimes employed as a way of articulating the metaphysical thesis of PHYSICALISM. The notion of supervenience, originally employed in ethics, was introduced into philosophy of mind by Donald Davidson (1970, 1973), who formulated the thesis that mental characteristics are supervenient on physical ones: "It is impossible for two events (objects, states) to agree in all their physical characteristics . . . and to differ in their psychological characteristics" (Davidson 1973: 716). This supervenience claim is weaker than certain other claims about physical-mental relations sometimes advocated in philosophy of mind—for instance, that mental characteristics are identical to, or are definable from, or are lawfully coextensive with, physical characteristics.

One commonly cited reason to favor physical/psychological supervenience over any of these stronger, more reductive, conceptions of the relation between the physical and the mental is that psychological characteristics allegedly are multiply realizable (i.e., multiply implementable) by physical ones. For instance, mental properties might get physically realized very differently in certain actual or possible nonhuman creatures (e.g., Martians) than in humans. Furthermore, for some species of actual or possible creatures (perhaps including humans), a given psychological characteristic might be physically multiply realizable within the species, or even in a single creature.

The physical characteristics that determine a given psychological characteristic M of a given creature (on a particular occasion when M is instantiated) are called the *supervenience base* for M (on that occasion). Typically the supervenience base will include not only the physical property P that physically realizes M in the creature with characteristic M, but also certain physical-structural characteristics of the creature in virtue of which the property P plays the causal role requisite for being a realization of M. For instance, the supervenience base for the property *wanting some ice cream* on a given occasion, will include not only the neurochemical property P that physically realizes this desire-property in a given person, but also various persisting structural features of the person's brain and body in virtue of which P plays a suitable desire-implementing causal role (e.g., the role of propelling the person's body toward a location where the person believes ice cream can be obtained).

Supervenience often figures in philosophical discussions of mental causation. It is sometimes suggested (e.g., Kim 1979, 1984) that causal efficacy and explanatory relevance are "transmitted" across levels of description, via supervenience connections, from physical characteristics to mental ones. The idea is that mental characteristics figure in "supervenient causation"—even though all human behavior, described as bodily motion, in principle is causally explainable in physico-chemical terms (see MENTAL CAUSATION).

A distinction is commonly made between intentional (representational) mental characteristics and qualitative (phenomenal) mental characteristics; and it is sometimes maintained that the former are supervenient on the physical in a way that the latter are not. (Intentional characteristics are the kind typically expressed by mentalistic locutions containing "that"-clauses, e.g., "believes that MIT is in Boston." Qualitative characteristics, or QUALIA, are the distinctive WHAT IT'S LIKE features of sensory experiences like seeing a bright red color patch, or smelling rotten eggs, or stubbing one's toe.) Intentional characteristics are widely thought to be *logically,* or *conceptually,* supervenient on physical characteristics (e.g., Chalmers 1996)—so that there is no "possible world" that is a perfect physical duplicate of the actual world, but differs from the actual world in the distribution of intentional mental properties. By contrast, it is sometimes claimed (e.g., Chalmers 1996) that qualia are not logically supervenient on the physical, because allegedly the following kinds of physical-duplicate worlds are conceptually coherent possibilities: (1) a physical-duplicate world in which color qualia are paired with the relevant neural states in the human visual cortex in ways that are systematically inverted relative to actual-world neural/qualia pairings (an "inverted qualia" world); and (2) a physical-duplicate world in which qualia are absent altogether (an "absent qualia" world).

Even if qualia are not logically supervenient on physical characteristics, they still might exhibit a weaker kind of dependence: *nomological* (i.e., lawful) supervenience. The nomological supervenience of qualia would mean there are fundamental laws of nature, over and above the basic laws of physics, linking certain physical (or perhaps certain functional) characteristics of certain physical systems (e.g., humans and other sentient creatures) with the concurrent presence of qualia—a view defended in Chalmers (1996). Arguably, such a position would be a version of naturalism about qualia, but not a version of physicalism. Issues of mental causation would arise for such a view, because it is sometimes maintained (e.g., Horgan 1987) that if qualia supervene on physical characteristics only nomically and not in a stronger way, then qualia are epiphenomenal—that is, they have no real causal efficacy or explanatory relevance vis-à-vis human behavior.

Supervenience issues also arise with respect to intentional mental characteristics. It is often claimed that for at least some intentional properties, the minimal supervenience base includes more than the intrinsic physical features of the person instantiating the property (at the time of instantiation); it also includes certain relational connections between the person and the wider environment. One very influential source for such claims is the TWIN EARTH thought experiment in Putnam (1975). An Earthling and a Twin Earthling who are just alike in all intrinsic physical respects could differ mentally: the Earthling is having a thought about water (viz., H_2O), whereas the Twin Earthling is having a thought about twater (viz., XYZ). The moral, apparently, is that the supervenience base for an intentional mental characteristic like *wanting some water* involves not merely the current intrinsic physical properties of the person who currently has this mental property, but also certain relational connections between the person and the person's physical—and/or social, and/or historical, and/or evolutionary—environment. Such mental properties are said to have *wide content,* because the supervenience base for such a property extends beyond the current intrinsic physical characteristics of the creature currently instantiating the property; wide-content characteristics, as the saying goes, are not supervenient upon "what's in the head." By contrast, intentional mental characteristics that do supervene upon a creature's current intrinsic physical characteristics are said to have NARROW CONTENT.

A variety of interrelated issues concerning wide and narrow content have received active discussion in recent philosophy, and have direct implications for the foundations of cognitive science. These include the following:

1. How should wide-content and narrow-content mental states (i.e., state-types) be characterized?
2. How pervasive is the phenomenon of wide content? Is it confined to beliefs and other mental states employing specific kinds of concepts (e.g., natural-kind concepts like "water" or "gold"), or is it much more widespread?

3. Do wide-content mental states have causal efficacy and explanatory relevance?
4. Should cognitive science concern itself with both wide-content and narrow-content psychological states, or should it rather focus on only one kind?
5. Is there really such a thing as narrow content at all?

Discussion of such questions has occurred in an intellectual climate where two broad currents of thought have been dominant. One approach assumes that most, or perhaps all, intentional mental states have both wide content and narrow content (e.g., Fodor 1980, 1987, 1991). A second approach eschews narrow content altogether, and construes mental intentionality as essentially a matter of suitable relational connections between intrinsic physical states of a creature and certain features of the creature's current environment and/or its evolutionary/developmental history (e.g., Dretske 1981, 1988; Millikan 1984; Fodor 1994). But some philosophers vigorously challenge both orientations—for instance, David Lewis (1994), whose dissident remarks are eminently sensible.

Two longer overview discussions of supervenience are Kim (1990) and Horgan (1993). Useful collections include Horgan (1984), Beckermann, Flohr, and Kim (1992), and Kim (1993).

Supervised Learning in Multilayer Neural Networks

Neural networks consist of simple processing units that interact via weighted connections. They are sometimes implemented in hardware but most research involves software simulations. They were originally inspired by ideas about how the brain computes, and understanding biological computation is still the major goal of many researchers in the field (Churchland and Sejnowski 1992). However, some biologically unrealistic neural networks are both computationally interesting and technologically useful (Bishop 1995).

A typical processing unit first computes a "total input," which is a weighted sum of the incoming activities from other units plus a bias. It then puts its total input through an activation function to determine the activity of the unit. The most common activation function is the logistic, $y = 1/1 + exp(-x)$. For deterministic analog units the activity that is communicated to other units is simply y. For binary stochastic units, y determines the probability that the activity of the unit is 1 rather than 0. For binary threshold units, the activity is 1 if the total input is positive and 0 otherwise. Sensory input to the network is typically handled by fixing the activities of some "input" units.

The most interesting property of NEURAL NETWORKS is their ability to learn from examples by adapting the weights on the connections. The most widely used learning algorithms are supervised: they assume that there is a set of training cases, each consisting of an input vector and a desired output or output vector. Learning involves sweeping through the training set many times, gradually adjusting the weights so that the actual output produced by the network gets closer to the desired output. The simplest neural network architecture consists of some input units with directed, weighted connections to an output unit. Such networks were extensively studied in the 1960s because there are very simple learning algorithms that are guaranteed to find the optimal weights when the output unit uses a linear or binary threshold activation function

(Widrow and Hoff 1960; Rosenblatt 1962). Unfortunately, such simple networks can only compute a very limited class of functions (Minsky and Papert 1969). They cannot, for example, compute the exclusive-or of two binary inputs.

The limitations of simple networks can be overcome by adding one or more intermediate, "hidden" layers of nonlinear units between the input and the output. The architecture remains feedforward, with each unit only receiving inputs from units in lower layers. With enough hidden units in a single layer, there exist weights that approximate arbitrarily closely any continuous, differentiable mapping from a compact input space to a compact output space. Finding the optimal weights is generally intractable, but gradient methods can be used to find sets of weights that work well for many practical tasks. Provided the hidden units use a nonlinearity with a well-behaved derivative, an algorithm called "backpropagation" (Rumelhart, Hinton, and Williams 1986) can be used to compute the derivatives, with respect to each weight in the network, of the error function. The standard error function is the squared difference between the actual and desired outputs, but cross-entropy error functions are more appropriate when the outputs represent class probabilities.

For each training case, the activities of the units are computed by a forward pass through the network. Then, starting with the output units, a backward pass through the network is used to compute the derivatives of the error function with respect to the total input received by each unit. This computation is a straightforward application of the chain rule and is as efficient as the forward pass. Given these derivatives, it is easy to compute the derivatives of the error function with respect to the weights.

There are many different ways of using the derivatives computed by backpropagation. In "on-line" learning, the weights are adjusted after each training case in proportion to the derivatives for that case. In "batch" learning, the derivatives are accumulated over the whole training set and then the weights are adjusted in the direction of steepest descent in the error function, or in some more sensible direction computed by a technique such as momentum, conjugate gradients, or delta-bar-delta. The simple on-line method is the most efficient for very large training sets in which the data are highly redundant, but batch conjugate gradient is faster and easier to use for small training sets. There are also constructive methods that add hidden units one at a time while keeping the incoming weights of earlier hidden units frozen (Fahlman and Lebiere 1990).

Feedforward neural networks that have one or more layers of logistic hidden units and are trained using backpropagation have worked very well for tasks such as discriminating similar phonemes (Lang, Waibel, and Hinton 1990) or recognizing handwritten digits (Le Cun et al. 1989; see also PATTERN RECOGNITION AND FEEDFORWARD NETWORKS). Performance is significantly improved if natural symmetries of the task are imposed on the network by forcing different weights to have the same values.

When training data are limited, a complicated network with a large number of weights is liable to overfit: it performs very well on the training data, but much less well on test data drawn from the same distribution. On the other hand, a simple network with few weights may perform poorly on both training and test data because it is unable to approximate the true function (Geman, Bienenstock, and Doursat 1992). Many different methods have been developed for optimizing the complexity of the network. If part of the training data is held out as a validation set, it is possible to try different numbers of hidden units and to pick the number that gives best performance on the validation set. The "early stopping" method, which is appropriate when computational resources are limited, stops the training of a complicated network as soon as its performance on the validation set starts to deteriorate. Another way of limiting the complexity of a network is to add a penalty to the error term. The simplest such penalty is the sum of the squares of the weights times a penalty coefficient, λ. This can be viewed in Bayesian terms as a zero-mean Gaussian prior which favors networks that have small weights. λ can be chosen using a validation set but this wastes training data and is awkward if different values of λ are required for the input-to-hidden and hidden-to-output weights. MacKay (1995) has developed Bayesian methods that estimate an appropriate λ without using a validation set.

Performance can almost always be improved by averaging the outputs of many different networks each of which overfits the data. Finding the appropriate weights to use when averaging the outputs can be viewed as a separate learning task (Wolpert 1992). The benefits of averaging increase as the networks' errors become less correlated so it helps to train networks on different subsets of the data (Breiman 1994). Training a net on data that earlier nets get wrong is an effective way of focusing computational resources on the difficult cases (Drucker, Schapire, and Simard 1993).

When fitting a network to data it is usual to search for a single good set of weights. The correct Bayesian method, by contrast, computes the posterior probability distribution over weight vectors and then combines the predictions made by all the different weight vectors in proportion to their posterior probabilities. MacKay's methods approximate the posterior by constructing a Gaussian distribution around each of a number of locally optimal weight vectors. Neal (1996) describes an efficient Monte Carlo method of approximating the full, multimodal posterior distribution. Rasmussen (1996) demonstrates that Neal's method gives better performance than many other neural network or statistical methods, but that it is no better than an equivalent statistical approach called Gaussian Processes.

Many varieties of feedforward net have been investigated. Radial basis function (RBF) networks use hidden units whose activations are a radially symmetrical function of the distance between the input vector and a mean vector associated with the unit (Broomhead and Lowe 1988). The usual function is a spherical Gaussian, but they can be generalized to have different variances on each input dimension or to have full covariance matrices. RBF networks can be fitted using the gradient computed by backpropagation. Alternatively, the means and variances of the hidden units can be set without reference to the desired outputs by fitting a mixture of Gaussian density models to the input vectors, or by simply using some of the training input vectors as means.

For tasks in which the data are expected to come from a number of different but unknown regimes, it is advantageous

to use a "mixture of experts" architecture containing a different network for each regime and a "gating" network that decides on the probability of being in each regime (Jacobs et al. 1991). The whole system is trained to maximize the log probability of the correct answer under a mixture of Gaussian distributions, where each expert computes the input-dependent mean of a Gaussian and the gating network computes the input-dependent mixing proportion. Each expert can specialize on a specific regime because it only receives significant backpropagated gradients for cases where the gating network assigns it a significant mixing proportion. The gating network can discover the regimes because it receives backpropagated derivatives that encourage it to assign the expert that works best for each case. With a hierarchy of managers, this system is a soft version of decision trees (Jordan and Jacobs 1994).

Surface Perception

When we view a scene, the world seems to be filled with objects that have particular shapes, colors, and material properties. The primary source of information that we use to acquire information about our world is visual, which relies on the light reflected off of object surfaces to a point of observation. Thus, our knowledge of object structure—or any aspect of our visual world—is determined by the structure of the surfaces of objects, since it is here that light interacts with objects. Surface perception refers to our ability to use the images projected to our eyes to determine the color, shape, opacity, 3-D layout, and material properties of the objects in our environment. In this discussion, some of the basic problems studied in this domain are briefly introduced.

The problem of surface perception is to understand exactly how the visual system uses the structure in light to recover the 3-D structure of objects in the world. A solution to this problem requires that the visual system untangle the different causes that operate collectively to form the variations in luminance that project images to our eyes. The reason this problem is so hard is that there are a number of different ways that the same image could have been physically generated. Consider, for example, the problem of recovering the apparent lightness of a surface. The same shade of gray can be created by a dimly illuminated white surface, or a brightly illuminated black surface. Yet we seem to be remarkably good at untangling the contributions of illumination from the contributions of reflectance, and recovering the lightness of a surface. One of the major areas of research in surface perception is in LIGHTNESS PERCEPTION, which is one of the oldest areas of research in vision science. Yet even today, we are only beginning to understand how the photometric and geometric relationships in an image interact to determine the perceived lightness of a surface.

Another primary difficulty in recovering surface structure is in classifying the different types of luminance variations that arise in images. Consider the problem created by understanding the cause of a simple luminance discontinuity. Abrupt changes in luminance can be generated by occluding contours, shadows, or abrupt changes in the reflectance of a surface. An incorrect classification of luminance edges would lead to a variety of perceptual disasters. For example, consider a scene in which a face is brightly illuminated from the left, casting a strong shadow on the

person's right cheek. If the boundary of this shadow is treated as an object boundary, the person's face would be split in pieces, and it would probably be impossible to recognize the underlying face. If the shadow boundary was interpreted as a change in the reflectance of the surface, the person's face would appear to have a large, dark stain. Both forms of misclassification would lead to distinct errors. In order to perceive the person's face as a homogeneously pigmented single object, the visual system must be capable of correctly classifying the shadow boundary as a shadow boundary, which can then provide information about the 3-D surface that generated the shadow.

A related problem arises when attempting to use luminance gradients ("shading") to determine perceived shape. The "shape from shading problem" refers to the difficulty in using luminance variations to reveal 3-D shape. However, the amount of light reflected off a 3-D surface to a point of observation depends on a number of variables, including the position and intensity of the light source, as well as the orientation and reflectance function of the surface. In order to use the luminance variations in an image to recover surface structure, the visual system must distinguish luminance variations due to changes in 3-D shape from changes in surface reflectance or changes in illumination. Virtually all models of this ability assume the existence of a single light source that has a known position, and further assume that the reflectance of a surface is known. The ability of our visual systems to recover shape from shading appears much more general than these models would suggest, but just how the visual system manages to use luminance gradients to infer 3-D shape in natural scenes remains largely unknown.

More generally, the visual system must be able to decompose a variation in luminance caused by intrinsic changes in surface properties (such as surface reflectance), from those caused by the variations that are extrinsic to a surface. There are two ways in which this decomposition seems to be accomplished. One method relies on image properties that provide a unique "signature" of their environmental cause to classify the causes of luminance variations. Such methods are usually described as "bottom-up" or data-driven processes, since they only depend on the form of the current input to the visual system. The other method is to use TOP-DOWN PROCESSING IN VISION to determine the causes of image structure, which relies on previously acquired information to classify ambiguous images. Both types of processes seem to operate when we view natural scenes in determining perceived surface structure.

One of the most challenging problems in the accurate recovery of surface structure is generated by the geometry of occlusion or camouflage. In cluttered scenes, many objects and surfaces are partially obscured by nearer, occluding surfaces, and some nearer surfaces are camouflaged by distant surfaces that have identical textural and reflectance properties. In order for the visual system to recover surface structure in these scenes, the visual system must be capable of distinguishing between those situations in which an object actually ends and those in which an object ends because it is partially occluded or obscured by a camouflaged background. Once it is determined that partial occlusion or camouflage is present, the visual system must

integrate the spatially separated scene fragments into a single surface. The perceptual interpolation of objects behind occluders is known as *amodal completion,* and was originally studied by workers in GESTALT PERCEPTION. A related phenomenon is the modal completion of surfaces and contours over image regions that are partially camouflaged by a more distant surface. Recent physiological work has demonstrated that there exist cells early in the cortical processing stream (V2) that respond to illusory contours, providing strong evidence that the interpolation of surface is truly a form of visual processing, and does not require more abstract "cognitive" processes to occur.

In summary, the problem of surface perception is difficult because the visual system is confronted with the problem of untangling the different physical causes of the images on our retinas, and filling in missing information when only portions of a surface are visible. Although much progress has been made in understanding how the visual system infers surface structure in some simplified images, much remains to be done before we have a full understanding of how our visual system works in the highly structured images created by natural scenes.

Syntax

Syntax is the study of the part of the human linguistic system that determines how sentences are put together out of words. Syntax interfaces with the semantic and phonological components, which interpret the representations ("sentences") provided by syntax. It has emerged in the last several decades that the system is largely universal across languages and language types, and therefore presumably innate, with narrow channels within which languages may differ from one another (Chomsky 1965; 1981b), a conclusion confirmed by studies of child language acquisition (Crain 1990 and numerous others).

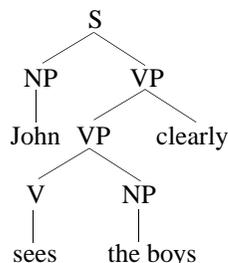
The term *syntax* is also used to refer to the "structure" of sentences in a particular language. One aspect of the syntactic structure of sentences is the division of a sentence into phrases, and those phrases into further phrases, and so forth. The range of phrase types is quite specific and generally considered to be innately determined (and hence not learned) and so are the rules that determine how phrases are formed from words and other phrases. Essentially, the inventory of phrase types is derived from the inventory of the parts of speech, or lexical categories (noun, verb, etc.). First, any part of speech can be the "head" or nucleus of a phrase. Then, larger phrases are built from a head by combining it with another phrase in one of three ways: the added phrase can express an argument of the head; it can modify the head; or it can be a "specifier" of the head:

(1) a. argument: see + the boy   [V NP]$_{VP}$
    b. modification: see + clearly   [VP Adv]$_{VP}$
    c. specification: the + boys   [Article N]$_{NP}$

The structure of a phrase is indicated by surrounding the parts of the phrase with brackets labeled with the name of the phrase; hence the notation [V NP]$_{VP}$ asserts that a Verb Phrase (VP) can consist of a verb followed by a Noun Phrase (NP). The theory of phrase structure is sometimes called X-BAR THEORY, as the phrasal labels are alternatively written with a "bar" over the lexical category instead of a P after it: V' (for VP), N' (for NP), and so on.

Principles of this sort determine that every sentence has as part of its linguistic description a tree-like structure, which shows how the component phrases are related to each other by these three relations:

(2) a.

```
                    S
                  /   \
               NP      VP
                |     /   \
             John   VP    clearly
                   /  \
                  V    NP
                  |     |
                sees  the boys
```


b. [[John]$_{NP}$[[sees]$_V$[[the]$_{Art}$[boys]$_N$]$_{NP}$]$_{VP}$[clearly]$_{Adv}$]$_{VP}$]$_S$

The two representations (a,b) are identical in their content—they both represent the phrase structure of the sentence *John sees the boys clearly.* The tree representation is often used because it is easier to read. "S" stands for *sentence.*

Ambiguity of phrasing arises when a single string of words can be associated with two different phrase structures according to the phrase definitions of a language; for example:

(3) a. John sees [the boys with the telescope]$_{NP}$
    b. John sees [the boys]$_{NP}$ with the telescope

In one structure, the boys have the telescope; in the other, John does.

Great uniformity is found in how the three relations in (1) are instantiated in languages. One dimension of variation is the position of the head in its phrase. In a language like English, the head uniformly precedes its arguments (except for the subject); in Japanese, the head uniformly follows its arguments:

(4) **English**   *Japanese*

	English		Japanese
VP:	[V NP]$_{VP}$	read a book	[NP V]$_{VP}$	sakana o taberu 'fish eat'
PP:	[P NP]$_{PP}$	to New York	[NP P]$_{PP}$	New York ni 'New York to'

We see here that in Japanese not only does the argument of the verb precede the verb, but the object of the preposition precedes the preposition (for which reason, it is called a *postposition*). Languages with postpositions instead of prepositions always show "object-verb" word order; because the verb and preposition are the heads of their respective phrases, this suggests that the head-order parameter is set once and for all for a given language, all phrases in that language taking the same value (Greenberg 1963).

Thus every language instantiates the "argument of" relation as a lexical item (the head) combined with a phrase (the argument), but languages differ in where the head stands in relation to the argument phrase. The rich concepts here—the notion "phrase," the notion "argument of," and so on—are innate; what must be learned is only the left-right order of head and argument. The ratio of learned things to innate things here is typical of syntax. The parameters of syntactic variation, of which head position is one, appear to be limited in number, and individually, limited in scope. The head parameter, for example, can only take "left" and "right" as values, meaning that there are only two types of languages in regard to head position.

Another aspect of the syntactic structure of a sentence is "movement" relations that hold between one syntactic position in a sentence and another. Among these are the relation of a question word in a question to the grammatical position in the sentence on which the question pivots:

(5) What$_i$ does John think that Bill wants t$_i$?

The position of the "trace" (t$_i$) is the "understood" position of the *wh*-word *what*—the question is about the "object" of

Bill's desires, so to speak. *What* is an "argument of" *wants* but does not appear in the correct position for such arguments; it has been "moved" to the front of the sentence. The relation between the moved *wh*-phrase and its understood position (marked by its trace, t_i) is called WH-MOVEMENT. (5) is understood to have a phrase-structure representation of the following form (its "d(eep) = structure") transformed into (5) by an operation moving the *wh*-word to the front:

(6) John does think that Bill wants what?

Wh-movement is an instance of what is called a "grammatical transformation."

    Wh-movement is a relation of very particular character, as the following examples might suggest, if examined closely:

(7) a. What$_i$ does John think that Bill said that Mary would like t_i?
   b. *What$_i$ does John think that t_i would please Bill?
   c. *What$_i$ does John think t_i time it is?
   d. *What$_i$ does John wonder who has t_i?

The prefixed asterisk is used to mark ungrammatical strings of words, but strings that would correspond to reasonable questions, if they were grammatical. (7a) suggests that the relation may span perhaps an arbitrarily large amount of sentence structure. But the rest of the examples suggest sharp limitations on the relation. The movement relation has been studied in great detail in a number of languages and language families. A core set of restrictions on the relation, some of which are illustrated in (7), have been found to hold universally. For example, (7d) illustrates what has been called the "Empty Category Principle" (ECP; Chomsky 1981a).

    The movement relation occurs in a number of sentence and clause types besides questions:

(8) a. [What a fool]$_i$ John turned   (exclamative)
    out to be t_i.
   b. The man who$_i$ Mary thinks   (relative clause)
    she met t_i.
   c. Happy$_i$ though Mary is t_i, she   (though-clause)
    is still insensitive to others.
   d. John$_i$ I think I saw t_i in the   (topicalized clause)
    store yesterday.
   e. John saw [more people]$_i$ than   (comparative clause)
    we thought he had seen t_i.

Exactly the same restrictions illustrated in (7) for questions hold for all these further types as well, suggesting the deep systematicity of the principles involved; for example, the ECP holds for comparative clauses, as the following shows:

(9) a. *John saw [more people]$_i$ that we thought that t_i were there.
   b. John saw [more people]$_i$ that we thought t_i were there.

    The mental computation of the relation of a *wh*-word to its trace is easily detected by psycholinguistic testing of on-line real-time sentence comprehension, on which it imposes an extra processing load.

    Languages can differ in some limited ways in this aspect of sentence structure—for example, in whether the *wh*-trace

relation is instantiated for a given sentence type in the language. Chinese, unlike English, does not use movement for questions; the *wh*-word stays in its "original" position (Huang 1982):

(10) Zhangsan xiangxin [shei mai-le shu]
    Zhangsan believes [who bought books]
    'Who does Zhangsan believe bought books?'

But if a language instantiates a sentence type with *wh*-movement, the movement will have the same very particular character it has in every other language that instantiates it.

    The syntax of a language describes a set of forms (as in (3)) with which a sound and meaning can be associated, and so mediates between these two palpable aspects of a sentence. The interface of syntax to the sound and meaning components of the language system seems again largely universal. For example, languages typically have pronouns like the English reflexive and reciprocal pronouns (*himself, each other*) that require antecedents in the same utterance in which the pronouns themselves occur; such pronouns are called anaphors (see ANAPHORA):

(11) a. John likes himself.
   b. *Why did John succeed? Because himself is ambitious.
   c. Why did John succeed? Because he is ambitious.

A universal property of anaphors is that their antecedents cannot be contained in a phrase that does not contain the anaphor itself:

(12) a. [John's mother]$_{NP}$ likes herself.
   b.*[John's mother]$_{NP}$ likes himself.

In both cases, *John* is contained in the subject NP *John's mother*; in the first case, the antecedent is *John's mother,* and so the "containment condition" is satisfied; but in the second case, *John* is the antecedent, so the condition is violated. This "containment condition" (known as the "c-command condition") is a part of Binding Theory (see BINDING THEORY), which treats in a general way pronominal antecedence and its relation to syntactic structure.

    Typically, the relation between anaphor and antecedent is governed by a locality condition—the anaphor and antecedent cannot be "too far apart;" in English, the pronoun cannot occur in an embedded clause that does not contain the antecedent:

(13) *John thinks that [Mary likes himself]$_S$

The English locality condition is not universal, however; languages differ in what "too far apart" means. In Icelandic, for example, the reflexive pronoun *sig* can be separated from its antecedent by a subjunctive clause boundary but not an indicative one:

(14) a. Jon$_i$ segir [að Maria elskar sig$_i$]$_{Subjunctive Clause}$
    'Jon says that Maria loves himself'
   b.*Jon$_i$ segir [að Maria elski sig$_i$]$_{Indicative Clause}$
   'Jon says that Maria loves himself'

The indices here indicate which NP is the antecedent of *sig*. Although the domain of anaphors is not fixed universally,

there is only a small list of possible domains (Wexler and Manzini 1982). Although Icelandic differs from English in the details of the locality condition, it obeys the same containment condition mentioned earlier, as do all languages.

As with the case of phrase types, what is universal in the syntax of anaphors is considerable: the notion of anaphor, the necessity of antecedents for anaphors, the containment condition for anaphors, and the notion of locality condition. Beyond this, we see a slim range of linguistic variation: the identification of the domain of locality for anaphors. The language learner has simply to identify the anaphors in her language and identify the domain of locality in order for the full behavior of anaphors to be determined.

The syntactic system interfaces with lexical knowledge as well. The syntactic system of a language defines a set of general sentence patterns for that language, but any given lexical item will fit in only a subset of these. For example, the English VP could be described as a pattern of the following sort:

(15) V NP NP PP AP S AdvP

where only the head (V) is a necessary part of the phrase; but different verbs will in general match only limited sub-patterns of this general pattern:

(16) a. think: [V S] "think that Bill was sick"
      b. persuade: [V NP S] "persuade him that Bill was sick"
                   [V NP PP] "persuade him of my good intentions"

These must be learned along with the verb's meaning and other properties (see WORD MEANING, ACQUISITION OF). It is an open but much pursued question how much of the syntactic parameterization of a language might be reducible to aspects of lexical learning (see SYNTAX, ACQUISITION OF). The principal obstacle to firm conclusions is that the LEXICON, or the human lexical ability, is comparatively less well understood than the syntactic system.

The most productive vein of research in syntax in recent years has been the comparison of closely related languages. The goal has been to discover the "minimum" differences between languages, as it stands to reason that these will correlate with the actual parameters of the syntactic system.

French and Italian are two closely related Romance languages with a signal difference in how the subject of the sentence is expressed. French, like English, requires a subject for every clause; but Italian permits the omission of subjects that are understood:

(17) a. Gianni credo che ha molto argento.   (Italian)
      b. *Jean pense que a beaucoup d'argent. (French)
      c. Jean pense qu'il a beaucoup d'argent. (French)
      d. John thinks that he has a lot of money. (English)
      e. *John thinks that has a lot of money.   (English)

By itself this difference between French and Italian might be of little general interest, but in fact it appears to correlate with other differences (Perlmutter 1978; Rizzi 1982). French is like English in blocking movement of the subject of embedded clauses when the "complementizer" *that* (*que* in French, *che* in Italian) is present, but Italian has no such restriction:

(18) a. Chi$_i$ credo che t$_i$ ha molto argento?   (Italian)
      b *Qui$_i$ pense-tu que t$_i$ a beaucoup d'argent? (French)
      c. *Who do you think that has a lot of money? (English)

And Italian permits its subject to appear in postposed position, after the verb, but French, like English, excludes this:

(19) a. Credo che t$_i$ ha molto argento Sergio$_i$.   (Italian)
      b. *Je crois que t$_i$ a beaucoup d'argent   (French)
         Sergio$_i$.
      c. *I believe that t$_i$ has lots of money Sergio$_i$. (English)

In all three cases, Italian differs from English in permitting the trace of a moved or deleted subject in subject position under various circumstances. As there are other language pairs that differ in the same way, it is likely that these three differences between French and Italian are related and that in fact each is a manifestation of a single grammatical "parameter" set differently for French and Italian, a parameter governing the expression of the subject. Experiments in language acquisition have confirmed this view (Hyams 1986).

The mapping of the syntactic parameters through detailed study of language comparisons like the one just mentioned has been the principal goal of research in syntax in the 1980s and '90s. The general theory of syntax has been forced to become quite abstract in order to accommodate the parameterizations in a straightforward way, but the compensation has been a deeper understanding of what the range of possible human syntactic systems looks like.

Syntax, Acquisition of

Probably there are very few fields in cognitive science that have shown as distinct a growth in the last decade as the

field of SYNTAX acquisition. The increase in preciseness and knowledge has been extremely large, so large as to make the field hardly recognizable when compared to work of much more than a decade ago. In this short piece, I can hardly do more than to mention a few of the very active areas of research and some of the major results.

Inflectional and Clausal Development

At one time, it was thought by almost every approach to syntax acquisition (e.g., Wanner and Gleitman 1982) that a major reason that children's utterances (e.g., *me no going*) seemed to be different from adults' utterances (e.g., *I am not going*) is that children did not know the (morphonological and/or morphosyntactic) properties of inflectional elements (e.g., English third singular *-s*), the case of pronouns, the existence of auxiliary verbs, and so on. It looked as if inflectional elements were omitted or that their properties were incorrectly known to the child. On the basis of extensive empirical research, the field has completely thrown over this idea, however. The main tool for this demonstration has been the correlation between word order and MORPHOLOGY in the optional infinitive stage of development (Wexler 1993; roughly up to 3;0, depending on the language). As Wexler showed, children in many languages often use nonfinite main verbs alongside finite main verbs, but they know the morphosyntactic and morphological properties of finiteness. One of the first examples was provided by Pierce (1992) concerning French. Finite and nonfinite verbs in French occur in different distributional positions—for example, French finite verbs precede negation *pas* and nonfinite verbs follow *pas*. Pierce determined the finiteness of the verb by morphological form and the word order by observing where the verb appeared with respect to *pas*. The following table from Wexler 1993, based in Pierce's data, shows the number of utterances with the relevant properties, from children around 2;0. Columns represent verb morphology, rows represent order of the verb and *pas*.

(1)	+finite	−finite
pas verb	11	77
verb *pas*	185	2

The stunning result is that despite the fact that children at this early age use very many nonfinite utterances (ungrammatical in matrix position) as well as finite utterances, they get the word-order facts correct. Even more stunning is the fact that, as Wexler (1993) showed, the correlation between morphology and word order holds over many different languages, despite very different constructions. Thus, Poeppel and Wexler (1993) showed that German children used nonfinite root verbs as well as finite ones, but they almost always placed the finite verbs in second position (correct for this V2 language) and the nonfinite ones in final position, again correct for German, an SOV language.

Wexler (1993) called the stage at which these root nonfinite forms occur the *optional infinitive* (OI) stage and showed that it occurred in many different languages. From the properties of the OI stage, it can be deduced that children at an extremely young age have learned the central parameter values of the clausal/inflectional syntax of their language. For example, the French children discussed above have learned that the finite verb raises around negation (to an inflectional position) whereas English-speaking children do not raise the verb (correct for their language). The German results show that German children know that German is a V2 language (there are many other related phenomena) and that German is an SOV language. Wexler (1996) hypothesized that *Very Early Parameter Setting* (VEPS) was true: namely, children have set the central clausal/inflectional parameters of their language correctly at an extremely early age, before 2;0, perhaps before they have entered the multiword utterance stage at about 1;6. Evidence to date suggests that VEPS is true.

Thus the learning of language-particular aspects of grammar (parameters) is extremely fast and might be mostly done (for central parameters) before children start speaking in more than single-word utterances. Thus crucial grammatical learning is a kind of perceptual learning, done without any kind of overt error made by the child, that can be corrected by an adult. At the moment, it can't be determined exactly how early children set parameters correctly because of a limitation of experimental method: the key instrument has been naturalistic production, and the data are extremely sparse before 1;6. The development of infant techniques in this field will be necessary to probe earlier.

Not only are the parameters set correctly (the morphosyntactic part), but for the most part, the morphophonological aspects of inflection are known. Thus Poeppel and Wexler (1993) showed that extremely young German children didn't make mistakes on (subject-verb) agreement: either a nonfinite verb was used or a correctly agreeing one. A further example is that children almost never use a third-singular verb in English with a first-person pronoun (**I likes candy*); there are almost no examples out of hundreds of possibilities (Harris and Wexler 1996). Children know that *-s* means third-person singular from an extremely early age. This contradicts earlier suggestions (Clahsen and Penke 1992) that children have a difficult time with agreement. The reason that this appeared to be so was that it wasn't understood that many of the child's forms are nonfinite forms.

One central mystery remains, alongside the discovery that children at the earliest observed ages know both the universal and language-particular aspects of clause structure, inflection, functional categories, and verb movement. This is the question of why they use optional infinitives at all. In his original paper, Wexler (1993) suggested that children had certain difficulties with *tense.* Other proposals have been made by Rizzi (1994), Hoekstra and Hyams (1995), Wexler (1996, 1997), and Schütze and Wexler (1996), among others. There is an intense debate as to the best model to explain the OI stage, a debate being carried out with a detail of syntactic and quantitative analysis of children's abilities that is truly astonishing compared to what was known only a decade ago. The rigorous theoretical analysis and detailed quantitative empirical study of early syntax has certainly pushed the field to a new level.

It is the foregoing work that has been primarily responsible for the fall from favor of the proposal by Radford (1990) that children do not have functional categories, for there is no reasonable way to account for the correlation between

morphology and word order if children do not have functional categories. For balance, let me point out that at least Atkinson (1996) remains not completely convinced. I should also point out that there is now at least a beginning array of experimental results on comprehension confirming the general outlines of the OI stage (Schonenberger et al. 1995; Rice, Wexler, and Redmond 1998).

Null Subjects

An important early major result about the development of inflection within the principles-and-parameters approach was Hyams' (1986) discovery that English-speaking children very often use null subjects (e.g., *baking cookies*), despite the fact that English is not a null-subject language (unlike Italian, in which subjects are typically omitted from the sentence). Hyams suggested that these children had "mis-set" the null-subject parameter, so that English-speaking children thought that null subjects were grammatical, as in Italian. Since Hyams's work, it has been discovered that in every language that has been studied at early ages in this regard, children use null subjects.

Occasionally it has been suggested that the null subjects are the result of some kind of memory deficit (Bloom 1990) or production constraint (Gerken 1991). However, the empirical evidence is not consistent with this idea (Hyams and Wexler 1993; Bromberg and Wexler 1995). The weight of this evidence suggests that indeed children at an early age consider some null subjects to be grammatical even when their language isn't a null-subject language.

Thus one major part of Hyams's proposal is still considered to be correct—namely, that null subjects are grammatical for children. However, a second major part of Hyams's proposal does not now seem to be correct (as Hyams herself agrees: e.g., Sano and Hyams 1994). Namely, it does not appear that children have mis-set the null-subject parameter. Rather, null subjects appear to be the product of the OI stage. Children know that English, for example, is not null-subject in the Italian sense, but they produce null subjects because certain clauses (those missing tense, according to the hypothesis of Schütze and Wexler 1996) allow a null subject. Probably the strongest evidence for this position is the result of Roeper and Rohrbacher 1995 and Bromberg and Wexler 1995 that in *wh*-questions, children use null subjects only when the sentence is an OI, when tense is missing (e.g., *where going*, but not **where is going*). If English were truly an Italian-style null-subject language, null subjects would be grammatical even with a tensed verb. (Any suggestion that subjects are dropped because the first part of the sentence is "difficult," e.g., Bloom 1990, can't hold for the large numbers of *wh*-questions with null subjects, because the *wh*-form is at the beginning of the sentence.)

Italian children, on the other hand, will allow *wh*-questions with null subjects, because Italian *is* an Italian-style null-subject language. Thus the null-subject parameter is consistent with Wexler's (1996) VEPS: children have even set the null-subject parameter correctly at the earliest observed age.

Greatly simplifying the myriad structures studied, I have tried only to give enough detail to suggest the theoretical and empirical richness of this part of the field at the current moment and to suggest how this richness of detail represents something quite new in the study of linguistic development. There are an extremely large number of interrelated crosslinguistic and cross-construction generalizations that must be accounted for by any theory of linguistic development, and any theory that does not account for at least a large subset of these phenomena can hardly lay claim to being a serious contender for consideration. It is primarily for this reason that theories that involve only very general mechanisms of learning, and no linguistic details, are not seriously considered by the field: they seem to be nonstarters from the standpoint of empirical coverage. The primary task facing these "general learning mechanism/statistical procedures" theories is to make even a small dent in the empirical coverage that the major theories can already account for.

Development of Chains and Maturation

Is there any delay in knowledge of syntactic properties, or do the youngest children know *everything* about syntax? Borer and Wexler (1987; 1992) claimed that A-chains (argument-chains) are delayed in development, perhaps into the third or fourth year. A-chains involve movement of an argument to another A-position (argument-type position, not operator position). A primary example given by Borer and Wexler is the A-movement involved in the raising of an object into the subject position in the verbal passive construction (e.g., *the fox was kicked by the lion*, where *the fox* was raised from object position after *kicked* to subject position; see also GRAMMATICAL RELATIONS). Such passive constructions are known to be delayed in English-speaking children (2- and 3-year-old children do not correctly understand who kicked who in *the fox was kicked by the lion*). Borer and Wexler (1987) showed that *adjectival* passives (e.g., *the toy is broken*), which do not contain A-chains, were very early in English-speaking children, and they argued that the semantic and structural complexity of adjectival and verbal passives were about on a par. They thus suggested that it was the A-chain representation that was disallowed by children until a later age. Thus the children couldn't represent verbal passive constructions.

Furthermore, Borer and Wexler (1987) argued that the delay in A-chains was *maturational*; that A-chains were delayed because of biological development. Since then, the issue of maturation versus learning has been a hot topic of debate in LANGUAGE ACQUISITION. There are no other explanations of growth/change that have been suggested, except for learning and maturation. Borer and Wexler raised an objection to a learning analysis for a delayed construction like the passive, namely the *Triggering Problem*: If change occurs in grammar because of a reaction to an input trigger, why does this change often take years? A tip-off that maturation may in fact be on the right track can be found in the OI stage. Note that in that stage all the properties that we know must be learned—namely, the ones that differ from language to language—are learned extremely early (VEPS). It is the *universal* (apparently) property of finiteness of root

clauses (morphology aside) that develops late. Thus a universal property is late, whereas an experience-dependent, learned property is early. This suggests maturation.

The topic of A-chains has recently been invigorated with a number of new constructions and languages studied (Babyonyshev et al. 1994, Snyder, Hyams, and Crisma 1995). One might expect that this topic will be a central one, as the development of complex syntax is investigated in the years to come.

Syntax-Semantics Interface

A commonplace observation about language is that it consists of the systematic association of sound patterns with meaning. SYNTAX studies the structure of well-formed phrases (spelled out as sound sequences); SEMANTICS deals with the way syntactic structures are interpreted. However, how to exactly slice the pie between these two disciplines and how to map one into the other is the subject of controversy. In fact, understanding how syntax and semantics interact (i.e., their interface) constitutes one of the most interesting and central questions in linguistics.

Traditionally, phenomena like word order, case marking, agreement, and the like are viewed as part of syntax, whereas things like the meaningfulness of a well-formed string are seen as part of semantics. Thus, for example, "I loves Lee" is ungrammatical because of lack of agreement between the subject and the verb, a phenomenon that pertains to syntax, whereas Chomky's famous "colorless green ideas sleep furiously" is held to be syntactically well-formed but semantically deviant. In fact, there are two aspects of the picture just sketched that one ought to keep apart. The first pertains to data, the second to theoretical explanation. We may be able on pretheoretical grounds to classify some linguistic data (i.e., some native speakers' intuitions) as "syntactic" and others as "semantic." But we cannot determine a priori whether a certain phenomenon is best explained in syntactic or semantics terms. So, for example, syntactic accounts of semantic deviance (in terms of mismatches of features) are possible. As are conceivable semantic accounts even of phenomena like agreement. To illustrate the latter case, one could maintain that a VP like "loves Lee" denotes a predicate that cannot be true of, say, the speaker. Hence, "loves Lee" predicated of the speaker results in something undefined. This account of the ungrammaticality of "I loves Lee" would qualify as semantic as it crucially uses notions like *truth* and *denotation,* which are the building

blocks of semantics. What is actually most likely is that agreement is ultimately a cluster of phenomena, whose optimal account will involve the interaction of both syntax and semantics (see Lapointe 1979). This is a simple illustration of how issues of interface arise and why they are so important. They concern both data and theory. It is not a matter of terminology but of which component is responsible for which phenomenon and how the modules of each component are set up, something that cannot be settled a priori once and for all (see MODULARITY AND LANGUAGE).

Perhaps the key issue at the interface of syntax and semantics concerns the nature of the mapping between the two, which has been at the center of much research within GENERATIVE GRAMMAR. An important approach, pursued especially within CATEGORIAL GRAMMAR and related lexicalist frameworks, has been dubbed by E. Bach the "rule-by-rule" hypothesis. It assumes that for each syntactic rule determining how two or more constituents are put together, there is a corresponding semantic rule determining how the respective meanings are to be composed. On this view, the interface task is to figure out which syntactic rules are mapped onto which semantic composition modes. A somewhat different line is pursued within transformational approaches to syntax such as the Government and Binding framework or the more recent Minimalist Program (see MINIMALISM). Within such approaches, there are no rules in the traditional sense but only very general schemata and principles that interact in yielding pairing of phonetic representations and logical forms. Logical forms (LFs) are syntactic representations where phenomena like scope and anaphoric links are unambiguously represented. For example, one possible LF for a sentence like (1a) would look roughly as (1b).

(1) a. An advisor was assigned to every student to help him out with his scheduling.
   b. [Every student$_i$] [an advisor was assigned to t$_i$ to help him$_i$ out with his$_i$ scheduling]
   c. Every student x is such that an advisor was assigned to x in order to help x with x's scheduling.

The way to understand a structure like (1b) is by interpreting the object "every student" (which has been moved from its surface position to the left periphery of the clause) as having wide scope over the subject "an advisor" and as binding the pronouns "him/his" in the adjunct (as per the informal paraphrase in (1c)). This interpretation is guaranteed by mapping structures such as (1b) into their meaning (i.e., their the truth-conditions or some other logically based representation of propositional content). The mapping usually employs three things: the lexical meaning of the words; a few universal semantic operations (like function application and abstraction); and a limited set of type-shifting or coercion mechanisms.

The lexical meaning of words is drawn from a restricted set of semantic types that correspond in systematic ways to syntactic categories. For example, the syntactic category "NP" encodes certain patterns of distribution (namely, the possibility of occurring in certain slots in the clause, like subject, object, prepositional object, etc.). The correspond-

ing semantic type will be that of individuals (in the case of referential NPs like "Luciano Pavarotti") or generalized QUANTIFIERS (in case of quantificational NPs like "at most two tenors" or "every red cat"). Similarly for the other syntactic categories: VPs will denote functions from individuals into truth values, and so on. In interpreting complex structures, say, for example [$_S$ Pavarotti [$_{VP}$ sings well]], one first checks the semantic type of the meaning of the constituents. Generally, one finds a function and an argument that can be combined by functional application. If, however, types don't match, something will have to be done. One possibility is resorting to a limited set of mechanisms that make the types fit (type shifting or coercion). This procedure is known as "type-driven interpretation" (Klein and Sag 1985; see also Partee 1987).

To illustrate typeshifting further, consider an adverb like "for two hours," which normally combines felicitously only with atelic verb phrases (i.e. VPs that express an activity lacking an inherent end point or culmination; see Verkuyl 1993 or Moens 1987, among many others):

(2) a.   John pushed the cart for two hours.   [atelic]
    b. ?? John reached the summit for two hours. [telic]

Now certain telic eventualities can combine with such adverbs in spite of their telicity. They must, however, be reinterpreted iteratively, thereby becoming atelic:

(3) a. Yesterday John knocked at the door once.   [telic]
    b. Yesterday John knocked at the door for
       two hours.   [telic]

The idea here is that the type of adverbials "for two hours" and that of telic activities don't match. But, in certain cases, one can interpolate a functor ITERATE that turns a telic individuality into an atelic one:

(4) A. FOR TWO HOURS (KNOCK)→undefined
    B. FOR TWO HOURS (ITERATE(KNOCK))→
       defined

Pinango, Zurif, and Jackendoff (1997) argue that type shifting of this sort has consequences for real-time processing. Type shifting can also be implemented on the rule-by-rule approach. Both the rule-by-rule approach and the LF-based one are compositional (see COMPOSITIONALITY) and strive to understand the universal properties of the syntax-semantics mapping. The main differences between them are mostly traceable to the different conceptions of syntactic structure that they are tailored on.

Live issues at the syntax-semantic interface include the following: What are the universal rules of semantic composition? We mentioned above function application and abstraction; is this all there is? What kinds of type-shifting operations (besides aspect-related ones like ITERATE) are there? Is type shifting restricted to the LEXICON or is it also used in the compositional part of the semantics? What are the mappings from syntactic categories into semantic types? Is there any crosslinguistic variation in any of the above? What role does the syntax-semantics mapping play in acquisition? To illustrate the variation issue, consider for example the status of mass nouns in English versus Italian. The following paradigm is representative:

(5) a.   Gold is rare
    b. *Oro e' raro
       'gold is rare'
    c.   L'oro e' raro
       'the gold is rare'

In English, mass nouns like *gold* have the same syntactic distribution as proper names and can occur without a determiner in the canonical argumental positions (subject, object, object of preposition, etc.). In Italian (or French), mass nouns behave instead just like singular-count common nouns in that they can never occur in subject or object position without a determiner (see (5b–c)). This difference might be syntactic in nature (*gold* and *oro* belong to two different syntactic categories). Or, it is also conceivable that they belong to the same syntactic category (say, the category N) but their semantic type is different. In Romance, mass nouns are mapped into predicates (true of any portion of the relevant substance). As such, they are suited to restrict a determiner but not to occur bare in argument position. On the other hand, in English mass nouns might be names of substances, which would explain their proper noun-like behavior. This second approach is based on the assumption that there is a certain degree of variability across languages in the way items belonging to the same syntactic category are mapped into the corresponding meanings (Chierchia forthcoming, 1998).

From the above considerations, it should be clear why questions that arise at the syntax-semantics interface are fundamental. The empirical domains where one can hope to find answers to such questions are very broad. They range from the study of quantification and ANAPHORA, to TENSE AND ASPECT, to the study of THEMATIC ROLES, and much more.

Taste

Taste, or gustation, in humans and other terrestrial mammals is an oral chemoreceptive, and also mechanoreceptive and thermoreceptive, sensory system. Gustatory receptor organs occur primarily in specialized epithelial structures, papillae, found in limited and species-characteristic regions of mammalian tongue and palate (Weijnen and Mendelson 1977; Finger and Silver 1987). The taste system normally responds during drinking, biting, licking, chewing, and swallowing.

Taste is a component of a cognitive system, *Flavor* (Gibson 1966; White 1996), which includes SMELL (especially retronasal olfaction), chemesthesis (common chemical sense), tactile (HAPTIC PERCEPTION) input from oral structures, proprioception from the temporomandibular joints, and, via bone conduction, auditory responses (AUDITION; McBride and MacFie 1990). Laboratory procedures (Cattalanotto et al. 1993) or respiratory disease (Doty 1995) can remove component sensory systems; smell is often a major factor.

Taste responses originate in epithelial-derived receptor cells which have a lifespan of a week or two, all spent within an intraoral cutaneous sensory structure called a taste bud. The receptor cells differentiate from precursor cells, move closer to the epithelial surface, contact one or more sensory neurons and other taste receptor cells, and often extend microvilli which are separated from the outside world only by the secretions of taste bud cells (Beidler 1971). The brief lifespan is presumably demanded by direct but indispensable interactions with the diverse and often intense chemical, thermal, and mechanical energy levels in the oral cavity.

No one biochemical or biophysical mechanism transduces all gustatory stimulus chemicals into biological events. Substantial differences between gustatory chemicals, and the requirement that responses be sensitive and selective over a million-fold concentration span, apparently underlie this diversity. Gustatory chemicals effective in humans range from hydrogen ions to relatively large and complex protein molecules, and encompass most classes and configurations of molecules (Pfaff 1985; Brand, et al. 1993; Beauchamp and Bartoshuk 1997).

Many different gustatory stimuli activate a single taste receptor cell or individual neurons of the afferent nerve that innervates that receptor cell (Simon and Roper 1993). However, there is disagreement concerning the implications of this breadth of responsiveness. The predominant view, known as the *basic tastes* model, proposes that only the most robust responses have a role in sensory processing, with the others filtered somewhere in the central nervous system. This conceptualization permits assignment of a receptor or neuron to one or two of the test stimuli, and categorization as a "N" best unit, "N" being the gustatory stimulus chemical that evoked the largest response. The theory asserts that direct linkages exist between the identified *best-stimulus,* the stimulated receptor cell or neuron, and a category of taste perception. However, no human gustatory SINGLE-NEURON RECORDINGS exist (Meiselman and Rivlin 1986; Halpern 1991). Most generalizations are made from laboratory rodents.

The *best-stimulus* and *best-response* outcomes provide neurophysiological support for the basic tastes model's claim that gustatory experience depends on four or five distinct, independent classes of "vertically integrated" taste stimuli, receptor cells, afferent neurons, and independent perceptual categories. The corresponding *basic or primary gustatory stimuli* and perceptual categories are commonly specified as an alkaloid derivative such as a quinine salt $\therefore$ bitter, the metallic salt NaCl $\therefore$ salty, an acid $\therefore$ sour, a saccharide such as sucrose $\therefore$ sweet, and monosodium glutamate plus a 5'-ribonucleotide $\approx$ umami.

Psychophysical evidence for the basic tastes model includes a single *basic taste* sufficing for human descriptions of aqueous solutions of pure chemicals, successful assignment of taste intensity into *basic tastes,* and inability to discriminate between a number of inorganic and organic acids, or between the sugars fructose, glucose, maltose, and sucrose (Bartoshuk, 1988). Further, in certain laboratory rodents in whom a pharmacological agent, amiloride, selectively blocks gustatory neural responses to small metallic salts, behavioral measures using the same agent show alteration of responses toward NaCl and KCl but not to sucrose.

Negating data for the basic tastes model include incompatibility with studies utilizing normal foods or many-component mixtures, inability to produce the range of human gustatory experiences by combining the primary or basic taste stimuli, discrimination between stimuli of a basic taste category, cross-adaptation failure within a basic taste, and frequent descriptions of many substances, including basic taste stimuli, using multiple basic taste terms and other words (side tastes).

An alternative theory is the *pattern* or *across fiber model,* utilized by a minority of investigators, which posits that relative responsiveness across an array of taste units with broadly overlapping but different sensitivity profiles is the initial sensory event. The number of gustatory response

"types" is left unspecified at greater than four. Psychophysical supporting data include cross-adaptation between "basic taste" categories, inability to identify the components of natural and laboratory mixtures, characterization of some aqueous solutions as complex or "more-than-one," and the cited negating data for the basic tastes model. Furthermore, if oral application of amiloride, a pharmacological blocker of an epithelial sodium channel (see supporting data for the basic tastes model, above), is combined in laboratory rats with a procedure in which drinking of NaCl is followed by injection of a mild poison (conditioned taste aversion for NaCl induced by injection of LiCl), subsequent behavioral avoidance generalizes beyond NaCl drinking to nonsodium salts such as KCl and NH_4Cl, which humans and rats normally categorize as quite different from NaCl. On the other hand, all supporting observations for the basic tastes model represent serious difficulties for the pattern model of taste.

A union of the basic tastes and pattern models might be possible following classic "fusion" CONCEPTS, since CATEGORIZATION neither precludes discrimination nor requires that processing reside primarily at the receptor level. Neither model addresses temporal aspects, although taste shows temporal integration over several seconds while stimulus durations of 50 msec are sufficient for taste PSYCHOPHYSICS.

Gustatory neuroanatomy is similar in all mammalian hindbrains. However, rostral organization in rhesus monkey and probably human differs dramatically from New World primates and most other mammals, with more direct brain stem connections and greater cortical representation (Getchell et al. 1991). The profound evolutionary implications remain unexplored.

Study of gustatory psychophysics as well as cognitive aspects offers many opportunities if investigations avoid excessive adherence to theoretical models. Taste is similar in outline to other perceptual systems, while also reflecting its unique role in adaptive behavior.

Technology and Human Evolution

Since the beginning of prehistoric archaeology, tools have been associated with prehistoric humans (called *Homo faber* by philosophers). The different stages of *Homo* have been related to their material culture, essentially lithic industries (assemblages of typical stone tools) that were the only artifacts to survive in number: *Homo habilis* is related with the Oldowan industry (from 1.9 million to 1.6 million years B.C.), *Homo erectus* with Acheulean (from 0.5 to 0.3 million years B.C., *Neandertal* with Mousterian (between 300,000 and 35,000 years B.C., *Homo sapiens* with Upper Paleolithic industries from (40,000 years B.C. on). Parallels were drawn between human evolution and CULTURAL EVOLUTION. But it was only in the 1960s that palaeontologists and prehistorians sought for theories relating technology and evolution. Sherwood Washburn (1960) proposed a model that related educated behavior to human evolution in a biocultural feedback system. In a quite different context, André Leroi-Gourhan (1964/1993) constructed a comprehensive theory of evolution that related the evolution of man and culture to the evolution of gesture/action and speech and to the exteriorization of physical and mental functions (by transfer of functions from mouth to hand and from hand to tools, and also from brain to books and to computer memory). In this theory, evolution, once the *Homo sapiens* stage is reached, is carried out through channels other than genetics: that is, the technological and the social realm. From the appearance of the first tool to the spread of *Homo sapiens,* there is a related evolution of *Homo* and technology. In the 1970s sociobiologists emphasized the relation between technology, as a learned behavior, and genetic evolution (E. O. Wilson 1975; see also SOCIOBIOLOGY). More recently a philosopher of science, Bernard Stiegler, proposed to see in this related evolution of man and its technology a phenomenon of epiphylogenesis as a new relation between the human organism and its environment: lithic technology and tools are preserved beyond the life of the individual who produced them and determine the relation of man with its environment, thus conditioning a part of the selection pressure (Stiegler 1992).

Research on prehistoric technology is becoming an important field within archaeological researches and a part of COGNITIVE ARCHAEOLOGY. It is based on flint-knapping experimentations, on refitting flint flakes, and on microwear and functional analysis of tools. It is a powerful approach to the cognitive abilities of prehistoric humans. The concept of *"chaînes opératoires"* (which presents technical productions as operational sequences of technical actions) introduced by Leroi-Gourhan (1964; Schlanger 1994) played a key role in its development, permitting the analysis of goals, intentions, realizations and their extent of variability, degree of anticipation and level of competence within a technological framework or technocomplex (Boëda 1994; Karlin and Julien 1994).

J. Pelegrin, whose conclusions are widely accepted, analyzes intellectual and physiological abilities of flint knappers in terms of knowledge and know-how. Knowledge includes concepts and mental representations of ideal tools and conceivable raw materials, and mental representations of a constellation of actions (gestures and results). Know-how includes the ability to imagine which actions are needed for a given task and to assess the results. It can be divided into an ideatory know-how, which critically assesses raw materials' potentials here and now and their consequences, and a sensorimotor know-how, which induces programming of knapping gestures and actions (Pelegrin 1990). This analytical framework has permitted the analysis of the "chaînes opératoires" characteristic of the main lithic industries, their increasing complexity and anticipatory strategies through time. Levels of complexity can be evidenced from the Oldowan to Upper Paleolithic industries according to number and variety of tasks and actions performed, from the intensity of preparation and rejuvenation of the core, from the degree of anticipation of the consequences of technical choices and gestures (Roche and Texier 1993). In the oldest lithic industries such as Oldowan, the ideational know-how is reduced to a simple repetition of elementary actions (Pelegrin 1990) but is associated with a motor know-how able to control the intensity and direction of hammer strokes. For Roche and Texier (1993), first bifaces (appearing in the late Oldowan) reflect an emerging concept poorly materialized by an insufficient sensorimotor know-how. The Acheulean bifaces already imply more complex conceptual and reflexive abilities: the final form of a biface is completely independent of the original raw material and includes a double symmetry; every flake removal results in modifying at the same time the edge contour and profile and the face thickness. Errors of judgment or poor sensorimotor control results in wasting raw material or even in rendering the core useless. For Pelegrin, technical aspects of hominization are achieved at this stage, even if numerous progressions are still to come.

A few British and American prehistorians and paleontologists interpret the same data in a quite different way and oppose what they call the "final object fallacy" (Wynn 1993). They privilege use upon conceptual creation in shaping the final product: polyhedrals and bolas (nearly perfect spheric stone balls) of the Oldowan are viewed as hammers that acquired their spheric shape through repeated use (Toth 1993); Mousterian sidescrapers as well acquire their shape through use (Dibble and Bar-Yosef 1995). However, Toth acknowledges that the double symmetry of later bifaces represent a conscious and planned shape (Toth and Schick 1993). At this stage, all agree that language is not necessary, but Toth and Schick consider that it could be incipient given the dominance of right-handed knappers. But most prehistorians advocate for language associated with Mousterian technology. All agree that the problem cannot be solved for the moment because there is no clear technological performance correlated with language (Ingold 1993; Wynn 1993).

Another problem has emerged with discoveries of remains from archaic *Homo sapiens* associated with Mousterian artifacts and technology, at the same time that remains from late Neandertals (Chatelperroniaa) were found

with an early Upper Paleolithic industry (Hublin et al. 1996). Similarly, first bifaces appear in late Oldowan in *Homo habilis* context. Thus, it is no longer possible to equate technocomplexes and human species. However, technology is opening a new field of investigation about the cognitive abilities of prehistoric humans.

Temporal Reasoning

Temporal reasoning problems arise in many areas of artificial intelligence (AI), including planning, reasoning about physical systems, discourse analysis, and analysis of time-dependent data. Work in temporal reasoning can be classified in three general categories: algebraic systems, temporal logics, and logics of action. Although useful for many practical tasks, there is little evidence that any of these approaches accurately model human cognition about time. Less formal but more psychologically grounded approaches are discussed in some of the work in AI on plan recognition (Schmidt, Sridhaven, and Goodson 1978), work in linguistics on SEMANTICS and TENSE AND ASPECT (Jackendoff 1983), and the vast psychological literature on MEMORY.

Algebraic systems concentrate on the relationships between time points and/or time intervals, which are represented by named variables. A set of either quantitative or qualitative equations constrain the values that could be assigned to the temporal variables. These equations could take the form of a constraint satisfaction problem (CSP), a set of linear equations, or even a set of assertions in a restricted subset of first-order logic. The goal of the reasoning problem may be to determine consistency, to find a minimal labeling of the CSP, or to find consistent bindings for all the variables over some set of mathematical objects. In

all of the algebraic systems described below, time itself is modeled as a continuous linear structure, although there has also been some investigation of discrete linear-time models (Dechter, Meiri, and Pearl 1991) and branching-time models (Ladkin, Angerm, and Rodriguez 1990).

The qualitative temporal algebra, originally devised by Allen (1983) and formalized as an algebra by Ladkin and Maddux (1994), takes time intervals to be primitive. There are thirteen primitive possible relationships between a pair of intervals: for example, before ($<$) meets (m) (the end of the first corresponds to the beginning of the second), overlaps (o), and so on. These primitive relationships can be combined to form 2^{13} complex relationships. For example, the constraint I_1 ($<$ m $>$) I_2 means that I_1 is either before, meets, or is after I_2. Allen showed how a set of such constraints could be represented by a CSP, and how path-consistency could be used as an incomplete algorithm for computing a minimal set of constraints. The general problem of determining consistency is NP-complete (Vilain, Kautz, and van Beek 1989).

Quantitative algebras allow one to reason about durations of intervals and other metric information. The simple temporal constraint problems (STCSP) of Dechter, Meiri, and Pearl (1991) are a restricted form of linear equations. A time interval I is identified with the pair of its starting point I_s and ending point I_e. Difference equations allow one to place constraints on the relative ordering of points. For example, $I_e - J_s \in [-\infty, 0]$ means that I is before J, and $I_s - I_e \in [3, 5]$ means that the duration of I is between 3 and 5 units. Because they are just linear programs, STCSPs can be solved in polynomial time. General TCSPs allow the right-hand side of an equation to be a union of intervals, rather than a single interval, and solving them is NP-complete. However, TCSPs still cannot express certain complex constraints, such as that two intervals are disjoint but unordered (I ($<$ $>$) J), which would involve four points ($I_e < J_s \mathbf{V} J_e < I_s$).

Many researchers have explored tractable subsets of these algebras. A subset is specified by the form of the constraints allowed in the statement of the problem instance. Vilain, Kautz, and van Beek (1989) noted that the subset of Allen's algebra that can be exactly translated into equalities and inequalities over start and end points is polynomial. Nebel and Bürckert (1995) generalized this to relations that can be translated into "ord-Horn constraints," the largest tractable subclass that includes all the primitive relations. Koubarakis (1996) and Jonsson and Bäckström (1996) further showed that tractablity still holds if such constraints contain linear combinations of variables. However, none of these classes can express interval disjointed ($<$ $>$), and in fact any tractable class that includes disjointedness cannot contain all of the primitive relations. Tractable classes including interval disjointedness include some of the "chordal graph" classes of Golumbic and Shamir (1993) and two of the algebras described in Drakengren and Jonsson (1997).

Temporal algebras say nothing about how time intervals or points are associated with events or propositions. In practice, some external mechanism (such as a planning system) generates interval and point tokens that are used to timestamp or index statements in a knowledge base. This external mechanism then computes some of the constraints between the temporal tokens that must hold according to the semantics of the knowledge base (for example, that a token associated with a proposition is disjoint from one associated with the negation of that proposition), and then asks the algebraic reasoning engine to compute consequences of those assertions.

By contrast, temporal logics (van Benthem 1983; Thayse 1989) directly represent the temporal relationships between propositions, and do away with any explicit tokens to represent time points or intervals. These are modal logics, which extend propositional or first-order logic with temporal operators. For example, propositional linear time temporal logic models time as a discrete sequence of states, and adds the modal operators next $\mathbf{O}$, always $\Box$, eventually $\Diamond$, and until U. For example, the formula $\Box p \supset \mathbf{O} q$ means that whenever p holds, then q must hold in the next state.

The most successful applications of temporal logics have been in the area of program verification (Emerson 1990). One approach to this task exploits the fact that any formula in linear temporal logic can be converted into a kind of finite automata called a Büchi automata. The input language to the automata is sequences of states. The automata accepts exactly those sequences that are models of the corresponding temporal logic formula. In this application, the program to be verified is written as a finite automata, and properties one wishes to verify are written as formulas in temporal logic. The negation of the temporal logic formula is then converted to a Büchi automata, which is then intersected with the program automata. It is then easy to check whether the combined automata accepts any inputs; if it does not, then the program satisfies the desired properties. The worst-case complexity of this procedure is high, because the automata may be exponentially larger than the formula.

Although temporal logics are frequently used in the verification and temporal database communities, they are just beginning to find widespread use in AI, particularly in PLANNING. Applications include the specification and verification of real-time, reactive planners (Rosenschein and Kaelbling 1995; Williams and Nayak 1997), and specification of temporal-extended goals and search control rules (Bacchus and Kabanza 1996).

Finally, temporal reasoning is implicitly performed by all systems used to represent and reason about action and change, such as the SITUATION CALCULUS (McCarthy and Hayes 1969) or dynamic logic (Harel 1979). The situation calculus is simply a style of using first-order logic, in which the final argument to a predicate represents the state in which it holds. Actions are functions from state to state. Thus, the semantics for the situation calculus is based on a discrete, forward-branching model of time. The general approach can also be used to model continuous branching time (Reiter 1996). Successful planning systems have also been built (Blum and Furst 1995; Kautz and Selman 1996) that use a discrete linear model of time, where states are simply natural numbers used to index time-varying predicates.

Tense and Aspect

With the exception of statements in textbooks in mathematics, almost everything that is expressed in natural languages involves time in some way. It is not easy to specify exactly what within the general realm of temporal reference should be subsumed under the headings *tense* and *aspect,* particularly because these terms have been used in widely divergent ways by different scholars in linguistics, logic and philosophy. Consider a declarative sentence such as (1) *The water was cold.* In its most common use, such a sentence "refers" to a definite time (point or period), although this time is not explicitly identified in the sentence itself. In English, the form of the verb tells us that the time is in the past—that is, prior to the time at which the sentence is uttered. Otherwise, one would have said (2) *The water is cold.* But in a language such as Mandarin Chinese, the sentence (3) *shuǐ hěn lěng* translates as both (1) and (2). Still, (3) shares with the English translations the property that it normally refers to a specific time when used. This kind of implicit time reference, then, is a universal property of human languages, which is independent of whether there is grammatical tense marking or not. Another universal property is the fundamentally deictic character of time reference—most spoken sentences refer to the time of speech, and even in those that do not, time reference usually takes the time of speech as the point of departure, one consequence being that the truth-value of a typical sentence in a natural language depends on when it is uttered. The study of tense in formal semantics focuses on these and similar phenomena, which are at least analytically distinct from the notion of *grammatical tense*—that is, the signaling of time reference by grammatical means such as verb inflection and auxiliaries. The *tense operators* of tense logic ("it has been the case that *p*", "it will be the case that *p*") as developed by Arthur Prior (Prior 1967) and reflected for example in Montague Grammar (Montague 1971) have only a partial overlap semantically and syntactically with the grammatical tenses of natural languages—they cannot for instance account for the implicit reference to a definite point in time characteristic of examples such as (1) or for the agreement-like character of the informationally redundant tense marker in a sentence such as (4) *It rained yesterday.*

The field of aspect displays a similar duality in that it may alternatively be seen as the ontology of those entities that are most intimately connected with time, such as events, processes, states, properties, and so on, or as the study of the grammatical phenomena that relate to such types of entities and their manifestation in time. With respect to the ontology of temporal entities, which is sometimes subsumed under labels such as *actionality* or *aktionsart,* the most well known taxonomy is that of Vendler (1967). Vendler distinguishes *states* (as exemplified by "love somebody"), *activities* ("run", "push a cart"), *accomplishments* ("draw a circle"), and *achievements* ("win a race"). These four categories may also be distinguished in terms of binary distinctions. States are opposed to the three others by lacking dynamicity. Activities are opposed to accomplishments and achievements by being atelic or unbounded—that is, unlike the latter, they do not have a well-defined endpoint or result-state. The difference between accomplishments and achievements may be described in terms of a distinction durative:punctual.

In the grammatical tradition, tense and aspect are usually seen as grammatical categories pertaining to the verb.

In actual grammatical systems, temporal and aspectual properties are commonly interwoven in the same forms, and many linguists nowadays talk of tense-aspect systems as integrated wholes. Tense-aspect markings arise through grammaticization processes out of phrasal constructions usually involving lexical morphemes. Future markers may, for example, develop out of constructions involving motion verbs such as *come* and *go*. Advanced stages of grammaticization lead to the rise of inflectional markings by the fusion of earlier free morphemes with the stem of the head word. The high degree of grammaticization of inflectional tense-aspect markers is reflected in their obligatory character and tendency to be used even if informationally redundant (see (4)).

Grammatical tense-aspect markings tend to fall into a relatively small number of crosslinguistic types characterized by their SEMANTICS and typical way of expression. A subset of those types are regularly expressed inflectionally, by affixes or stem alternations (e.g., "strong verbs" in Germanic languages). The tense-aspect markings most frequently found in inflectional systems are imperfective, perfective, past, and future markings. The opposition between imperfective and perfective forms the core of a large part, maybe the majority, of all inflectional tense-aspect systems. Perfective verb forms prototypically express completed events in the past, as in Mandarin Chinese *shé shǐ le* 'the snake died', where *le* is a perfective marker; imperfective forms prototypically express on-going activities or states that hold at the point of speech (but also habits), as in Modern Standard Arabic *yaktubu rasa:'ilan* 'he is writing a letter', where *yaktubu* is the imperfective form of the verb. The temporal reference properties may be overridden, however. Past markings may be applicable to all verb forms (as in English) or only to imperfective ones. Future markings are less often inflectional than the ones already discussed. Due to their special epistemological status, statements about the future tend to have modal nuances tinging the purely temporal character of grammatical futures.

Among tense-aspect markings that are usually expressed periphrastically (constructions involving more than one word) are progressives (a common diachronic source for imperfectives) as in English *I am singing,* and perfects (a common source for both pasts and perfectives), as in English *I have sung.* Progressives differ from imperfectives in having a narrower range of uses. The semantics of perfects is often described in terms of "current relevance" or in terms of an identity between "reference time" and "speech time" (in the terminology of Reichenbach 1947). Combinations of perfects and pasts yield pluperfects, used to express an event taking place before a reference time in the past.

Further types include habituals and generics, experientials (used to express that something took place at least once in the past), narratives (used to express that an event directly follows another in a narration), and markings of remoteness distinctions (e.g., hodiernal or "today" pasts versus hesternal or "yesterday" pasts).

Teuber, Hans-Lukas

Hans-Lukas Teuber (1916–1977) was born in Berlin to Dr. Eugen Teuber, a psychologist, and Rose Knopf, a teacher. His father was the founder of the primate center on Tenerife in the Canary Islands, which later became famous as the site of Wolfgang's experiments on apes. After a classical education at the French College in Berlin, he studied biology and philosophy at the University of Basel.

In 1941, Teuber came to the Department of Psychology at Harvard University as a graduate student, and in the same year married Marianne Liepe, an art historian. She came to play a central and crucial role in the extended families that later made up his laboratory at New York University and his department at MIT.

Teuber's most important educational experiences in graduate school were probably the two years he spent away from Harvard in the U.S. Navy. In that period he began to work with the neurologist Morris B. Bender at the San Diego Naval Hospital on the effects of human brain lesions. This collaboration lasted more than fifteen years and produced a series of important neuropsychological articles, particularly on the effects of penetrating head wounds on visual and haptic function.

After returning to Harvard, he completed his doctoral dissertation in 1947 on a study of the effects of psychotherapy on teenagers at risk for delinquency. Teuber found that the experimental and control groups did not differ. This experience probably contributed to his lifelong skepticism of psychotherapists, as well as most other types of clinicians. In spite of this attitude, throughout his life Teuber spent an enormous amount of time counseling his colleagues, students, and research subjects with their personal problems.

In 1947, Teuber established his Psychophysiological Laboratory at the New York University-Bellevue Medical Center. Neuropsychological research on head-injured war veterans and other patients flourished there, as well as new lines of research on children and infrahuman animals. The work of Teuber and his colleagues in this period played a major role in the transformation of the study of human brain function from collecting case studies of florid neurological curios to a systematic experimental neuropsychology (e.g., Semmes et al. 1960; Teuber, Battersby, and Bender 1960). Among their major innovations were the use of matched control groups; the study of patients chosen on the basis of their brain damage and not their symptoms; follow up of patients beyond the stage of acute symptoms; use of nonverbal tests (he called them "monkified," as they were often derived from the animal laboratory); and, above all, the introduction of modern psychophysical methods with their rigor of instrumentation and statistical analysis.

Teuber came to the Massachusetts Institute of Technology in the fall of 1961 to organize a new department of psychology. Over the next decade this became a world center for the neuro- and cognitive sciences. Uniquely at the time, it brought together neuroanatomy, neurophysiology, neuropsychology, cognitive psychology, linguistics, COMPUTATIONAL NEUROSCIENCE, and philosophy into an interacting community and became a model for the establishment of similar neuroscience centers abound the world. Today the department continues to flourish as the Department of Brain and Cognitive Sciences.

Teuber was a charismatic teacher at every level. For a number of years he taught the introductory psychology course (twice a term for both terms) and it was taken by virtually every undergraduate at MIT. He was a brilliant speaker and particularly skilled at summing up conference proceedings. His theoretical and review papers helped to set the foundation for contemporary neuroscience (e.g. Teuber 1955, 1960, 1978).

Teuber's contributions extended far beyond the institutions he founded and the experimental and theoretical papers he wrote. He was a consummate organizer, synthesizer, and sponsor of research on the brain, as well as the mentor of many of today's leading brain researchers. His concern for others went beyond counseling and support. He resigned in protest as chair of the Advisory Committee to the Surgeon General of the U. S. Army over the use of psychedelic drugs on human subjects, he was instrumental in establishing the first MIT Review Committee on Human Subjects, and he was supportive of anti-Vietnam War activity at MIT. As he put it in a posthumously published address to the 21st International Psychology Congress (Teuber 1978), "our particular science is as central as physics, and ultimately more so. But it is also capable of as much abuse . . . All of us here will have to abide by a new kind of Hippocratic oath, never to do harm, always to heal rather than hinder, to make life richer, and to make it free."

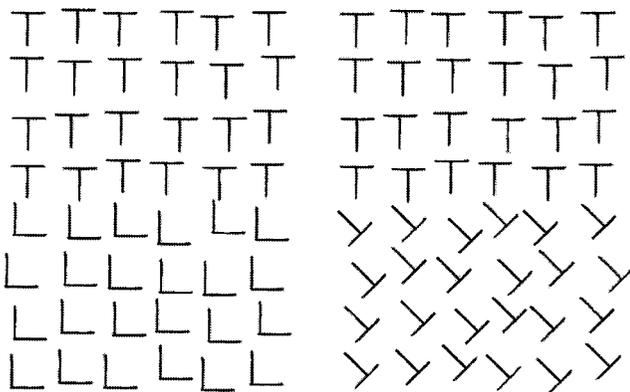
Texture

Visual texture is a perceptual property of image regions. In this respect texture is analogous to perceived brightness, COLOR, DEPTH, and MOTION. Just as we can describe a region of an image as bright or dark, red or green, near or far, or moving up or down, we can describe it as having a mottled, striped, or speckled texture. Note that none of these descriptions is redundant or inconsistent with any of the others; saying that a region is bright red, distant, and moving up does not in any way constrain its textural properties. In natural images visual texture frequently is related to qualities of surfaces indicating roughness or smoothness or other physical properties.

The English word *texture* derives from the Latin *texere*, meaning "to weave." "Texture" was first used to describe the character of a woven fabric as smooth, ribbed, twilled, and so forth. Similarly, in describing visual texture we refer to such properties of an image region as granularity, periodicity, orientation, and relative order or randomness.

Interest in the perception of visual texture has both applied and theoretical roots. Texture rendition is important for creation of natural-looking images. However, because of its high level of spatial detail, digital representation of image texture can also be expensive in terms of storage and transmission bandwidth. Therefore, it is useful to understand what characteristics of texture are perceptually important so that these can be represented efficiently. From the standpoint of understanding visual processes texture is also of interest because texture perception differs in some ways from more general visual perception.

The most basic manifestation of this difference can be seen in the fact that regions containing visually discriminable structure do not always form distinct textures. For example, as noted by Beck (1966; see also an example in Bergen 1991) a bipartite region containing upright T and L shapes appears as a uniformly textured area while a bipartite region containing upright and tilted T shapes (or tilted T and upright L shapes) shows a clear division into two visually distinct areas (see figure 1). This greater effectiveness of the orientation difference is not predicted by pattern discrimination properties: T, L, and tilted T shapes are all easily distinguishable when inspected as individual patterns within the texture image. This phenomenon is referred to variously as "texture segregation," "texture-based segmentation" or "preattentive," "instantaneous," or "effortless" texture discrimination. It can also be described as the tendency for some pairs of textured stimuli to induce the formation of an illusory contour between regions of different spatial structure (see SHAPE PERCEPTION, GESTALT PERCEPTION, SURFACE PERCEPTION). One of the major areas of activity in the study of texture perception has been to try to isolate the stimulus characteristics that support this phenomenon. Descriptions of these characteristics have included local features (e.g., Beck 1966, 1982; Julesz 1981), pixel statistics (e.g., Julesz 1962, 1975), and linear filters (e.g., Harvey and Gervais 1978, 1981; Richards and Polit 1974; Beck, Sutter and Ivry 1987; Bergen and Adelson 1988). For reviews of this work see Bergen (1991) and Graham (1991).

A rather ubiquitous idea found in this body of work is that texture segregation is based on a simplified analysis of spatial structure. According to this view, the reason that some texture pairs segregate and others do not is that the


texture analysis process does not possess the powers of discrimination present in more sophisticated processes such as VISUAL OBJECT RECOGNITION, AI. Thus, the nonsegregating textures (such as those composed of the T and L shapes in the example) look the same to the (hypothetical) texture analysis process even though they look different to the (hypothetical) pattern discrimination process. Possible reasons that the visual system would perform such a simplified analysis involve issues of speed and complexity. It may be more important to have rapid (or "early") information about texture structure than to respond to all visible structure differences. This would be the case if texture-based segmentation has an orienting or ATTENTION control function. Alternatively, it may simply be too expensive of processing resources to make a more detailed analysis of texture structure. Texture stimuli have the inherent characteristic of spatial density as compared to the relative sparsity of other visual characteristics. Dense, more complex processing may not be a biologically feasible option.

Texture segregation is most strongly driven by simple differences in local spatial structure such as granularity (coarseness or spatial frequency content), orientation, and sign-of-contrast. These are also the kinds of spatial characteristics that most strongly determine the physiological responsiveness of cells in the early stages of mammalian VISUAL CORTEX (see also VISUAL ANATOMY AND PHYSIOLOGY). This coincidence raises the intriguing possibility that texture properties are actually computed at this rather early stage of visual processing. This possibility has been associated with all of the different styles of texture descriptions described earlier; at a qualitative level local feature extraction, analysis of image statistics, and analysis of spatial frequency content are all plausible (although crude) descriptions of early cortical processing.

The relationship between models of early visual processing (particularly those based on some understanding of mammalian cortex) and texture perception phenomena has been the basis for computational and psychophysical investigations. Examples include Caelli (1985), Turner (1986), Malik and Perona (1990), Bergen and Landy (1991), Chubb and Landy (1991), Graham (1991), and Landy and Bergen (1991). The underlying information representation in most of these studies is a collection of linear filters sensitive to different scales and orientations of spatial structure, possibly with a preceding static nonlinearity. These models (sometimes referred to as "energy models" or "filter models") provide a good description of texture phenomena for certain classes of stimuli. Heeger and Bergen have demonstrated that for textures of relatively "random" structure such models can be used as the basis for synthesis of textures that match a target texture in appearance. This procedure also demonstrates the limitations of this kind of representation: for textures with nonlocal or quasi-periodic structure, physiologically motivated filter models do not successfully capture texture structure. Promising extensions to this approach can be found in the work of Popat and Picard (1993) and De Bonet (1997), which uses more explicit spatial information to represent more coherent structure.

It is possible that the image characteristics that are commonly referred to as "texture" actually fall into two different

Figure 1.

categories: texture and pattern. In this case a representation comprising both components may be necessary to give a complete description. This may also mean that attempts to associate visual texture perception phenomena with the properties of visual brain components may succeed in the sense that aspects of texture perception can be related to individual or group properties of neurons, but fail in the sense that there is no single neural system displaying all of the properties of "texture".

Thalamus

The thalamus is a component of the brain of every mammal: it looks like a pair of small eggs, one underneath each of the cerebral hemispheres. Its volume is 2 percent and 4 percent of the volume of the cortex. It has a simple position in the overall architecture: virtually all information arriving at the CEREBRAL CORTEX comes from the thalamus, which receives it from subcortical structures. This architecture is shown in figure 1. In particular, all visual, auditory, tactile, and proprioceptive information passes through the thalamus on its way to cortex; all planning and motor information generated by the CEREBELLUM or by the BASAL GANGLIA is passed through the thalamus to cortex; and emotional or motivational data from the AMYGDALA and the mammilary body passes through the thalamus also. The main exceptions to this are (1) the direct pathway from the olfactory bulb to olfactory cortex; (2) a supplementary direct pathway from the amygdala to prefrontal cortex; and (3) diffuse neuromodulatory projections from various brain stem nuclei to cortex. These facts give rise to the classic view that the thalamus is a passive relay station which generates virtually all the information bearing input to the cortex. This view is strengthened by the simplicity of the internal connections in the thalamus: the pathways above are built from a homogeneous population of excitatory "relay" cells which give off almost no local collaterals in the thalamus, but synapse strongly on layer IV (and deep layer III) cortical neurons. Finally, this "feedforward" pathway is topographically organized, with various nuclei of the thalamus projecting to various areas of cortex and a "rod–to–column" pattern within each nucleus (Jones 1985: fig 3.20, 3.22, and p. 811).

BUT the above picture has omitted one fundamental fact: *all projections from thalamus to cortex are reciprocated by feedback projections from cortex to thalamus of the same or even larger size.* For instance, Sherman and Koch (1986) estimate that in cat there are roughly 10^6 fibers from the lateral geniculate nucleus in the thalamus to the VISUAL CORTEX, but 10^7 fibers in the reverse direction! As Jones says, "Can it be that such a highly organized and numerically dense projection has virtually no functional significance? One doubts it. The very anatomical precision speaks against it. Every dorsal thalamic nucleus receives fibers back from all cortical areas to which it projects; . . ." (Jones 1985: 819).

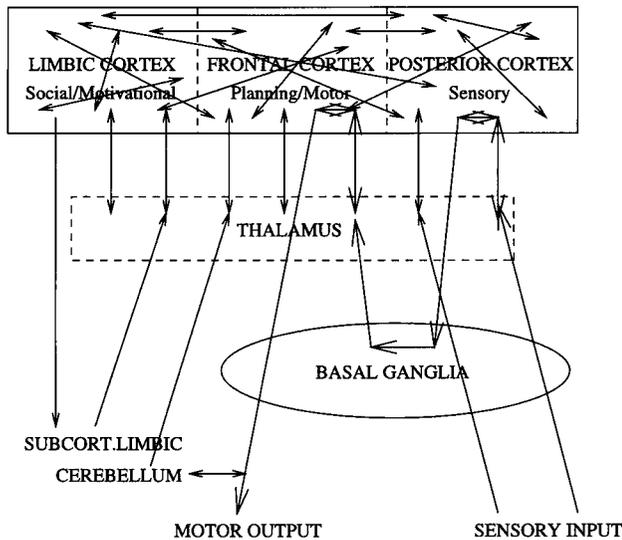
Feedback pathways are the hallmark of mammalian brains. Lower animals have brains which are, by and large, constructed on a feedforward, modular architecture. In the total reorganization that formed the mammalian telencephalon, two vast families of feedback pathways appear: the corticothalamic pathways just described and the corticocortical feedback pathways, by which virtually all nonlocal connections within the cortex (the myelinated tracts in the white matter connecting distinct cortical areas) are


Figure 1. A simplified schematic of the architecture of mammalian brains, indicating the main connections of the thalamus.

reciprocated. This architecture is also indicated schematically in figure 1. From an information-processing point of view, modeling the role of these feedback pathways seems to be one of the first steps in making sense of cortical anatomy. And since the corticothalamic feedback is relatively simple, this would seem to be a prime target for models.

Perhaps the most accepted model for this feedback is that it is used to *gate* the information which reaches cortex, allowing the cortex to selectively attend to part of the data at a given time. Rather striking evidence for this was discovered by Singer and coworkers (Singer and Schmielau 1976; Singer 1977; Varela and Singer 1987): they found that cortical feedback was used to selectively enhance visual input from the two eyes at points where they were viewing a surface in the fixation plane. This highlights objects on the plane of fixation and suppresses objects which are nearer or farther. Subsequently Crick (1984) developed a specific mechanism for such gating, based on a small group of thalamic cells called the reticular nucleus. In his view, such thalamic gating might underlie the psychophysical results of Treisman (1980) implicating serial search in some visual tasks. The attention hypothesis has been used to explain effects in humans after thalamic strokes (Rafal and Posner 1987) and after direct electrode stimulation in the course of neurosurgery (Ojemann 1983). Very suggestive results on the enhancement and inhibition caused by coricothalamic feedback from S1 to VPM in rat have been discovered by Ghazanfar and Nicolelis (1997).

Does mere gating require such a massive backprojection? Beautiful evidence for a subtler role of corticothalamic feedback was discovered recently by Sillito and co-workers (1994). They found that cortical feedback caused thalamic relay cells responding to different parts of a coherent visual stimulus to synchronize. More precisely, an extended moving bar excites multiple thalamic relay cells whose receptive fields lie at different positions along the bar. When cortical feedback was intact, the spike trains of these cells showed strong correlations which were absent if either the feedback was interrupted or if the stimulus was not coherent (e.g., being made up of two bars). This suggests that information can pass back and forth between thalamus and cortex and that important nonlocal patterns are recognized during this iterative operation. Further evidence is found in Nicolelis et al. (1995).

Several models for such iterative algorithms have been proposed. The earliest, to my knowledge, was the ALOPEX theory of Harth et al. (1987), described as follows: "A model is proposed in which the feedback pathways serve to modify afferent sensory stimuli in ways that enhance and complete sensory input patterns, suppress irrelevant features, and generate quasi-sensory patterns when afferent stimulation is weak or absent." I have elaborated this theory (see Mumford 1991–2, 1993), describing the role it imputes to the thalamus as that of an "active blackboard." The basic idea is that there are multiple cortical assemblies which respond to the presence of distinct nonlocal visual patterns; in a noisy ambiguous real-world stimulus, many of these will respond to varying degrees. These assemblies then compete to enhance the features they depend on while inhibiting their rival's features *via their feedback on both the thalamic relay cells and the thalamic inhibitory interneurons.* A related idea has been implemented in tracking algorithms in Isard and Blake (1996): their ALGORITHM infers multiple competing hypotheses which kill each other off as evidence accrues. One hopes that advances in recording techniques and the use of more realistic stimuli will enable tests of these hypotheses to be made in the coming decade.

Thematic Roles

Grammatical studies, both traditional and contemporary, have recognized that formal distinctions, involving the case or syntactic position of the arguments of a verb or other part of speech, correlated significantly with intuitive semantic distinctions, involving the relations of those arguments to the action or state indicated by the verb. In simple English sentences with two or three nominal arguments, for example, where only syntactic position visibly distinguishes their relation to the verb, we can see that the first, subject position regularly belongs to the initiator of the action, or *agent;* that the direct object position regularly belongs to the recipient of the action, the *patient* or more generally the *theme;* and that the indirect-object position, if there is one, regularly belongs to the person or thing for the sake of which the action is done, or the *goal* of the action:

(1) John hit Bill (≠ Bill hit John).

(2) The circuit controls the memory chip (≠ the memory chip controls the circuit).

(3) The girl gave the boy the dog (≠ the boy gave the girl the dog, the girl gave the dog the boy, etc.).

In languages with rich case systems, the cases will give information about the semantic relations of agent, patient, goal, and some others, including location and instrument. English, typically among languages with impoverished case systems, signals these relations through prepositions. The cases themselves also correlate with syntactic positions (e.g., with nominative as the case of the subject and accusative as the case of the direct object), so that the formal side comprises both syntactic and morphological elements; the relations between these elements are a subject of intense crosslinguistic study within linguistic theory (see GRAMMATICAL RELATIONS).

The semantic relations between a verbal form and its arguments, as in (1)–(3), were dubbed *thematic roles* Gruber (1965); the term *theta-roles* is also in common use, with the same meaning. The notion of a thematic role extends also to the *adjuncts* of the verbal form, elements that, like the goal, instrumental, and locative phrases in (4), are not obligatory but optional (as indicated by parentheses).

(4) I reproduced the picture (for my mother) (in the dining room) (with a pencil).

Following standard terminology, say that a verb *selects* an array of arguments and *permits* an array of adjuncts, each of which bears a given thematic role. The thematic roles of arguments must be syntactically realized: hence we do not have sentences like **John hit,* meaning that John hit someone. Conversely, and with greater generality, no thematic role can be distributed over more than one element, whether it be argument or adjunct; thus, for example, instrumental phrases cannot be repeated, as in (5).

(5) *The prisoner escaped with a bribe with a machine gun.

There is, then, for each simple clause a one-to-one correspondence between a certain set of theta-roles and their realization in certain syntactic positions, perhaps in construction with specific cases and/or prepositions (or postpositions). That human languages obey this correspondence principle is the *theta-criterion* in the sense of Chomsky 1981.

Assuming the theta-criterion and a preliminary grasp of the content of typical thematic roles, theoretical studies have endeavored to discover a full inventory of the thematic roles in principle admissible in human languages, and the syntactic or morphological conditions on the appearance of elements with those roles. Languages generally exhibit a hierarchy among thematic roles, realizing agents as subjects and themes as direct objects; for important surveys, see Rappaport and Levin 1988 and Jackendoff 1987. These studies have also shed light on the scope and limits of certain syntactic alternations. For instance, as observed Fillmore (1968), English and other languages have pairs such as (6)–(7).

(6) The bees swarmed in the garden.

(7) The garden swarmed with bees.

That such pairs should exist would follow if the verb *swarm* were specified for locative (*in the garden*) and instrumental (*with bees*) thematic roles, with either thematic element free to occupy the subject position. On the other hand, there are alternations that are not fully productive, as in (10)–(11) versus (8)–(9):

(8) I stuffed the pillow with feathers.

(9) I stuffed feathers into the pillow.

(10) I filled the pail with water.

(11) *I filled water into the pail.

The syntactic distribution shown may be predicted from the meaning of the verbs, in that *stuff,* but not *fill,* can take the direct object as its theme.

The subject position is crucially distinguished from others, in that it alone can be occupied by an expletive, as in (12)–(13):

(12) *It* is snowing.

(13) *There* are cats on the roof.

Furthermore, there are verbs whose sole argument may be argued to originate, not in the subject position but in the position of the direct object, the so-called *unaccusative* verbs. For these reasons, among others, it has been useful to distinguish the elements in close construction with the verb—the *internal* arguments—from the single element that will appear as the subject in a simple clause—the *external* argument (the terminology and much of the discussion is due to Williams 1980).

Besides the above and other syntactic studies, semantic research has considered the question how thematic roles contribute to meaning. On one view of the matter, discussed by Carlson (1984), Higginbotham (1989), and Parsons (1990), among others, thematic roles are relations between events or states and the things that participate in them. The semantics of (1), for instance, would then be expressed as (14).

(14) *e* is a hitting event and Agent (John, *e*) and Patient (Bill, *e*)

Alternatively, it has been suggested that the content of thematic roles is to be located in semantic postulates governing the verbs that assign them (see Dowty 1988).

Theorem Proving

See DEDUCTIVE REASONING; LOGIC; LOGICAL REASONING SYSTEMS

Theory of Mind

Understanding other people is one of the most fundamental human problems. We know much less, however, about our ability to understand other minds than about our ability to understand the physical world. The branch of cognitive science that concerns our understanding of the minds of ourselves and others has come to be called "theory of mind," though it should perhaps be called "theory of theory of mind." It involves psychological theorizing about our ordinary, intuitive, "folk" understanding of the mind.

A number of different disciplines have collaborated in this effort. Philosophers have debated the nature and origin of our understanding of the mind, our FOLK PSYCHOLOGY, at length. Comparative psychologists have explored the evolution of this capacity. One currently prevalent theory of the evolution of cognition suggests that the capacity to understand, and so manipulate, our conspecifics was the driving force behind the development of distinctively human intelligence (Byrne and Whiten 1988). There has also been extensive work on primates' ability to understand mental states. The most recent work suggests that these abilities are fragmentary, at best, compared to the abilities of humans (Povinelli 1996; Tomasello, Kruger, and Ratner. 1993; see PRIMATE COGNITION). Clinical psychologists have proposed that the disorder of AUTISM involves a deficit in "theory of mind" capacities. Social psychologists explore our understanding of aspects of the mind such as the stability of personality traits (Nisbett and Ross 1980). Anthropologists suggest that fundamental assumptions about the mind may differ across cultures (Shweder and Levine 1984).

The most extensive "theory of mind" research, however, has been developmental (see Astington, Harris, and Olson 1988; Perner 1991; Wellman 1990). Children seem to understand important aspects of the mind from a strikingly early age, possibly from birth, but this knowledge also undergoes extensive changes with development. Early research focused on the child's understanding of belief and reality, and on the period between three and five years of age. Several significant and correlated changes seem to take

place at about this time. Wimmer and Perner (1983) found that children of this age had difficulty understanding the fact that beliefs could be false. In one experiment, for example, children saw a closed candy box. When they opened it, it turned out that there were pencils inside it, rather than the candy they had been expecting. The children were asked what another person would think was in the box at first, before they opened it. Three year-olds consistently said that the children would think that there were pencils in the box. They did not understand that the other person's belief could be false. Gopnik and Astington (1988) demonstrated that children make this same error when they are asked about their own immediately past false beliefs. Children say that they, too, thought that there were pencils in the box, just as they predict that the other person will think there are pencils there. Flavell and his colleagues showed that three year-olds have a similar problem understanding the distinction between appearance and reality. For example, children who were shown a sponge painted to look like a rock insisted that the object both really was a sponge and also looked like a sponge (Flavell, Green, and Flavell 1986). Finally, children at three also seem to have difficulty understanding the sources of their beliefs. In one experiment children learned about an object that was hidden under a tunnel by either seeing it, feeling it, or being told about it. Although children could identify the object, they could not identify how they came to know about the object (O'Neill and Gopnik 1991). These investigators suggested that these linked developments indicate a new understanding of the representational character of belief between the ages of three and five.

Some recent studies suggest that the first signs of this understanding of false belief may emerge when children place the problem in the context of their earlier understanding of desire or perception (Flavell et al. 1990; Moses 1993; Gopnik, Meltozoff, and Slaugnter 1994), or when they are confronted with counterevidence to their incorrect views (Mitchell and Lacohee 1991; Bartsch and Wellman 1989), and that they may demonstrate some implicit knowledge of belief before they make that knowledge explicit (Clements and Perner 1994). However, this very early understanding appears to be, at best, fragile and incomplete in comparison with the robust and coherent knowledge of belief demonstrated at four or five.

More recent studies have investigated both a wider range of ages and a wider range of mental states. There is extensive evidence that children understand important aspects of desire well before age three. These include the facts that desires can be unfulfilled, that desires determine emotions, and even that desires may differ in different people (Perner 1991; Wellman 1990; Wellman and Woolley 1990). Similarly, even two-and-a-half year olds seem to understand aspects of visual perception. They understand, for example, that two people may see different things if they are on opposite sides of a screen (Masangkay et al. 1974). Three-year-olds also seem to understand important aspects of pretense and imagination, and they can use this understanding to make a general distinction between mental and physical entities (Harris and Kavanaugh 1993; Wellman and Estes 1986; Woolley and Wellman 1990). For example, they understand that pre-

tending to be a rabbit is different from being one, or that an imagined toy is private and intangible while a real toy is not. Bartsch and Wellman (1995) have conducted extensive studies of early spontaneous conversations about mental states. They have demonstrated that children between eighteen months and three years of age do not just display these abilities in laboratory tasks, but they also spontaneously explain human action in these terms, and shift from desire to belief explanations.

As we study younger and younger infants it becomes more difficult to be certain that they are making genuinely mentalistic ascriptions to others. However, studies of nonverbal behavior suggest that even infants understand certain aspects of the mind. Studies of infant IMITATION (Meltzoff and Moore 1977) suggest that there are innate links between children's perception of the actions of others and their perception of their own internal kinesthetic states; newborns who see another person produce a particular gesture will produce that gesture themselves (Meltzoff and Gopnik 1993). Similarly, very young infants show special preferences for human faces and voices, and engage in complex nonverbal communicative interactions with others (Trevarthen 1979). By nine months infants begin to follow the gaze of others and to point objects out to them (Butterworth 1991). In the behavior known as "social referencing," infants who are faced with an ambiguous situation turn to check the adult's facial expression and regulate their actions in accordance with it (Campos and Sternberg 1980). These very early abilities suggest that there is a strong innate component to our "theory of mind."

However, other aspects of our understanding of the mind do not appear to be in place until well after five years of age. For example, although children understand EMOTIONS at a very early stage, they only understand the difference between real emotion and emotional expression at around six (Harris 1989). Similarly, understanding the inferential character of the mind appears to be quite difficult. Children who can understand simple cases of false belief still have difficulty when the questions involve multiple interpretations of ambiguous stimuli or more complex sources of information (Chandler and Helm 1984; Taylor 1988; Wimmer, Hogrefe and Sodian 1988). Finally, children appear to understand fundamental facts about conscious phenomenology, such as the existence of "the stream of consciousness," at a surprisingly late age. Six-year-olds, for example, reported that people could consciously decide to turn over in the midst of a deep dreamless sleep, or conversely, that a person who was awake but just sitting still doing nothing would have no thoughts or internal experience at all (Flavell, Green, and Flavell 1995).

As always in developmental psychology we have a better sense of when various developments take place than of the mechanisms that underlie these changes. Several different accounts of these underlying mechanisms have been proposed in the literature (see Carruthers and Smith 1995). Leslie (1994) and Baron-Cohen (1995) have suggested that the developments reflect the maturation of an innate theory of mind module, by analogy with similar modular theories of language and perception. In fact, in Leslie's view several different modules mature in succession. Harris (1991) has

argued for a "simulation" theory of many theory of mind developments. On this view advances in the child's understanding of the mind reflect an increasing ability to simulate or imagine the experiences of others. Dunn suggests that socialization and social interaction may play a crucial role in children's development of a theory of mind (Dunn et al. 1991). In support of this view, there is evidence that younger siblings have a more advanced theory of mind than older siblings (Perner, Ruffman, and Leekam 1994) and that parent's conversations about mental states influence children's understanding of the mind (Dunn et al. 1991). Probably the most widely held view, however, is what has been called "the theory theory" (Perner 1991; Wellman 1990; Gopnik 1993; Flavell, Green, and Flavell 1995). Originally advanced in philosophy (see SIMULATION VS. THEORY-THEORY) this view also is part of a more general theoretical approach that explains children's COGNITIVE DEVELOPMENT by analogy to scientific theory change (Carey 1985; Gopnik and Meltzoff 1997; Wellman 1990). On this view children develop a succession of theories of the mind that they use to explain their experience and the behavior of themselves and others. Like scientific theories, these intuitive or naive theories postulate abstract coherent mental entities and laws, and they provide predictions, interpretations, and explanations. The theories change as children confront counterevidence, gather new data, and perform experiments. One consequence of this view is that the philosophical doctrine of first-person authority is incorrect; our knowledge of our minds is as theoretical as our knowledge of the minds of others. More broadly, the recent research suggests that empirical evidence from developmental psychology may be brought to bear on classic problems in the philosophy of mind.

Thought and Language

See LANGUAGE AND THOUGHT; LANGUAGE OF THOUGHT

Time in the Mind

Research on temporal perception goes back to the nineteenth century. In 1860, Karl Ernst von Baer introduced the notion of perceptual moment suggesting that different durations of the moments result in a different flow of subjective time. In 1865, Ernst Mach looked for Weber's law in temporal perception, and he observed that 30 ms is apparently the lowest limit for subjective durations. Then, in 1868 Frans Cornelis Donders presented the reaction time paradigm, which remains the basis for chronometric analyses of mental processes. In the same year, Karl von Vierordt investigated temporal integration using the paradigm of stimulus reproduction. These ideas embedded in the conceptual framework of PSYCHOPHYSICS as promoted by Gustav Theodor Fechner, set the stage for many decades, but then interest in temporal mechanisms of perception and cognition in general declined. Only recently has temporal perception become a central issue again, because cognitive processes cannot be understood without their temporal dynamics.

At least two independent temporal processing systems have been described that are basic for perceptual and cognitive processes and that are characterized by discrete time sampling. Both these systems are fundamental for the instantiation of perceptual acts, of cognitive processing, or of volitional MOTOR CONTROL. First, some observations on a high-frequency processing system generating discrete time quanta of 30 ms duration are mentioned. Then, a low-frequency processing system setting up functional states of approximately 3 seconds, which is believed to be the operative basis for what we refer to as "subjective present," is addressed. In between those two temporal processing levels additional timing mechanisms come into play that are fundamental for motor control, especially for the repeated initiation of movements.

Evidence for a high-frequency processing system derives from studies on temporal order threshold. If the temporal sequence of two stimuli has to be indicated, independent of sensory modality a threshold of approximately 30 ms is observed. Sensory data picked up within 30 ms are treated as cotemporal, that is, a relationship of separate stimuli with respect to the before-after dimension cannot be established (Pöppel 1997). Temporal order threshold being identical in different sensory modalities (Hirsh and Sherrick 1961), thus, also indicates a lower limit for event identification. Temporal order analysis of the speech signal seems to be the basis for phoneme identification, a disturbance of temporal acuity being associated with language disorders such as APHASIA and LANGUAGE IMPAIRMENT (Tallal, Miller, and Fitch 1993; see also DYSLEXIA).

Support for distinct processing stages comes from a variety of studies using qualitatively different paradigms. Under stationary experimental conditions response distributions of reaction times (Harter and White 1968) and of pursuit (Pöppel and Logothetis 1986) or saccadic eye movements (see EYE MOVEMENTS AND VISUAL ATTENTION and OCULOMOTOR CONTROL) show multimodal characteristics with a 30 ms separation of distinct response modes. These multimodalities can be explained on the basis of neuronal oscillations. After the transduction of a stimulus a relaxation oscillation with a period of 30 ms is initiated, which is triggered instantaneously by the stimulus. Such an oscillatory mechanism being under environmental stimulus control allows integration of information from different sensory modalities, that is, data from various sources can be collected within one period, which defines a basic system state (Pöppel 1997). Possibly, the separate response modes represent similar successive and discrete decision-making stages as are assumed in high-speed scanning of short-term memory.

Some neurophysiological observations support the notion of discrete temporal processing on the basis of system states

implemented by oscillations. The auditory evoked potential (see ELECTROPHYSIOLOGY, ELECTRIC AND MAGNETIC EVOKED FIELDS) in the midlatency region shows an oscillatory component with a period of 30 ms. This component is a sensitive marker for the anesthetic state because it selectively disappears during general anesthesia. Oscillations with a period of 30 ms represent functional system states that are prerequisites for the establishment of events. If temporal coherence within a neuronal network as expressed by oscillations is removed as with general anesthetics conscious representation is interrupted (Schwender et al. 1994). Events cannot be implemented as functional "building blocks" of conscious activity.

A low-frequency mechanism, independent of a high-frequency mechanism implementing system states for event identification, binds successive events up to approximately 3 seconds into perceptual and action units (Fraisse 1984; Pöppel 1997). Support for such a binding operation comes from studies on spontaneous alteration rates of ambiguous figures (see ILLUSIONS). If stimuli can be perceived with two perspectives (like the Necker cube), there is an automatic shift of perceptual content after 3 seconds (Schleidt and Kien 1997; Gomez et al. 1995). Such a perceptual shift is true also for ambiguous auditory material like the phoneme sequence CU-BA-CU . . . where one hears either CUBA or BACU. The spontaneous alteration rate in the two modalities suggests that after an exhaust period of 3 seconds, attentional mechanisms (see ATTENTION and ATTENTION AND THE HUMAN BRAIN) are elicited that open sensory channels for new information; if the physical stimulus remains the same, the alternative interpretation of the stimulus will gain control. Metaphorically, the brain asks every 3 seconds "what is new?" and with unusual stimuli like the ambiguous material the temporal eigen-operations of the brain are unmasked.

Temporal integration up to 3 seconds is also observed in sensorimotor behavior. If a subject is requested to synchronize a regular sequence of auditory stimuli with finger taps, stimuli are anticipated by some tens of milliseconds. Stimulus anticipation with high temporal precision is, however, possible only up to interstimulus intervals of 3 seconds. If the next stimulus lies too far in the future, that is, more than 3 seconds, it is not possible to program an anticipatory movement that is precisely related to the stimulus (Mates et al. 1994).

Because the experiments referred to (and others) employ qualitatively different paradigms covering perceptual processes, cognitive evaluations, or movement control, it is proposed that temporal integration up to 3 seconds is a general principle of the neurocognitive machinery. This integration is automatic and presemantic, that is, the temporal limit is not determined by what is processed, but by intrinsic time constants. Because of the omnipresence of temporal integration, it can be used for a pragmatic definition of the subjective present, which is characterized phenomenally by a feeling of nowness, or one can relate temporal integration to singular single states of being conscious (see CONSCIOUSNESS and CONSCIOUSNESS, NEUROBIOLOGY OF).

Additionally, on a different timing level control of motor performance can be registered. Two categorically distinct speed modes with frequencies of 2 Hz and 5 Hz in the sequential initiation of motor behavior are most prominent and can be assessed in simple finger tapping tasks. Nevertheless, they represent basic temporal movement characteristics. Fast automatic movements in the maximum speed in finger tapping can be performed with interresponse intervals of 150 to 200 ms, representing a frequency of approximately 5 Hz. The speed in a personally chosen finger-tapping task is performed with interresponse intervals around 500 ms, representing a frequency of approximately 2 Hz (Fraisse 1982). These two different frequency modes are also seen in other movement tasks and are associated with distinct sensorimotor control processes, the 2-Hz movement being under voluntary control and allowing the collection of somatosensory information, the maximum speed 5-Hz performance requiring only coarse preattentive control (Kunesch et al. 1989). In sensorimotor synchronization where the frequency of a pacer signal has to be reproduced accurately by finger taps, the notion of the categorical difference of the two frequency modes is complemented. The subjective representation of every single finger tap is possible only when a subject is tapping to interstimulus intervals of above 300 ms (Peters 1989). The single taps cannot be temporally resolved in somatosensory perception with interstimulus intervals below 300 ms. This threshold of approximately 300 ms marks the categorical change in motor performance, dividing the aforementioned two motor control processes into automatized movement and voluntarily controlled behavior.

Tone

One of the fundamental goals of phonological theory is to determine how, starting with a complete phonetic description of a language, we can establish a small number of discrete categories along the various dimensions in which speech sounds may vary (see PHONOLOGY and PHONETICS). These discrete categories along each phonetic dimension are the values assumed by DISTINCTIVE FEATURES, and in any given language they must be rich enough to distinguish utterances that differ with regard to their word choice or their grammatical information, but no richer; other phonetic detail is excluded from such a phonological description. *Pitch* is the name given to the frequency of pulsation of the vocal cords during speech; it describes a continuous variable, which can range from about 50 Hz, at the bottom of a man's range, to about 400 Hz, at the top of a woman's range. *Tone* refers to the small number of discrete categories necessary for analyzing pitch in a phonological fashion.

Tone is normally analyzed as a property not of individual segments (or sounds), but of syllables. From a descriptive point of view, the pitch of syllables may be either (roughly) constant throughout, or it may have a more complex, dynamic pitch—typically rising or falling. In the first case, such syllables are phonologically assigned a single "level" tone; in the second, in almost all cases, the syllable is analyzed as being assigned a sequence of more than one level tone, and it is this sequence of distinct tones that gives rise to the "dynamic" or "contour" pitch: a sequence of low tone plus high tone gives rise to a rising pitch, and so on. The number of distinct tonal levels (corresponding to different levels of pitch) varies from language to language, but two, three, and four levels of tone are not at all uncommon,

and a few languages with even more levels have been reported in the literature. In the neutral intonational pattern of English, a word with initial accent such as "wedding" has a high tone on the first syllable and a low tone on the second syllable, whereas a monosyllabic word such as "man" has a falling pitch, which is to say, the syllable is associated with a sequence of two tones, high and low, in that order.

The term *tone language* is traditionally used to refer to those languages that use differences in tone in order to distinguish between distinct lexical items (that is, distinct words; Pike 1948; Hyman 1978; McCawley 1978; Goldsmith 1994). Such systems may seem exotic from a European perspective, but tone languages are quite common around the world, including a large number of Asian languages (including notably the well-studied Sino-Tibetan languages; Yip 1995), most African languages (especially the well-studied Niger-Congo languages; Odden 1995), and many Mesoamerican languages, especially the Oto-Manguean languages. It is appropriate to bear in mind that in these languages, tone is just as often used to manifest grammatical categories as it is to mark lexical contrasts. For example, in many Bantu languages of Africa, the verb will consist of six or more syllables, composed of a polysyllabic stem with several prefixes. The first syllable of the stem is the lexical root, and its tone is a lexical (that is, idiosyncratic) property. The tones of the following syllables of the stem, however, will be determined by the tense of the sentence, and they are thus considered to express grammatical information.

Languages are often divided into three categories, from a prosodic point of view: tone languages, pitch-accent languages, and intonational languages, but the boundaries between these categories can be difficult to discern at times (see PROSODY AND INTONATION). Pitch-accent systems share in common with tone languages relatively strict principles determining the tone assigned to each syllable, and thus the pitch at which each syllable will be uttered, but rather than utilize tonal differences as such in the LEXICON, pitch-accent systems characteristically employ a single tonal melody (e.g., low-high-low, constant across the language), and assign it to an entire phonological word. However, such languages employ an assignment algorithm that recognizes that one syllable is prosodically special, the syllable that is called "accented." The accented syllable bears a special mark in the lexicon, and tone mapping will typically make that accented status be phonetically unique in some fashion, by making it the final high of the word, or the first high, or through some other means. The information that is thus transmitted by the pitch pattern is which syllable is accented, rather than what the tonal melody is. The location of the pitch accent will in some languages be predictable by simple rule, in others by complex rules involving the interaction of the morphemes involved, and in yet others be simply stipulated in the lexicon. Tokyo Japanese is a familiar example of a pitch-accent system. However, some systems exist (including other dialects of Japanese) that contain two distinct tonal patterns, and lexical items must be marked as to which tonal pattern is appropriate. Systems of this sort share functional characteristics with tone languages, and

blur the boundary between tone languages and pitch-accent languages.

Intonational languages (a category that includes English) generally allow pragmatic factors to influence the tone and the pitch of an utterance to a greater degree than would a tone or pitch-accent language. Most intonational languages (French is an exception) share with pitch-accent systems the characteristic of marking exactly one syllable as accented, and using the location of that accented syllable in the algorithm that maps an intonational pattern to the phonological word. However, it is very difficult—indeed, at this point, it seems impossible—to draw a sharp boundary between those aspects of intonation that can be adequately handled with discrete linguistic categories and those that blend gradually into the noncategorical aspects of general communicative behavior. A consideration of the intonation of ironic, polite, or highly emotional speech quickly encounters this problem.

As these remarks suggest, one of the most important characteristics of tonal patterns in language is their considerable autonomy with respect to the other characteristics of spoken language, which are produced largely by the mouth and nose. This autonomy is manifested in several ways, including: (1) the numerical mismatch, or many-to-many relationship, found between tones and syllables; (2) the retention of a tone despite the synchronic or diachronic loss of a tone (so-called tonal stability); and (3) the existence of morphemes that consist solely of one or more tonal specifications (so-called floating tones). These observations are closely linked to the foundations of autosegmental phonology (Goldsmith 1990). In addition to the numerical mismatch between tones and syllables, tone languages often display a temporal mismatch between the tones and the syllables of a given morpheme. The consequence of this is that it is not at all uncommon to find in tone languages that a morpheme is underlyingly (or analytically) composed of both tones and syllables, and yet the tone(s) of the morpheme will be consistently realized on a different syllable, either earlier or later than the syllable(s) pertaining to that morpheme.

Top-Down Processing in Vision

Perception represents the immediate present, what is happening around us as conveyed by the pattern of light falling on our RETINA. And yet the current pattern of light alone cannot explain the stable, rich experience we have of our surroundings. The problem is that each retinal image could have arisen from any of a vast number of possible 3-D scenes. That we rapidly perceive only one interpretation tells us that we see far more than the immediate information falling on our retina. The highly accurate guesses and inferences that we make rapidly and unconsciously are based on a wealth of knowledge of the world and our expectations for the particular scene we are seeing. The influences of these sources beyond the images on the retina are collectively known as top-down influences.

Both top-down analyses and the complementary bottom-up processes use local cues to assign depth to the regions of an image. They differ in the manner in which they resolve the ambiguity of the local cues. A bottom-up analysis, part of MID-LEVEL VISION and SURFACE PERCEPTION, makes direct links between local geometrical features and depth. For example, whenever one object partially covers another, the visible contours of the more distant object terminate at the outer boundary of the nearer one, forming what are called T-junctions. When a T-junction is encountered in an image, this logic can be reversed: the stem of the T is designated a contour of a more distant, partially hidden object and the top of the T is assigned to the outer boundary of a nearer object.

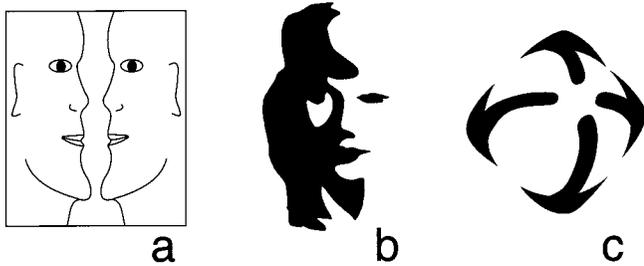
A top-down process, on the other hand, depends on the content of the image and its analysis by processes of HIGH-LEVEL VISION. Cues operate by suggesting objects—a nose contour might suggest a face, for example—and then stored information about that object's structure can be applied to the assignment of depth in the image. Other features in the image are then examined to verify or reject the postulated object. The cues used for the initial selection of potential objects are not limited to the current images but include pre-


Figure 1.

ceding images as well as nonvisual sources which affect our expectations for the scene. The sources of object knowledge which are called upon may be built up over both evolutionary or individual time scales.

Our guesses for appropriate internal models are best when we know what to expect in a scene. Upon opening a door to a classroom, for example, we expect to see desks and a black or white board. If these elements are present in the scene, they are rapidly interpreted. Incongruent elements are seen less reliably, as Biederman (1981) showed when he reported increased errors in identifying fire hydrants presented in kitchens or sofas floating over city streets than when they were presented in their usual contexts. As Biederman's example demonstrates, top-down analyses work because there is a great deal of semantic redundancy in the content of a scene—noses are expected to be seen along with mouths, cars with roads, classrooms with desks, and sofas with coffee tables; moreover, noses, cars, and sofas have typical shapes so that once a few distinctive features have implied the presence of say, a car, the other expected features of a car can be verified or even just assumed to be present.

Textbook examples of top-down processing typically make use of images with two or more equally likely interpretations which are sometimes referred to as ILLUSIONS. A hint as to which interpretation to see may then trigger one or the other, as in the examples shown here. (a) Two faces, or one vase, or one face behind a vase (Costall 1980); (b) a man playing a saxophone seen in silhouette, or a woman's face in sharp shadow (Shepard 1990); and (c) a sphere in a four-point setting or a white angel (Tse 1998). In these instances, the 2-D positions of light and dark values are unchanged as we alternate our percepts, but new positions in depth are assigned to each point, some areas change from being dark shadow to dark pigment, and some regions change from being disconnected surfaces to continuous pieces.

Where do these new assignments come from when the 2-D pattern is the same in all cases? We cannot invoke a bottom-up analysis of the depth cues in the image since they would be inconclusive (insufficient to unambiguously assign depth). For some of the examples above we have to be told what to see before the image becomes organized as the intended 3-D object. On the other hand, some of us see some of the interpretations spontaneously, implying that some characteristic features in the image have suggested a familiar object (a nose outline or eye-like shape could suggest a face) and our visual system then matched a possible 3-D version of such an object to the image. In both cases,

our final perception is arrived at through the intermediate step of a guess or a suggestion of a possible object.

Once the presence of an object has been verified, our knowledge of that object can continue to constrain the interpretation of otherwise ambiguous dynamic changes to the object. For example, Chatterjee, Freyd, and Shiffrar (1996) have shown that the perception of ambiguous apparent motion involving human bodies usually avoids implausible paths where body parts would have to cross through each other.

Undoubtedly, the process of top-down matching of a candidate object to the image data occurs for natural images, not just the highly artificial ones shown in the figures above. Because of the extra information present in natural images, it is rare to have two alternative interpretations available. Nevertheless, the speed with which we organize and perceive the world around us arises to a great extent from the excellent (top-down), unconscious guesses we make based on sparse cues coming from either the actual or the expected content of the retinal image.

See HAPTIC PERCEPTION

Transparency

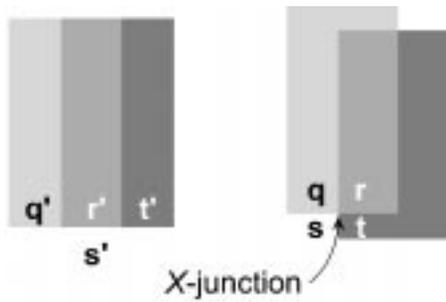
The light projecting to a given point in the RETINA possesses but a single value of color and intensity. When *transparency* is perceived, however, this light is interpreted as being reflected off of two (or sometimes more) surfaces lying in different depth planes. Perceptual transparency is a type of SURFACE PERCEPTION and illustrates the visual system's remarkable ability to reconstruct the three spatial dimensions of the environment given a stimulus (i.e., the retinal images) with only two. There are an infinite number of possible environmental causes of any particular pattern of retinal stimulation. The perception of transparency relies, as does visual perception in general, upon *context* to determine the most likely interpretation. For example, whereas region *r'* in figure 1 *(left)* is usually interpreted in terms of the color


Figure 1.

of a single surface, region *r (right),* an identical shade of gray, is seen to arise from light reflected off of two surfaces. This difference in perceptual interpretation is due to the presence of a contextual cue known as an *X-junction.*

X-junctions are the single most important monocular cue for transparency. They are defined by the presence of four contiguous regions (*q,r,s,t*; see figure 1) of an image with a characteristic spatial arrangement. Psychophysical studies have shown that the intensity relationships between these four regions must lie within certain bounds for perceptual transparency to occur. When X-junctions elicit a perception of transparency, two regions (*q* and *s* in figure 1) are seen as differently colored parts of the unoccluded background and the other two regions (*r* and *t* in figure 1) appear to be viewed through a foreground transparent surface (the darker rectangle). Perceptual psychologists have developed several simple physical models to account for the perception of transparency (e.g., Beck et al. 1984; Matelli 1985). Though differing slightly in their details, the optical properties of *transmittance* and *reflectance* are generally invoked in these models.

Transmittance refers to the multiplicative attenuation of background intensity. One way to think of transmittance is to imagine that transparent surfaces are generally opaque but have holes (like a fine wire mesh) too small to resolve (Kersten 1991; Richards and Witkin 1979; Stoner and Albright 1996). Transmittance is then the proportion of the surface with holes. *Reflectance,* on the other hand, refers to the fraction of incident light reflected off of a surface. If the surface is a foreground transparent surface, this light adds to that reflected off of the background surface. X-junctions that elicit a sense of transparency are usually those in which the four sub-regions possess intensities consistent with physically realizable values of transmittance and reflectance, giving credence to the idea that the visual system possesses a tacit model of the physics of transparency. Given the relative rarity of transparent surfaces in natural scenes, however, it might seem puzzling that the visual system would devote neural machinery to its detection. An alternative possibility is that perceptual transparency depends upon mechanisms that typically process the more common visual phenomena of *shadows* and *opaque occlusion. Shadows* and *opaque occlusion* are ubiquitous in natural scenes and, moreover, can be thought of as defining limiting cases of perceptual transparency.

Objects that lie between a light source and another object cast shadows such that the intensities of the shadowed

regions appear multiplicatively diminished relative to the unshadowed regions. Shadows yield X-junctions that can be mimicked by a transparent surface possessing a transmittance less than one and having zero reflectance. Because the changes in intensities are purely multiplicative, the *contrast* (defined here as the intensity of one region divided by the intensity of another) between two adjacent regions in shadow should be the same as the contrast between spatially contiguous regions that lie out of shadow. Thus, if the X-junction in figure 1 were due to shadow-like transparency, the contrast between "unshadowed" regions *q* and *s* would be equal to that between their corresponding "shadowed" regions *r* and *t.*

Opaque occlusion, on the other hand, results in total contrast attenuation—regions *r* and *t* of figure 2 have identical intensities and hence no contrast exists between them. Opaque occlusion is associated with the presence of a contextual cue known as a *T-junction.* T-junctions are defined by the presence of three adjacent regions of differing intensity. In figure 2, these regions are *q, s,* and *r/t* (which form a single continuous region). The contrast reduction associated with opaque occlusion provides a very important cue for the depth ordering between surfaces. Indeed, the strength of the depth-ordering cue provided by transparent occlusion is directly proportional to the degree of contrast reduction with opaque occlusion providing the most potent cue. X-junctions associated with multiplicative transparency and T-junctions define two ends of a continuum within which perceptual transparency is most likely. Given this tight association between the stimulus conditions defining shadows, transparency, and opaque occlusion, it is tempting to speculate that transparency is detected by neural mechanisms that evolved to process shadows and opaque occlusion rather than transparency.

The neural mechanisms underlying the perception of transparency are only beginning to be understood. There are two important facets of this process. One is the detection of X-junctions suggestive of transparent overlap. As of this writing, no one has looked explicitly for neuronal responses to X-junctions. Baumann, van der Zwan, and Peterhans (1997) have, however, discovered neurons in area V2 of the macaque monkey that appear to encode the depth-ordering information implied by T-junctions. Whether, as the observations made above suggest, these neurons also respond selectively to X-junctions awaits an answer.

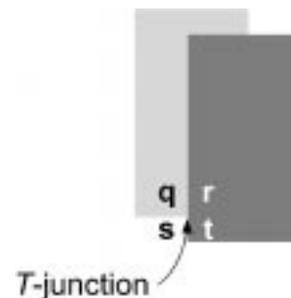
A second important facet of the neural processing of transparency is the existence of a multivalued representation


Figure 2.

of a particular surface property. For static displays there are at least two attributes that have multivalued perceptual representations—surface reflectance and depth. The neural correlates of these multivalued representations have yet to be identified. For dynamic stimuli, more than one motion may be seen to project upon the same point in the retinal images. It has been shown that the perception of "motion transparency" interacts with the perception of transparency of these other attributes. Thus, when overlapping gratings moving in different directions are superimposed ("plaid patterns") in a manner that produces X-junctions which elicit a percept of transparency in static images, a perception of motion transparency (also known as "motion noncoherency") results: the two gratings are seen to move independently (Stoner, Albright, and Ramachandran 1990). Conversely, when plaid patterns have X-junctions inconsistent with transparent overlap, motion transparency is unlikely to occur. Neural correlates for motion transparency have been located (Stoner and Albright 1992). When stimulated with perceptually transparent moving plaid patterns, each of the two gratings activates a separate population of directionally tuned neurons in area MT. Conversely, when stimulated with nontransparent stimuli, a single population of MT neurons, sensitive to the composite motion of the plaid pattern, is activated. A plausible neural substrate for this type of transparency, at least, therefore appears to have been identified.

Turing, Alan Mathison

Alan Mathison Turing (1912–1954), British mathematician and logician, was born in London and was educated at Sherborne School and King's College Cambridge. The originality and precocity of his mathematical thinking soon became apparent—not always to his advantage. A preference for supplementing theory with experiments (particularly of the kind that he could carry out himself) and an obsession with working everything out from first principles also developed during his school days. These traits distinguished him all his life. Thus he was elected a fellow of King's College Cambridge for a dissertation on the central limit theorem in probability theory. He had rediscovered this from scratch, being in ignorance of the previous work. His disinclination to build on the work of others sometimes slowed him down, but it preserved his forceful originality.

The contribution to LOGIC for which he is best known is his 1936–1937 paper. He set out to demonstrate rigorously what many already believed—that Hilbert's program, requiring a decision procedure to evaluate the truth or falsehood of any mathematical statement, was a logical impossibility.

Turing's search for a precise definition of "decision procedure" led him to devise and analyze the abstract notion of a computing machine. The invitation to Princeton that followed was prompted by his teacher M. H. A. Newman in a letter to Alonzo Church. With Stephen Kleene, Church had arrived at the same result as Turing by different means (see CHURCH-TURING THESIS). In fact the mathematical functions described in Gödel and Herbrand's system as general-recursive, in Church and Kleene's as lambda-definable, and in Turing's as computable all constitute identically the same class.

Soon after Turing returned to Cambridge from his two years in Princeton, World War II broke out. He wrote two further papers in mathematical logic but was mainly occupied with his work for the Foreign Office in the British cryptographic establishment at Bletchley Park. His major

contribution to the breaking of the Enigma code made it possible routinely to read this German traffic, used widely in submarine warfare. He also made one of the important contributions in the breaking of Fish, the highest-level German cipher, and indirectly to the development for this work of the Colossus high-speed electronic computers (Good 1993).

At the end of the war Turing joined the National Physical Laboratory. In early 1946 he submitted initial design ideas for the NPL's groundbreaking "Automatic Computing Engine" ACE. He spent 1947 on leave of absence at King's College, during which he wrote on semigroups (published in 1950) and on "intelligent machinery" (published posthumously). Earlier in that same year Turing delivered a lecture to the London Mathematical Society. Taking the Pilot ACE as his point of departure, he formulated the main principles and future modes of application of practical embodiments of his Universal Turing Machine. These included their use to simulate human cognition. On the latter, his proposals were:

1. Programming can be done in symbolic logic and will then require the construction of appropriate interpreter/translator programs.
2. MACHINE LEARNING is needed so that computers can discover new knowledge inductively from experience as well as deductively.
3. Humanized interfaces are required to enable machines to adapt to people, so as to acquire knowledge tutorially.

These three points have been substantiated during the intervening fifty years. Their integration finds its most explicit expression in modern INDUCTIVE LOGIC PROGRAMMING, particularly in its applications to computer-assisted discovery of new CONCEPTS in the applied sciences.

Turing reinforced his second point in the final and rarely cited section of his *Mind* paper (1950) with calculations demonstrating the infeasibility of alternative means of equipping machines with the requisite knowledge. At least two attempts in the 1980s at general intelligent systems paid a price for neglecting his arguments, notably the CYC project of the MCC Corporation and the Fifth Generation project of the MITI department of the Japanese government (see Michie 1994). Both projects used explicit programming as their only KNOWLEDGE ACQUISITION tool.

Turing's celebrated 1950 paper in *Mind* described what became known as the "Turing test." Through a postulated imitation game, the intelligence of a machine is tested via its ability to sustain humanlike discourse. Several simple computer programs have since been able to deceive human observers into believing that a person and not a machine is "conversing" with them. This has accordingly led some to dismiss the Turing test as invalid. Closer reading of the paper shows that Turing was concerned with a machine's ability to *answer* questions, not to deflect them with counterquestions, as is done by the above-mentioned programs.

In the postwar period Turing also engaged in experimentation with CHESS mechanization. In the early 1950s he turned his attention to the mathematical description of the biological phenomenon of morphogenesis. He was still working in this area in 1954, when he died just eleven days short of his forty-second birthday.

Turing's Thesis

See CHURCH-TURING THESIS

Tversky, Amos

Amos Tversky (1937–1996) was a cognitive and mathematical psychologist who was passionately committed to advancing knowledge of human judgment and DECISION MAKING, and the similarities between them. Tversky's contributions to these subjects, put forward with a research style that combined rigorous mathematical analysis with elegant empirical demonstrations and simple examples of irresistible force and clarity, had a profound influence on scholars in numerous disciplines. Indeed, one measure of Tversky's impact is how much his ideas have generated excitement and altered curricula in such varied fields as psychology, economics, law, medicine, political science, philosophy, and statistics.

Much of Tversky's research demonstrated that the thought processes governing people's judgments and choices are not as thorough or rigorous as people would like to believe, or that certain formal theories would have them believe. With his frequent collaborator Daniel Kahneman, Tversky identified a number of JUDGMENT HEURISTICS, or "rules of thumb," that people use to guide their judgments in numerous domains. Each heuristic consists of some "natural assessment," such as similarity, ease of retrieval from memory, or CAUSAL REASONING, that is coopted to tackle a difficult judgmental problem that people lack the cognitive mechanisms to solve readily with precision. Tversky and Kahneman likened heuristics to perceptual cues used to apprehend the world: both generally serve the individual well, but both can give rise to systematic error. The clarity of an object, for example, is one cue to its distance. The cue is generally helpful, because the closer something is, the more distinct it appears. On a hazy day, however, objects seem further away than they really are. Thus, the source of general accuracy, clarity, is also the very cause of predictable error.

Tversky and Kahneman identified several heuristics, such as availability, representativeness, and anchoring-and-adjustment. Most of their research, however, has focused on the first two. People employ the availability heuristic when they judge the size of a category or the probability of an event by the ease with which relevant instances can be brought to mind. The heuristic often yields accurate judgments: all else being equal, it is easier to think of examples from large categories than small ones. But extraneous factors can make examples from certain categories disproportionately easy (or difficult) to recall and thus render ease of generation misleading. Most people, for example, mistakenly assume that there are more English words that begin with "r" than words that have "r" in the third position. Availability is a poor guide in this context because it is so much easier to "find" words that begin with a particular letter than it is to find those that have the target letter anywhere else. The availability heuristic has been tied to people's distorted estimates of the likelihood of various health risks, and to the fact that collaborators often claim more credit for the success of a joint venture than there is credit to go around.

The representativeness heuristic consists of reducing complex judgments to relatively simple similarity assessments. It reflects people's unstated assumptions that outcomes typically resemble the processes that generated them, effects typically resemble their causes, and category members typically resemble their category prototypes. There is doubtless some truth to these assumptions (and hence some legitimacy to the use of representativeness), but just how much is impossible to say. What *is* clear is that these assumptions do not always hold, and where they break down can be found some telling judgmental errors. Tversky and Kahneman have shown, for example, that the representativeness heuristic plays a role in the "gambler's fallacy," in people's insensitivity to regression to the mean, in a misplaced faith in results based on small samples, and in the underutilization of "base rate" information or the prior probability of events.

The main thrust of Tversky and Kahneman's work on judgment—that people have cognitive capacity limitations and so must simplify some of the complex problems they confront—is fundamentally inconsistent with at least one widely touted model of human behavior, namely, the rational actor of economic theory. Economists contend that people are highly rational utility maximizers who compute any action's likely effect on their total wealth, and choose accordingly (see ECONOMICS AND COGNITIVE SCIENCE).

Tversky and Kahneman argued that people's choices—economic or otherwise—are often a good deal simpler. People typically do not monitor a prospect's likely effect on their final asset position. Rather, they pay attention to whether a given course of action might result in a gain or loss from the status quo (or some other salient reference point), and they are highly sensitive to how choices are presented or "framed." Tversky and Kahneman provided an account of these and other deviations from the standard normative model of expected UTILITY THEORY in a descriptive theory of decision making known as prospect theory.

Prospect theory captures several important elements of how people make decisions. One is the asymmetry between gains and losses. A loss of a given size generates more pain than an equally large gain yields pleasure. This asymmetry is what underlies many of the most powerful framing effects. Courses of action can sometimes be described either in the language of gains or losses, thereby invoking very different processes and producing markedly different decisions. For example, consumers are less likely to use credit

cards if the difference between the cash and credit price is described as a "credit card surcharge" (a loss) rather than a "cash discount" (a foregone gain).

Prospect theory and the work it has inspired has driven a wedge between prescriptive and descriptive theories of choice. No single theory can be both prescriptively valid and descriptively accurate because the axioms of rational choice are normatively beyond dispute (see RATIONAL CHOICE THEORY), and yet the violations of these axioms are too reliable to be dismissed.

Among the topics that occupied Tversky's attention during the last years of his life was "support theory," a model of subjective probability based on the insight that people's probability judgments derive from descriptions of events, not from the events themselves. Support theory sheds light on a number of important phenomena, such as *subadditivity,* or the fact that the judged probability of an event increases when it is described in terms of its constituent elements. People judge it more likely, for example, that someone would die of "heart disease, cancer, or some other natural cause" than simply of "natural causes."

Nearly all of Tversky's research touched on the enduring question of the relative contribution of the heart and the mind to human irrationality. Cognitive scientists tend to approach this issue by emphasizing the mind and trying to determine how much of the fallibility of human reason can be explained in purely cognitive terms. Although Tversky would hardly deny that people's wants and passions often get the better of them (indeed, he did influential research on that topic too), much of his work demonstrates that many of our most egregious, most interesting, and most predictable mistakes are indeed entirely cognitive. His research makes it clear that many of our erroneous judgments and problematic decisions are the product, in his words, of "illusions, not delusions."

—Thomas Gilovich

Twin Earth

Twin Earth thought experiments originate with Hilary Putnam 1975. Twin Earth features in the context of arguments about INDIVIDUALISM. Individualism is the thesis that psychological properties are essentially intrinsic, like being made of gold, as opposed to being partly relational, like being a planet. Anti-individualism is the denial of individualism. Examples like the following often motivate anti-individualism. Suppose that in 1750 there was a planet, Twin Earth, exactly like Earth in all respects except that where Earth had H_2O, Twin Earth had a chemically different compound, XYZ. XYZ is like water in macroscopic respects. Nobody on Earth or Twin Earth could have detected the difference between them in 1750. But a modern-day chemist could distinguish them in her laboratory. Now we consider an Earth person, Oscar, and his identical twin on Twin Earth, T-Oscar. Oscar and T-Oscar are molecule-for-molecule replicas, identical in all intrinsic, physical respects. (Pretend that humans are not made out of water). Each twin uses "water" to apply to his local wet substance. And, let us suppose, each twin utters the words "Water is good for plants."

An anti-individualist might argue along the following lines. First, XYZ is not water. Chemistry informs us that water is H_2O, and, by hypothesis, XYZ is not H_2O. Second, Oscar's word "water" refers to water (H_2O) and nothing else: if Oscar had been confronted with a glass of XYZ and said "That's water," he would have been wrong. But T-Oscar's word "water" refers to XYZ and nothing else: if T-Oscar had been confronted with a glass of XYZ and said "That's water," he would have been right, because he would have been speaking Twin English. Third, when each twin utters "Water is good for plants," the utterance expresses the contents of his belief. Both twins understand their words and both speak sincerely, so what they say is precisely what

they believe. But what the twins say is different: Oscar says that water is good for plants, and that is what he believes. What T-Oscar says and believes is something we might put as "T-water is good for plants," where "T-water" is a non-technical word for XYZ.

Anti-individualists take the example to show that the contents of a person's beliefs are partly determined by his physical environment. Indeed, they are partly determined by factors that he does not know about, such as the underlying chemical constitution of water. Variant examples are designed to show that features of the social environment are also relevant. Here is one due to Tyler Burge (1979; adapted). Alf suffers from arthritis. One day, Alf wakes up with a pain in his thigh and comes to believe that his arthritis has spread. "Oh no! My arthritis has spread to my thigh," he mutters. He goes to his doctor who tells him that arthritis is, by definition, inflammation of the joints, and that therefore he cannot have arthritis in his thigh. Alf stands corrected and revises his belief.

We now turn to a new Twin Earth story. Again, Twin Earth is like Earth, barring one difference. Although the medical community on Earth applies "arthritis" only to inflammations of the joints, on Twin Earth they use it more generally, so that it would apply to the condition in Alf's thigh. Now T-Alf, Alf's twin, wakes up and mutters "Oh no! My arthritis has spread to my thigh."

Burge argues that while Alf believes he has arthritis in his thigh, T-Alf does not. T-Alf's word "arthritis" doesn't apply only to inflammations of the joints and hence does not express the concept of arthritis. Burge concludes that the contents of one's concepts are partly determined by the linguistic usage of those members of the community to whom one would (and should) defer. Recall that Alf accepts the doctor's assertion that by definition arthritis is a condition of the joints. It is in part because Alf is thus disposed to be corrected that his concept is a concept of arthritis and hence applies only to inflammations of the joints. T-Alf defers to different experts who use "arthritis" differently, and so has a different concept. This is so in spite of the exact similarity of the twins in all intrinsic respects.

Individualists have objected to the anti-individualist construal of the Twin Earth experiments and put forward counterarguments of their own. Responses to the Twin Earth examples have mainly been of two kinds.

The first kind of response concedes that, in the relevant cases, the twins' CONCEPTS refer to different things. For example Oscar's concept refers to water and T-Oscar's to T-water. But, it is argued, the essential psychological nature of a concept is not always given by what it refers to. Thus it is possible to hold that the twins' concepts are of exactly the same psychological type even though they refer to different things. This response needs to be supported by some method of individuating concepts that will generate the result that the twins' concepts are indeed of the same psychological type. (See Fodor 1987; Searle 1983; Loar 1988 for different attempts to do this.)

The second kind of response utilizes a distinction between commonsense intuition and science. It concedes that people have the intuition that the twins' concepts are different. But it holds that this is merely due to an unscien-

tific conception of psychological states. Thus, while there is an intuition that, for example, Oscar's concept applies to H_2O but not to XYZ, and T-Oscar's to XYZ and not to H_2O, this intuition is wrong. In fact, both Oscars' concepts applied both to H_2O and to XYZ, and were identical even in respect of what they referred to. A scientific psychology, not bound to preserve intuitions, would thus treat the twins as psychologically indistinguishable (Segal 1989, 1991; Crane 1991).

Typology

Typology is the systematic study of the ways in which languages are similar to and differ from one another. More specifically, the study of language universals concerns those properties that are common to all languages (see LINGUISTIC UNIVERSALS), whereas typology is concerned with the systematic variation across languages, although in practice both studies must be carried out simultaneously and are often subsumed under either the term *typology* or the term *language universals research.* As such, the subject matter of the typological approach to language does not differ from that of other approaches, such as GENERATIVE GRAMMAR (as illustrated in Haegeman 1997). Methodologically, however, the two approaches tend to differ in the extent to which each is data driven (typology) versus theory driven (generative grammar), although in recent years the two approaches have tended alternately to approach and recede from one another. Given the rate at which languages are dying out—an estimated 90 percent of the world's languages will be extinct or moribund by the end of the twenty-first century (Hale et al. 1992)—the data-driven typological approach assumes increased importance as much of the very data on which linguistic theorization is based is disappearing before us. Overviews of the field of typology are provided in Comrie (1989), Croft (1990), and Whaley (1997).

The relation between language universals and language typology can be seen in two parameters that are often used to distinguish different kinds of language universals. First, language universals can be absolute, that is, exceptionless, or tendencies, that is, occurring with a frequency that cannot plausibly be attributed to chance or other external factors (such as demographics). An example of an absolute universal is that all languages have consonants. (Examples will necessarily be somewhat banal, to avoid having to go into too much detail.) An example of a universal tendency is that nearly all languages have nasal consonants, although a few—3.2 percent of the languages in the sample used by Maddieson (1984: 60)—do not. In practice, it is often impossible to tell whether a universal is an absolute or rather a very strong tendency to which exceptions happen not to have been found. A second distinction is that between implicational and nonimplicational universals. The two universals previously cited are nonimplicational, inasmuch as each refers to only one linguistic property without relating it to other properties. An implicational universal, by contrast, has the structure "if *p,* then *q,*" where *p* and *q* are two linguistic properties. An example of an absolute implicational universal is: If a language has distinct reflexive pronouns in the non-third person, then it also has distinct reflexive pronouns in the third person. "If *p,* then *q*" is to be interpreted strictly as material implication, that is, three possibilities are allowed: "*p & q,*" "*~p & ~q,*" "*~p & q,*" while one is disallowed: *"p & ~q."* Thus, in the example cited, there are languages like English with distinct reflexive pronouns in the non-third person (e.g., *me* versus *myself*) and in the third person (e.g., *him* versus *himself*), languages with no reflexive pronouns at all (e.g., Old English *me* "me, myself," *hine* "him, himself"), languages with reflexive pronouns only in the third person (e.g., French *me* "me, myself," but *le* "him," *se* "himself"), but no languages with distinct reflexives only in the non-third person. An example of an implicational tendency is that languages with verb-initial word order in the clause nearly always have prepositions ("if verb-initial, then prepositional"), although a handful of verb-initial languages have postpositions, such as Yagua, spoken in Peruvian Amazonia. Implicational universals provide a typology of languages by dividing languages into the three types allowed by the universal, plus, in the case of an implicational tendency, the rare fourth type.

Although typology has a history going back to the eighteenth century (Greenberg 1974), a major impetus to the modern study of typology was the volume Greenberg (1966b), in particular Greenberg's own contribution to that volume (Greenberg 1966a). In the early work inspired by Greenberg's model, the emphasis was primarily and explicitly on the empirical side of typological work, attempting to find out what nonimplicational universals could plausibly be put forward, and to find out what correlations among different linguistic features might plausibly serve as the basis of implicational universals. More recently—for a survey of recent approaches to typology and universals, Shibatani and Bynon (1995) may be consulted—the importance of explaining language universals has come increasingly to the fore (e.g., Butterworth, Comrie, and Dahl 1984; Hawkins 1988). A number of different kinds of explanations have been proposed.

As suggested also by generative grammar, some universals probably reflect innate properties of the human cognitive apparatus. For instance, it has been observed that syntactic properties are, with only a few exceptions that can probably be accounted for in other ways, "structure-dependent" (see SYNTAX). By this is meant that they require identification of elements of syntactic structure for their operation. In English, for instance, questions can be formed from corresponding statements by inverting the order of subject and auxiliary verb, as with *can the new professor speak Polish?* in relation to *the new professor can speak Polish.* A priori, a much simpler rule would be to invert the first two words of the sentence, or to put the words of the sentence in the inverse order, yet human languages invariably or almost invariably go for structure-dependent rules like the English rule just discussed, which involve sophisticated parsing of syntactic structure. Given that there is no aprioristic reason for this preference, it almost certainly reflects an innate constraint. (This leaves open, incidentally, whether the constraint relates specifically to the language faculty or whether it is a more general cognitive constraint. At least in this case, the linguistic constraint is probably a special case of the general pattern-seeking preference of human cognition, for which arbitrary strings are difficult to handle, while imposition of structure facilitates processing, as seen trivially in the breakdown of seven-digit telephone numbers into groups of three plus four.)

Processing considerations seem to be a major factor constraining cross-linguistic variation. An example from the early generative literature is the difficulty of processing self-embedded constructions, for instance where a relative clause is included internally within another relative clause, as in *the boy [that the man [that I saw] caught] took the apple,* although a slight change of construction to avoid the self-embedding produces a readily interpretable sentence: *the apple was taken by the boy [that was caught by the man [that was seen by me]].* A detailed theory relating word order universals (both absolute and tendencies) to processing constraints is developed by Hawkins (1994).

This leads into the area of functional motivations for language universals, including not only the needs of processing but also other considerations from SEMANTICS and PRAGMATICS. For instance, the universal stated above that "if a language has distinct reflexive pronouns in the non-third person, then it also has distinct reflexive pronouns in the third person" does not have any obvious formal explanation; this universal is no simpler in formal terms than its empirically incorrect opposite "if a language has distinct reflexive pronouns in the third person, then it also has distinct reflexive pronouns in the non-third person." But as soon as one starts thinking about the semantic function of pronouns, a plausible explanation emerges. First- and second-person pronouns are uniquely determined by the speech situation, with the speaker referred to in the first person and the hearer in the second person. They thus do not change within an utterance, and whether a language says *I hit myself* or *I hit me* does not affect the content, that is, marking reflexivity is in a sense redundant in the first and second persons. Third person pronouns can potentially refer to any other entity in the universe of DISCOURSE, so it is useful to have different forms that enable distinctions among potential referents to be maintained, as in the case of *he$_i$ hit himself$_i$* versus *he$_i$ hit him$_j$*. Quite generally, as predicted, pronoun systems tend to make more referential distinctions in the third person than in the other persons, as when English distinguishes gender in the third person singular *(he, she, it)* but not in the first person *(I)* or the second person *(you)*. Comrie (1984) shows how certain language universals can plausibly be related to pragmatics, for instance universals of imperative formation to the pragmatic function of imperatives in encoding the speech act of directive (Searle 1969): because directives require that the addressee carry out a certain action, many languages have a constraint that only imperatives with the addressee as agent are possible, that is, they allow the equivalent of *eat the bread!* but not of *be eaten by the lion!;* no language shows the inverse pattern.

Uncertainty

Almost all information is subject to uncertainty. Uncertainty may arise from inaccurate or incomplete information (e.g.,

how large are the current U.S. petroleum reserves?), from linguistic imprecision (what exactly do we mean by "petroleum reserves"?), and from disagreement between information sources. We may even be uncertain about our degree of uncertainty. The representation of uncertainty is intrinsic to the representation of information, which is its dual.

Many schemes have been developed to formalize the notion of uncertainty and to mechanize reasoning under uncertainty within KNOWLEDGE-BASED SYSTEMS. Probability is, by far, the best-known and most widely used formalism. However, apparent limitations and difficulties in applying probability have spawned the development of a rich variety of alternatives. These include heuristic approximations to probability used in rule-based expert systems, such as certainty factors (Clancy and Shortliffe 1984); fuzzy set theory and FUZZY LOGIC (Zadeh 1984); interval representations, such as upper probabilities and Dempster-Shafer belief functions (Shafer 1976); NONMONOTONIC LOGICS and default reasoning (Ginsberg 1987); and qualitative versions of probability, such as the Spohn calculus and kappa-calculus. There has been controversy about the assumptions, appropriateness, and practicality of these various schemes, particularly about their use in representing and reasoning about uncertainty in databases and knowledge-based systems. It is useful to consider a variety of criteria, both theoretical and pragmatic, in comparing these schemes.

The first criterion concerns epistemology: What kinds of uncertainty does each scheme represent? Like most quantitative representations of uncertainty, probability expresses degree of belief that a proposition is true, or that an event will happen, by a cardinal number, between 0 and 1. Fuzzy set theory and fuzzy logic also represent degrees of belief or truth by a number between 0 and 1. Upper probabilities and Dempster-Shafer belief functions represent degrees of belief by a range of numbers between 0 and 1, allowing the expression of ambiguity or ignorance as the extent of the range. Qualitative representations of belief, such as nonmonotonic logic (Ginsberg 1987) and the kappa-calculus, often represent degrees of belief on an ordinal scale.

In the frequentist view, the probability of an event is the frequency of the event occurring in a large number of similar trials. For example, the probability of heads for a bent coin is the frequency of heads from a large number of tosses of that coin. Unfortunately, for most events, it is unclear what population of similar trials one should use. When estimating the probability that a chemical is carcinogenic, should you compare it with all known chemicals, only those tested for carcinogenicity, or only those chemicals with a similar molecular structure? Therefore, in practical reasoning, the personalist (also known as Bayesian or subjective) interpretation is often more useful: In this interpretation, the probability of an event is a person's degree of belief, given all the information currently known to that person. Different people may reasonably hold different probabilities, depending on what information they have.

It is important to be able to represent uncertain relationships between propositions as well as degrees of belief. A conditional probability distribution for proposition a given b, P($a \mid b$), expresses the belief in a given the state of b. Belief networks, also known as BAYESIAN NETWORKS (Pearl 1988), provide an intuitive graphical way to represent qualitative uncertain knowledge about conditional dependence, and independence, among propositions.

A common source of uncertainty is linguistic imprecision. We find it useful to say that a river is "wide," without explaining exactly what we mean. Even from the personalist view, an event or quantity must be well specified for a meaningful probability distribution to be assessable. It is therefore important to eliminate linguistic imprecision, by developing unambiguous definitions of quantities, as a first step to encoding uncertain knowledge as probabilities. Instead of asking for the probability that a river is "wide," one might ask for the probability that it is wider than, say, 50 meters. Without such precision, vagueness about meaning is confounded with uncertainty about value.

Fuzzy set theorists argue that, because imprecision is intrinsic in human language, we should represent this imprecision explicitly in any formalism. For example, the linguistic variable "wide river" may be represented by a fuzzy set with a membership function that associates degrees of membership with different widths. A river 5 meters wide has membership 0 in "wide river;" a river 100 meters wide has membership 1; and intermediate widths have intermediate degrees of membership.

A second criterion for comparison of schemes is descriptive validity: Does the scheme provide a good model of human reasoning under uncertainty? There has been extensive experimental research by behavioral decision theorists on human judgment under uncertainty, which documents systematic divergences between human judgment and the norms of probabilistic inference (Kahneman, Slovic, and Tversky 1982; see PROBABILISTIC REASONING, TVERSKY, and JUDGMENT HEURISTICS). People use mental heuristics that often provide a qualitative approximation to probabilistic reasoning, such as in explaining away (Wellman and Henrion 1993). But they also exhibit systematic biases. There has been little experimental research on the descriptive validity of nonprobabilistic schemes, although there is little reason to expect that any simple mathematical scheme will fare well as a descriptive model.

Poor descriptive validity is a deficiency in a psychological theory, but not necessarily in a scheme for automated reasoning. Indeed, if the automated scheme exactly duplicated human commonsense reasoning, there would be less justification for the automated systems. If we believe that the formal scheme is based on axioms of rationality, as is claimed for probabilistic reasoning, it may be preferable to our flawed human reasoning for complicated problems in defined domains. That is why we rely on statistical analysis rather than informal reasoning in science.

A third criterion is ease of knowledge engineering: Is it practical to express human knowledge in this formalism? Knowledge engineers use a variety of tools for eliciting numerical probabilities (Morgan and Henrion 1990) and structuring complex uncertain beliefs using *belief networks* (Pearl 1988) and influence diagrams (Howard and Matheson 1984). Fuzzy logic provides a variety of ways of eliciting fuzzy variables. Nonmonotonic logical and other

qualitative representations appear easy for people to express uncertain knowledge, although there have been few practical large-scale systems.

A fourth criterion is ease of data mining: Is it practical to extract and represent knowledge from data using this scheme? Increasingly, knowledge-based systems are supplementing or replacing knowledge encoded from human experts with knowledge extracted by experts from large databases using a wide variety of statistical techniques. The probabilistic basis of statistics, and Bayesian techniques for combining judgmental and data-based knowledge, give probabilistic techniques a major advantage on this criterion.

A fifth criterion concerns the tractability of computation with large knowledge bases: Modular rule-based schemes, such as certainty factors and fuzzy logic rules, are efficient, with linear computation time. Exact probabilistic inference in belief networks is NP hard; that is, potentially intractable for very large belief networks. However, effective approximate methods exist, and probabilistic inference is practical for many real knowledge bases. Higher-order representations, such as Dempster-Shafer and interval probabilities, are intrinsically more complex computationally than conventional probabilistic representations.

A sixth criterion is the relation of the scheme to making decisions. In practice, uncertain inference becomes valuable primarily when it is used as the basis for important decisions. Subjective probability is embedded in decision theory and UTILITY THEORY, developed by VON NEUMANN and Morgenstern to provide a theory for RATIONAL DECISION MAKING. Utility theory provides a way to express attitudes to risk, especially risk aversion. There have been several attempts to develop fuzzy utilities, however decision theories for nonprobabilistic representations are less developed, and this is an important area for research.

Humans or machines can rarely be certain about anything, and so practical reasoning requires some scheme for representing uncertainty. We have a rich array of formalisms. Recent developments on knowledge engineering, and inference methods for probabilistic methods, notably Bayesian belief networks and influence diagrams, have resolved many of the apparent difficulties with probability, and have led to a resurgence of research on probabilistic methods, with many real world applications (Henrion, Breese, and Horvitz 1991). Fuzzy logic has also had notable success in applications to approximate control systems. However, each method has its merits and may be suitable for particular applications.

Unity of Science

The view that scientific knowledge should be integrated has a long history, with roots in Aristotle and the French Encyclopedists. Perhaps as a consequence of the ever increasing specialization in science, scientists have found it important to work in an interdisciplinary manner where they can draw upon the research skills and knowledge bases of scientists trained in other disciplines. Thus, attempts at integration at the level of individual laboratories, and at higher levels such as that of professional societies, have become relatively commonplace in modern science. Cognitive science itself represents one such integratory effort that began with collaborative conferences (the MIT Symposia on Information Theory in the 1950s) and collaborative research groups (the Center for Cognitive Studies at Harvard in the 1960s), and became institutionalized with funding by the Sloan Foundation in the 1970s and 1980s) and the founding of the Cognitive Science Society in 1978 (Bechtel, Abrahamsen, and Graham 1998).

The modern interest in unity of science stems largely from the work in the 1930s and 1940s of logical positivists of the Vienna Circle, especially the logician-philosopher Rudolf Carnap and the sociologist Otto Neurath. (Today the logical positivists have acquired the image of conservatives, but politically they were liberals and social democrats, and scientifically they advocated a pluralist and Enlightenment conception of science.) One of the driving concerns of Carnap and Neurath was epistemic. The nineteenth century witnessed the birth of many new scientific disciplines, especially in the life sciences and social sciences: cytology, physiological chemistry, psychology, anthropology, and so forth. These various disciplines employed different vocabularies and different methods of investigation, raising the question of whether they were generating real knowledge. One way Carnap and Neurath proposed to evaluate the epistemic status of those inquiries was in terms of their unity with other scientific pursuits, especially physics, which, despite the major controversies occurring within it in the wake of Einstein, was taken as a paragon of a scientific discipline. (One prominent forum for the positivists' proposals was the *Encyclopedia of Unified Science,* which Carnap and Neurath, in collaboration with the American pragmatist Charles Morris, began to edit in 1938.)

The tool for unifying other disciplines with physics was reduction of two different sorts. The first was reduction of theoretical claims of each science to a base class of sentences whose truth value could be directly determined through observation (Carnap 1928). Thus, all legitimate disciplines would be seen to have a similar base in that their theoretical claims were reducible, through logical analysis, to observations. Carnap initially proposed that the observational basis for all sciences lay in phenomenal reports, but eventually he followed Neurath in requiring only a reduction to observational reports of physical states (Carnap 1934). Such a reduction would show that all science relied on similar empirical foundations and tools of logic for securing their theoretical claims. The proponents of this approach never succeeded in developing an adequate logical analysis to ground theoretical claims in observation. The call for such reductions, however, had a significant influence in furthering the behaviorist movement in psychology, because it claimed to rely only on observations of behavior and laws relating such behaviors to stimuli or reinforcements.

The other sort of reduction Carnap and Neurath advanced was theory reduction, wherein theories of a higher-level science would be reduced to those of more basic sciences. (The best source for this view of reduction is Nagel 1961.) Such a reduction required both translation laws that connected the vocabulary of the higher-level science with that used in the more basic science (higher-level entities might, for example, be characterized in terms of their composition from lower-level entities) and derivations of the laws of the higher-level science from those of the more basic science under specified boundary conditions. It is important to note that success in developing such reductions was viewed not as eliminating the reduced theory but as providing epistemic support for it; thus, a reduction of PSYCHOLOGICAL LAWS to those of neuroscience in this view would provide support for the psychological laws. The theory reduction model has been seriously promoted as a framework for unifying psychology and neuroscience by such theorists as Patricia Churchland (1986); unlike the positivists, though, she focuses on the process of theory development, and proposes a coevolutionary research program in which both neuroscience and psychology will evolve until they are unified by a reduction (McCauley 1996). However, as with the attempt to reduce theoretical claims to observation claims, the attempt to reduce higher-level theories to lower-level ones has encountered serious objections. For further discussion, see REDUCTIONISM and Bechtel (1987).

A variation on the reductionist framework for unifying science that rejects the attempt to ground all theories in physics has emerged several times in the development of the study of cognition. This approach tries to show that a common theoretical framework applies at a number of levels of organization in nature, with the unification provided by this theoretical framework. Cybernetics (a theoretical framework emphasizing the role of feedback in maintaining stable states in complex systems; WIENER 1948) and General Systems Theory (von Bertalanffy 1951) both offered general frameworks that were intended to apply to biological and cognitive systems at a variety of different levels. One reason neither program endured was that at the time it was difficult to develop successful detailed empirical hypotheses about cognition within these frameworks; as a result, in the 1960s and 1970s most inquiries into cognition assumed some form of autonomy of the cognitive system from both the underlying neural structures and its situated context in the world. Today advocates of dynamical systems theory, though, have revitalized unificationist aspirations by offering the mathematical and geometrical models of dynamical systems as unifying frameworks (for applications to cognitive science, see Port and van Gelder 1995).

Another model of unification, developed by Lindley Darden and Nancy Maull (1987), rejects the insistence on a common theoretical framework. Darden and Maull propose instead that interfield theories, which establish connections between phenomena that have been studied in two or more fields of inquiry without making any one of them more basic, constitute the vehicle of unification. Such linkages constitute a discovery heuristic in that what is known about one set of phenomena can then suggest hypotheses about the other set of phenomena (Wimsatt 1976). The fruitfulness of such interfield theorizing can be seen within cognitive science. For example, Chomsky's initial proposals for transformational grammars in linguistics were intended to provide a finite characterization of the grammatically well-formed sentences in a language, not as models of language processing. But George Miller and other early cognitive psychologists attempted to employ them as process models in linguistics and to predict reaction times for processing sentences based on the number of transformations required to generate the sentence in Chomsky's grammar. This effort to forge an interfield connection, though initially promising, died when Chomsky revised his linguistic analysis in ways that no longer could account for such data (Reber 1987). Other attempts to develop interfield connections from linguistics to psychology have proven more successful (Abrahamsen 1987) and current efforts of cognitive grammarians to ground grammatical structures on general cognitive abilities (Langacker 1987) represent the attempt to develop connections in the opposite direction. Moreover, links between linguistics and neuropsychology prompted fruitful rethinking of the classical analysis of APHASIA as analyses in terms of syntax and semantics replaced those based on comprehension and production (Bradley, Garrett, and Zurif 1980).

So far discussion has focused on unification via theories, a natural consequence of the focus on theories in twentieth century philosophy of science. But increasingly theorists are recognizing other forms of unification in science, ones where research techniques and tools become the vehicle of integration. The development of cognitive neuroscience has been fostered in part by the integration of behavioral measures of cognitive psychology (e.g., reaction time studies and error analysis) with tools for studying brain activity (e.g., SINGLE-NEURON RECORDING and evoked potentials). In this light, the recent development of neuroimaging tools (POSITRON EMISSION TOMOGRAPHY and function MAGNETIC RESONANCE IMAGING) is particularly interesting. The resulting images, which indirectly measure neural activity, are interpreted functionally by applying the subtraction method developed by the nineteenth century Dutch psychologist Frans Cornelis Donders, so that images of the brain active in one task are subtracted from those of the brain active in another task, with the intent of revealing the brain structures responsible for the additional component of processing required in the second task (Posner and Raichle 1994).

Although the dreams of unity of science via reduction advanced by the positivists have generally not panned out, unification and integration, viewed in a more patchwork manner, are a routine part of modern science. Scientists regularly rely on phenomena studied in other disciplines to constrain their own studies or explain what seems inexplica-

ble in their field alone. Tools and techniques are widely shared between related disciplines. The resulting picture is a network of local integration, not one of global unification.

Unsupervised Learning

Unsupervised learning studies how systems can learn to represent particular input patterns in a way that reflects the statistical structure of the overall collection of input patterns. By contrast with SUPERVISED LEARNING or REINFORCEMENT

LEARNING, there are no explicit target outputs or environmental evaluations associated with each input; rather, the unsupervised learner brings to bear prior biases as to what aspects of the structure of the input should be captured in the output.

Unsupervised learning is important because it is likely to be much more common in the brain than supervised learning. For instance there are around 10^8 photoreceptors in each eye whose activities are constantly changing with the visual world and which provide all the information that is available to indicate what objects there are in the world, how they are presented, what the lighting conditions are, and so forth. Developmental and adult plasticity are critical in animal vision (see VISION AND LEARNING)—indeed, structural and physiological properties of synapses in the neocortex are known to be substantially influenced by the patterns of activity in sensory neurons that occur. However, essentially none of the information about the contents of scenes is available during learning. This makes unsupervised methods essential, and, equally, allows them to be used as computational models for synaptic adaptation.

The only things that unsupervised learning methods have to work with are the observed input patterns $\mathbf{x}$ which are often assumed to be independent samples from an underlying unknown probability distribution $P_I[\mathbf{x}]$, and some explicit or implicit a priori information as to what is important. One key notion is that input, such as the image of a scene, has distal independent *causes,* such as objects at given locations illuminated by particular lighting. Because it is on those independent causes that we normally must act, the best representation for an input is in their terms. Two classes of method have been suggested for unsupervised learning. Density estimation techniques explicitly build statistical models (such as BAYESIAN NETWORKS) of how underlying causes could create the input. Feature extraction techniques try to extract statistical regularities (or sometimes irregularities) directly from the inputs.

Unsupervised learning in general has a long and distinguished history. Some early influences were Horace Barlow (see Barlow 1989), who sought ways of characterizing neural codes; Donald MacKay (1956), who adopted a cybernetic-theoretic approach; and David MARR (1970), who made an early unsupervised learning postulate about the goal of learning in his model of the neocortex. The Hebb rule (HEBB 1949), which links statistical methods to neurophysiological experiments on plasticity, has also cast a long shadow. Geoffrey Hinton and Terrence Sejnowski, in inventing a model of learning called the Boltzmann machine (1986), imported many of the concepts from statistics that now dominate the density estimation methods (Grenander 1976–1981). Feature extraction methods have generally been less extensively explored.

Clustering provides a convenient example. Consider the case in which the inputs are the photoreceptor activities created by various images of an apple or an orange. In the space of all possible activities, these particular inputs form two clusters, with many fewer degrees of variation than 10^8, that is, lower *dimension.* One natural task for unsupervised learning is to find and characterize these separate, low dimensional clusters.

The larger class of unsupervised learning methods consists of maximum likelihood (ML) density estimation methods. All of these are based on building parameterized *models* $P[\mathbf{x};G]$ (with parameters G) of the probability distribution $P_I[\mathbf{x}]$, where the forms of the models (and possibly prior distributions over the parameters G) are constrained by a priori information in the form of the representational goals. These are called *synthetic* or *generative* models, because, given a particular value of G, they specify how to synthesize or generate samples $\mathbf{x}$ from $P[\mathbf{x};G]$, whose statistics should match $P_I[\mathbf{x}]$. A typical model has the structure:

$$P[\mathbf{x};G] = \sum_{\mathbf{y}} P[\mathbf{y};G]P[\mathbf{x}|\mathbf{y};G]$$

where $\mathbf{y}$ represents all the potential causes of the input $\mathbf{x}$. The typical measure of the degree of mismatch is called the Kullback-Leibler divergence:

$$KL[P_I[\mathbf{x}], P[\mathbf{x};G]] = \sum_{\mathbf{x}} P_I[\mathbf{x}]\log\left[\frac{P_I\mathbf{x}}{P\mathbf{x};G}\right] \geq 0$$

with equality if and only if $P_I[\mathbf{x}] = P[\mathbf{x}; G]$.

Given an input pattern $\mathbf{x}$, the most general output of this model is the posterior, *analytical,* or *recognition* distribution $P[\mathbf{y} \mid \mathbf{x};G]$, which recognizes which particular causes might underlie $\mathbf{x}$. This analytical distribution is the statistical inverse of the synthetic distribution.

A very simple model can be used in the example of clustering (Nowlan 1990). Consider the case in which there are two values for y (1 and 2), with $P[y=1] = \pi$; $P[y=2] = 1 - \pi$, where π is called a mixing proportion, and two different Gaussian distributions for the activities $\mathbf{x}$ of the photoreceptors depending on which y is chosen: $P[\mathbf{x} \mid y=1] \sim N[\mu_1, \Sigma_1]$ and $P[\mathbf{x} \mid y=2] \sim N[\mu_2, \Sigma_2]$ where μ are means and Σ are covariance matrices. Unsupervised learning of the means determines the locations of centers of the clusters, and of the mixing proportions and the covariances characterizes the size and (rather coarsely) the shape of the clusters. The posterior distribution $P[y=1|\mathbf{x}; \pi, \mu, \Sigma]$ reports how likely it is that a new image $\mathbf{x}$ was generated from the first cluster, that is, that $y=1$ is the true hidden cause. Clustering can occur (with or) without any supervision information about the different classes. This model is called a *mixture of Gaussians.*

Maximum likelihood density estimation, and approximations to it, cover a very wide spectrum of the principles that have been suggested for unsupervised learning. This includes versions of the notion that the outputs should convey most of the information in the input; that they should be able to reconstruct the inputs well, perhaps subject to constraints such as being independent or sparse; and that they should report on the underlying causes of the input. Many different mechanisms apart from clustering have been suggested for each of these, including forms of Hebbian learning, the Boltzmann and Helmholtz machines, sparse coding, various other mixture models, and independent components analysis.

Density estimation is just a heuristic for learning good representations. It can be too stringent—making it neces-

sary to build a model of all the irrelevant richness in sensory input. It can also be too lax—a look-up table that reported $P_I[\mathbf{x}]$ for each $\mathbf{x}$ might be an excellent way of modeling the distribution, but provides no way to represent particular examples $\mathbf{x}$.

The smaller class of unsupervised learning methods seeks to discover how to represent the inputs $\mathbf{x}$ by defining some quality that good features have, and then searching for those features in the inputs. For instance, consider the case that the output $y(\mathbf{x}) = \mathbf{w} \cdot \mathbf{x}$ is a linear projection of the input onto a weight vector $\mathbf{w}$. The central limit theorem implies that most such linear projections will have Gaussian statistics. Therefore if one can find weights $\mathbf{w}$ such that the projection has a highly non-Gaussian (for instance, multimodal) distribution, then the output is likely to reflect some interesting aspect of the input. This is the intuition behind a statistical method called projection pursuit. It has been shown that projection pursuit can be implemented using a modified form of Hebbian learning (Intrator and Cooper 1992). Arranging that different outputs should represent different aspects of the input turns out to be surprisingly tricky.

Projection pursuit can also execute a form of clustering in the example. Consider projecting the photoreceptor activities onto the line joining the centers of the clusters. The distribution of all activities will be bimodal—one mode for each cluster—and therefore highly non-Gaussian. Note that this single projection does not itself characterize well the nature or shape of the clusters.

Another example of a heuristic underlying good features is that causes are often somewhat global. For instance, consider the visual input from an object observed in depth. Different parts of the object may share few features, except that they are at the same depth, that is, one aspect of the disparity in the information from the two eyes at the separate locations is similar. This is the global underlying feature. By maximizing the mutual information between different outputs that are calculated on the basis of the separate input, one can find this disparity. This technique was invented by Becker and Hinton (1992) and is called IMAX.

Utility Theory

The branch of decision theory concerned with measurement and representation of preferences is called utility theory. Utility theorists focus on accounts of preferences in RATIONAL DECISION MAKING, where an individual's preferences cohere with associated beliefs and actions. *Utility* refers to the scale on which preference is measured.

Identification of preference measurement as an issue is usually credited to Daniel Bernoulli (1954/1738), who exhibited a prospect (probability distribution over outcomes) that had infinite expected monetary value, but apparently not infinite utility. Bernoulli resolved the "St. Petersburg paradox" by suggesting that utility be logarithmic in monetary amounts, which in this case would yield a finite expected utility.

That utility could apply to all sorts of outcomes, not merely monetary rewards, was first argued forcefully by Jeremy Bentham (1823/1789), who proposed a system for tabulating "pleasures" and "pains" (positive and negative utility factors), which he called the "hedonic calculus" (regrettably, as critics henceforth have confounded the idea of universal preference measurement with hedonism). Bentham further argued that these values could be aggregated across society ("greatest good for the greatest number"), which became the core of an ethical doctrine known as utilitarianism (Albee 1901).

Although modern economists are quite reluctant to aggregate preferences across individuals, the concept of individual utility plays a foundational role in the standard

neoclassical theory. Recognition of this role was the result of the so-called marginal utility revolution of the 1870s, in which Carl Menger, W. Stanley Jevons, Francis Ysidro Edgeworth, Léon Walras, and other leading "marginalists" demonstrated that values/prices could be founded on utility.

The standard theory of utility starts with a preference order, $\lesssim$, typically taken to be a complete preorder over the outcome space, ϑ. $y \lesssim x$ means that x is (weakly) preferred to y, and if in addition $\neg (x \lesssim y)$, x is strictly preferred. Granting certain topological assumptions, the preference order can be represented by a real-valued utility function, U: $\vartheta \to R$, in the sense that $U(y) \leq U(x)$ if and only if $y \lesssim x$. If U represents $\lesssim$, then so does $\varphi \circ U$, for any monotone function φ on the real numbers. Thus, utility is an ordinal scale (Krantz et al. 1971).

Under UNCERTAINTY, the relevant preference comparison is over prospects rather than outcomes. One can extend the utility-function representation to prospects by taking expectations with respect to the utility for constituent outcomes. Write $[F,p; F']$ to denote the prospect formed by combining prospects F and F' with probabilities p and $1 - p$, respectively. If $F(\omega)$ denotes the probability of outcome ω in prospect F, then

$$[F, p; F'](\omega) \equiv pF(\omega) + (1 - p)F'(\omega).$$

The *independence axiom* of utility theory states that if $F' \lesssim F''$, then for any prospect F and probability p,

$$[F', p; F] \lesssim [F'', p; F].$$

In other words, preference is decomposable according to the prospect's exclusive possibilities.

Given the properties of an order relation, the independence axiom, and an innocuous continuity condition, preference for a prospect can be reduced to the *expected* value of the outcomes in its probability distribution. The expected utility $\hat{U}$ of a prospect F is defined by

$$\hat{U}(F) \equiv E_F[U] = \sum_{\omega \in \vartheta} U(\omega)F(\omega)$$

For the continuous case, replace the sum by an appropriate integral and interpret F as a probability density function. Because expectation is generally not invariant with respect to monotone transformations, the measure of utility for the uncertain case must be cardinal rather than ordinal. As with preferences over outcomes, the utility function representation is not unique. If U is a utility function representation of $\lesssim$ and φ a positive linear (affine) function on the reals, then $\varphi \circ u$ also represents $\lesssim$.

Frank Plumpton Ramsey (1964/1926) was the first to derive expected utility from axioms on preferences and belief. The concept achieved prominence in the 1940s, when John VON NEUMANN and Oskar Morgenstern presented an axiomatization in their seminal volume on GAME THEORY (von Neumann and Morgenstern 1953). (Indeed, many still refer to "vN-M utility.") Savage (1972) presented what is now considered the definitive mathematical argument for expected utility from the Bayesian perspective.

Although it stands as the cornerstone of accepted decision theory, the doctrine is not without its critics. Allais (1953) presented a compelling early example in which most individuals would make choices violating the expectation principle. Some have accounted for this by expanding the outcome description to include determinants of regret (see Bell 1982), whereas others (particularly researchers in behavioral DECISION MAKING) have constructed alternate preference theories (Kahneman and TVERSKY's 1979 prospect theory) to account for this as well as other phenomena. Among those tracing the observed deviations to the premises, the independence axiom has been the greatest source of controversy. Although the dispute centers primarily around its descriptive validity, some also question its normative status. See Machina (1987, 1989) for a review of alternate approaches and discussion of descriptive and normative issues.

Behavioral models typically posit more about preferences than that they obey the expected utility axioms. One of the most important qualitative properties is risk aversion, the tendency to prefer the expected value of a prospect to the prospect itself. For scalar outcomes, the risk aversion function (Pratt 1964),

$$r(x) = \frac{-U''(x)}{U'(x)},$$

is the standard measure of this tendency. Properties of the risk aversion measure (e.g., is constant, proportional, or decreasing) correspond to analytical forms for utility functions (Keeney and Raiffa 1976), or stochastic dominance tests for decision making (Fishburn and Vickson 1978).

When outcomes are multiattribute (nonscalar), the outcome space is typically too large to consider specifying preferences without imposing some structure on the utility function. Independence concepts for preferences (Bacchus and Grove 1996; Gorman 1968; Keeney and Raiffa 1976)—analogous to those for probability—define conditions under which preferences for some attributes are invariant with respect to others. Such conditions lead to separability of the multiattribute utility function into a combination of subutility functions of lower dimensionality.

Modeling risk aversion, attribute independence, and other utility properties is part of the domain of decision analysis (Raiffa 1968; Watson and Buede 1987), the methodology of applied decision theory. Decision analysts typically construct preference models by asking decision makers to make hypothetical choices (presumably easier than the original decision), and combining these with analytical assumptions to constrain the form of a utility function.

Designers of artificial agents must also specify preferences for their artifacts. Until relatively recently, Artificial Intelligence PLANNING techniques have generally been limited to goal predicates, binary indicators of an outcome state's acceptability. Recently, however, decision-theoretic methods have become increasingly popular, and many developers encode utility functions in their systems. Some researchers have attempted to combine concepts from utility theory and KNOWLEDGE REPRESENTATION to develop flexible preference models suitable for artificial agents (Bacchus and Grove 1996; Haddawy and Hanks 1992; Wellman and Doyle 1991), but this work is still at an early stage of development.

Vagueness

Vague expressions, such as "tall," "red," "bald," "heap," "tadpole," and "child," possess borderline cases where it is unclear whether or not the predicate applies. Some people are borderline tall: not clearly tall and not clearly not tall. It seems that the unclarity here is not merely epistemic. There need be no fact of the matter about which we are ignorant: the borderline predications are *indeterminate,* neither true nor false, and are exceptions to the principle of bivalence (which is a key feature of classical LOGIC). Relatedly, vague predicates lack well-defined extensions. On a scale of heights, there is no sharp division between the tall people and the rest. If candidates for satisfying some vague *F* are arranged with spatial closeness indicating similarity, no sharp line can be drawn round the cases to which *F* applies. Vague predicates are thus naturally described as having fuzzy boundaries: but according to classical SEMANTICS, all predicates have well-defined extensions, again suggesting that a departure from classical conceptions is needed to accommodate vagueness.

Vague predicates are also susceptible to sorites paradoxes. Intuitively, a hundredth of an inch cannot make a difference as to whether a person counts as tall: such tiny variations, which cannot be discriminated by the naked eye (or even by everyday measurements), are just too small to matter. This insensitivity to imperceptible differences gives the term its everyday utility and seems part of what it is for "tall" to be a *vague* height term lacking sharp boundaries— which suggests [S1] if *X* is tall, and *Y* is only a hundredth of an inch shorter than *X*, then *Y* is also tall. But imagine a line of men, starting with someone seven-foot tall, and each of the rest a hundredth of an inch shorter than the man in front of him. Repeated applications of [S1] as we move down the line imply that each man we encounter is tall, however far we continue. And this yields conclusions that are clearly false, for instance, that a man five feet high, reached after three thousand steps, still counts as tall. Similarly, there is the ancient example of the heap (Greek *soros,* hence the paradox's name). Plausibly, [S2] if *X* is a heap of sand, then the result *Y* of removing one grain will still be a heap. So take a heap and remove grains one by one; repeated applications of [S2] imply that even a solitary last grain must still count as a heap. Familiar ethical "slippery slope" arguments share the same sorites structure (see, e.g., Walton 1992 and Williams 1995).

Borderline-case vagueness must be distinguished from mere underspecificity (as in *"X* is an integer greater than thirty,"* which may be unhelpfully vague but has sharp boundaries). Nor is vagueness simple AMBIGUITY: "tadpole" has a univocal sense, though that sense does not determine a well-defined extension. Context-dependence is different again. Who counts as tall may vary with the intended comparison class; but fix on a definite context and

"tall" will remain vague, with borderline cases and fuzzy boundaries.

A theory of vagueness must elucidate the logic and semantics of vagueness. The simplest approach argues that appearances are deceptive; we can retain classical logic and semantics for vague terms after all. On this *epistemic view* borderline case predications are either true or false, but we do not and cannot know which. The sorites paradox is avoided by denying principles like [S1]: there is a sharp divide between the tall men and the others in our series, though we are ignorant of where this boundary lies and so wrongly assume that it does not exist. For an ingenious defense of this initially surprising view, see Williamson (1994).

Competing theories reject classical logic and semantics. One option is to countenance nonclassical *degrees of truth,* introducing a whole spectrum of truth values from 0 to 1, with complete falsity as degree 0 and complete truth as degree 1 (see, e.g., Machina 1976). Borderline cases then each take some intermediate truth value, with "X is tall" gradually decreasing in truth value as we move down the sorites series. When Y is only a hundredth of an inch shorter than X, the claim "if X is tall, Y is also tall," which appears true, may actually be slightly less than completely true. Repeated application of the sorites principle [S1] then introduces an additional departure from the truth at each step, eventually reaching falsity.

The degree theory is typically associated with an infinite-valued logic or FUZZY LOGIC, and various versions have been proposed. It is normally assumed at least that, if $V(P)$ is the value of P, then

$$V(\text{not-}P) = 1 - V(P)$$
$$V(P \ \& \ Q) = \text{minimum of } V(P), V(Q).$$

But suppose Tek is taller than Tom, and V(Tek is tall) is 0.5, V(Tom is tall) = 0.4. Then, by the standard rules, V(Tom is tall and Tek is not) = 0.4. Such a result is arguably implausible. If Tek is taller than Tom, then is it not entirely ruled out that Tom should be tall and Tek not—that is, should not V(Tom is tall and Tek is not) = 0? (see Chierchia and McConnell-Ginet 1990: Chapter 8, for more examples). However, not all degree theorists accept that the propositional connectives obey truth-functional rules (see Edgington 1997).

The other popular option is *supervaluationism.* The basic idea is to treat vagueness as a matter of semantic indecision, as if we have not settled which precise range of heights to count as tall. A proposition involving "tall" is true (false) if it comes out true (false) on all the ways in which "tall" could be made precise (ways, that is, which preserve the truth-values of uncontentious cases of "X is tall"). A borderline case, "Tek is tall," will thus be neither true nor false, for it is true on some ways of making "tall" precise and false on others. But a classical tautology like "either Tek is tall or he is not tall" *will* still come out true because it remains true wherever a sharp boundary for "tall" is drawn. In this way, the supervaluationist adopts a nonclassical *semantics* while aiming to minimize divergence from classical *logic* (see Fine 1975). On any way of making "tall" totally precise, there will be some X who counts as tall when Y a hundredth

of an inch shorter does not, making [S1] false. So because [S1] is false on each precisification, [S1] counts as false *simpliciter.* But note, nobody counts as the last tall man on *every* precisification of "tall," so supervaluationism avoids commitment to a sharp boundary.

Both the supervaluationist and the degree theorist can naturally accommodate a range of linguistic phenomena. For example, both can give semantic treatments of comparatives. The degree theorist may say that "X is taller than Y" counts as true just if "X is tall" is true to a greater degree than "Y is tall." The supervaluationist may say that the comparative claim holds if the ways of making "tall" precise which make Y count as tall are a proper subset of those that make X count as tall. Likewise, both theorists can deal with various modifiers: for example "X is quite tall" is true if "X is tall" has a sufficiently (but not too) high degree of truth, or alternatively if "X is tall" is true on sufficiently many (but not too many) precisifications of "tall." (See Kamp 1975; Zadeh 1975.)

Vision and Learning

Learning is now perceived as the gateway to understanding the problem of INTELLIGENCE. Because seeing is a factor in intelligence, learning is also becoming a key to the study of artificial and biological vision. In the last few years both computer vision—which attempts to build machines that see—and visual neuroscience—which aims to understand how our visual system works—are undergoing fundamental changes in their approaches. Visual neuroscience is beginning to focus on the mechanisms that allow the CEREBRAL CORTEX to adapt its circuitry and learn a new task. Instead of building a hardwired machine or program to solve a specific visual task, computer vision is trying to develop systems that can be trained with examples of any of a number of visual tasks. The challenge is to develop machines that learn to perform visual tasks such as visual inspection and visual recognition from a set of training examples or even in an unsupervised way from visual experience.

This reflects an overall trend—to make intelligent systems that do not need to be fully and painfully programmed for specific tasks. In other words, computers will have to be much more like our brain, learning to see rather than being programmed to see. Biological visual systems are more robust and flexible than machine vision mainly because they continuously adapt and learn from experience. At stake are engineering as well as scientific issues. On the engineering side the possibility to build vision systems that can adapt to different tasks can have enormous impact in many areas such as automatic inspection, image processing, video editing, virtual reality, multimedia databases, computer graphics, and man-machine interfaces. On the biological side, our present understanding of how the cortex works may radically change if adaption and learning turn out to play a key role. Instead of the hardwired cortical structures implied by classical work, for instance by Harvard's David Hubel and Torsten Wiesel, we may be confronted with significant NEURAL PLASTICITY—that is, neuron properties and connectivities that change as a function of visual experience over time scales of a few minutes or seconds.

There are two main classes of learning techniques that are being applied to machine vision: *supervised* and *unsupervised* learning algorithms (see UNSUPERVISED LEARNING). Supervised learning—or *learning-from-examples*—refers to a system that is trained, instead of programmed, by a set of examples. The training thus can be considered as using input-output pairs. At run-time the trained system provides a correct output for a new input not contained in the training set. The underlying theory makes use of function approximation techniques, neural network architectures, and statistical methods. Systems have been developed that learn to recognize objects, in particular faces (see FACE RECOGNITION), systems that learn to find specific objects in cluttered scenes, software that learns to draw cartoon characters from an artist's drawings, and algorithms that learn to synthesize novel image sequences from a few real pictures and thereby promise to achieve extremely high compression in applications such as video conference and video e-mail. So far the most ambitious unsupervised learning techniques have been used only in simple, "toy" examples, but they represent the ultimate goal: learning to see, from experience, without a teacher.

In computer vision tasks (see COMPUTATIONAL VISION) the input to the supervised learning system is a digitized image or an image sequence and the output is a set of parameters estimated from the image. For instance, in the ALVIN system, developed by Dean Pomerleau (1993) at Carnegie Mellon University for the task of driving a car, the input is a series of images of the road and the output is degrees of steering. In recognition tasks the output parameters consist of a label identifying the object in the image (see VISUAL OBJECT RECOGNITION, AI).

The analysis problems of estimating object labels as well as other parameters from images is *the* problem of vision. It is the *inverse* of the classical problem of classical optics and modern computer graphics, where the question is how to synthesize images corresponding to given 3-D surfaces as a function of parameters such as direction of illuminant, position of the camera and material properties of the object. In the supervised learning framework it is natural to use a learning module to associate input parameters to output images. This module can then synthesize new images. Traditional 3-D computer graphics simulates the physics of the world by building 3-D models, transforming them in 3-D space, simulating their physical properties, and finally rendering them by simulating geometrical optics. The learning-from-examples paradigm suggests a rather different and unconventional approach: take several real images of a 3-D object and create new images by generalizing from those views, under the control of appropriate pose and expression parameters, assigned by the user during the training phase.

A large class of SUPERVISED LEARNING schemes suggests directly a view-based approach to computer vision and to computer graphics. Though it cannot be seen as a substitute for the more traditional approaches, the learning-from-examples approach to vision and graphics may represent an effective shortcut to several problems.

An obvious application of the supervised learning framework is recognition of 3-D objects. The idea is to train the learning module with a few views of the object to be recognized—in general, from different viewpoints and under different illuminations—and the corresponding label (as output), without any explicit 3-D model. This corresponds to a classification problem as opposed to the regression problem of estimating real-valued parameters associated with the image. An interesting demonstration of the power of this view-based paradigm is the development of several successful face recognition systems.

Even more difficult than recognizing an isolated specific object is detecting an object of a certain class in a cluttered image. Again, supervised learning systems have been developed that can be trained to detect faces, cars, and people in complex images.

The key problem for the practical use of most learning-from-examples schemes is often the insufficient size of the training set. Because input vectors typically have a high dimension (like the number of pixels in an image), the required number of training examples is very high. This is the so-called *curse of dimensionality*. The natural idea is to exploit prior information to generate additional *virtual* examples from a small set of real example images. For instance, knowledge of symmetry properties of a class of 3-D objects allows the synthesis of additional examples. More generally, it is possible to learn *legal* transformations typical for a certain class of objects from examples drawn from images of objects of the same class.

The example-based approach is successful in practical problems of object recognition, image analysis, and image synthesis. It is not surprising therefore to ask whether a similar approach may be used by our brain. Networks that learn from examples have an obvious appeal given our knowledge of neural mechanisms. Over the last four years psychophysical experiments have indeed supported the view-based schemes and physiological experiments have provided a suggestive glimpse on how neurons in the IT cortex may represent objects for recognition (Logothetis, Pauls, and Poggio 1995 and references therein). The experimental results seem to agree to a surprising extent with the view-based models.

Visual Anatomy and Physiology

In primates visual processing is carried out in many different parts of the brain. Described here is the basic anatomy and physiology of the RETINA, the lateral geniculate nucleus of the THALAMUS, the striate cortex, higher cortical visual areas, the superior colliculus, and the accessory optic system (AOS).

The retina: Five major classes of neurons have been discerned in the primate retina: photoreceptors, horizontal cells, bipolar cells, amacrine cells, and ganglion cells. Several subclasses have been discerned within each of these cell types. The rod and cone photoreceptors subserve night and day vision. In humans and many primates three kinds of cones have been discerned that have maximum sensitivity for either short-(blue), medium-(green), or long-wavelength (red) light. All photoreceptors hyperpolarize to light, yield only graded potentials, and use the neurotransmitter glutamate. Bipolar cells form two major classes, the ON and OFF types, which by virtue of sign-inverting and sign-conserving synapses, respectively, depolarize and hyperpolarize to light. Several subclasses of ON and OFF bipolar cells have been identified. There are numerous classes of amacrine cells that use a variety of different neurotransmitters that include dopamine, acetylcholine, and serotonin. The ganglion cells are the output cells of the retina. Each ganglion cell is sensitive to a small area of the visual field, called the receptive field of the cell. Most commonly the shape of the receptive field is circular and consists of two regions, a central excitatory one which, when stimulated by light or dark spots (for the ON and OFF cells respectively), elicits a vigorous burst of action potentials in the cell, and a concentric inhibitory surround area produced largely by virtue of the horizontal cell network. As a result of this arrangement, responses arise predominantly when a local difference in luminance or chrominance is detected within the receptive field.

Two major classes of the primate ganglion cells are the midget and parasol cells. The midget ganglion cells, as their name implies, are quite small; in central retina their receptive field center is composed of but a single cone, rendering them thereby, in trichromatic primates, wavelength-selective. The parasol cells, by contrast, are much larger and receive input both in the center and surround of their receptive fields from several different cone types. As a result of convergent input from the receptors, the parasol cells are more sensitive to contrast but cannot provide information about differences in wavelength. Midget and parasol cells come in two subvarieties, the ON and the OFF. The ON cells are excited by light increment and the OFF cells are excited by light decrement. The midget system is believed to make a significant contribution to the processing of fine detail and color, and the parasol system to the processing of rapid motion and luminance changes. In central vision the midget cells outnumber the parasol cells ten to one. This ratio declines with increasing eccentricity; in the far periphery the two cells types are just about equally numerous. Another group of retinal ganglion cells receives convergent input from ON and OFF bipolar cells as a result of which they discharge to both light increment and light decrement.

Such cells make extensive projections to the superior colliculus.

The optic nerve consists of the axons of the retinal ganglion cell. In animals with lateral eyes, such as fish and amphibians, most of the axons in the optic nerve of each eye cross over at the optic chiasm to the contralateral hemisphere. In higher mammals with forward-looking eyes, only the axons of ganglion cells in the nasal hemiretinae cross over at the chiasm; the temporal hemiretinae project ipsilaterally. This arrangement makes it possible for corresponding points in the retinae of the two eyes to reach the same sites in cortex to realize binocular vision.

The retinal ganglion cell axons terminate in several central structures that include the lateral geniculate nucleus of the thalamus, the superior colliculus (called the optic tectum in reptiles and amphibians), and the terminal nuclei.

The lateral geniculate nucleus of the thalamus: The two lateral geniculate nuclei, one on each side of the brain, are laminated thalamic structures. Each receives input from the nasal hemiretina of one eye and the temporal hemiretina of the other, thereby representing the contralateral visual hemifield. In primates there are six layers for central vision, three of which receive input from one eye and three from the other. The midget retinal ganglion cells project to the top four parvocellular layers, whereas the parasol cells project to the bottom two magnocellular layers. The number of layers reduces to four for peripheral representation, two of which are parvocellular and two magnocellular. The interlaminar layers contain small cells innervated by several classes of small retinal ganglion cells. The retinal projections are orderly, thereby creating a neat topographic arrangement in the structure. The receptive field properties of single cells are quite similar to those seen in retinal ganglion cells. Their responses, however, can be modulated by the extensive inputs the lateral geniculate nucleus receives directly or indirectly from the cortex.

The striate cortex: The striate cortex is an expanse of cortical tissue that in higher mammals comprises a large portion of the occipital lobe. Transverse sections of this tissue, when stained with cresyl violet, reveal a distinct striation in layer 4, called the stripe of Gennary; this stripe is not evident in other cortical regions and thereby provides an easy anatomical delineation of the area. The striate cortex, often called V1 (for visual 1), spans a thickness of approximately 2 mm of gray matter; six major laminae have been discerned, some of which have subsequently been divided into several sublaminae. In primates the striate cortex is the major recipient zone of the input from the dorsal lateral geniculate nucleus of the thalamus; fibers terminate most profusely, but not exclusively, in layer 4c, which has two subdivisions, 4cα and 4cβ. The inputs to 4cα and 4cβ arise, respectively, from the magnocellular and parvocellular divisions of the lateral geniculate nucleus.

The visual field is represented in an orderly manner along the surface extent of the striate cortex with more space allocated for central than for peripheral vision. Each cell in the striate cortex is sensitive to a relatively small region of the visual field, the receptive field area of the cell. By virtue of elaborate excitatory and inhibitory connections, the input from the lateral geniculate nucleus is reorganized to yield six major changes in receptive field properties: (1) selectivity for the orientation of edges, (2) selectivity for the direction of stimulus movement, (3) selectivity for the spatial frequency of repetitive stimuli such as textures, (4) selectivity for color along several directions in color space in addition to the red/green and blue/yellow axes seen in the retinal ganglion cells and in the lateral geniculate nucleus, (5) sensitivity for both light increment (ON response) and light decrement (OFF response) in many cells, and (6) selectivity for binocular activation that gives rise to stereoscopic depth perception. Orientation-specific cells in the striate cortex appear to form several distinct classes that include the so-called simple and complex cells. The receptive fields of simple cells subdivide into spatially separate regions, within each of which responses are produced for either light increment (ON response) or light decrement (OFF response) but not both. Complex cells, which commonly receive input from both eyes, do not exhibit such subdivision; they typically respond to both light increment and decrement throughout their receptive fields. Furthermore, their receptive fields are larger than those of simple cells.

In addition to the laminar organization of the striate cortex, columnar organization has also been revealed, most notably for orientation specificity. Within each column cells have the same orientation. The columns form stripes along the cortical surface with neighboring columns showing progressive shifts in orientation preference. This arrangement, coupled with columnar organization for ocular dominance, is modular. Each module, sometimes called a "hypercolumn," measures approximately 1 mm by 1 mm with a depth of 2 mm; it is conceived to be a self-contained processing unit for a given location of the visual field within which the basic attributes believed to be necessary for the analysis of the visual scene are contained. These include a full representation of neurons for the local analysis of orientation, direction, spatial frequency, color, and depth. The columnar organization seen in the striate cortex is believed to optimize encoding and visual analysis.

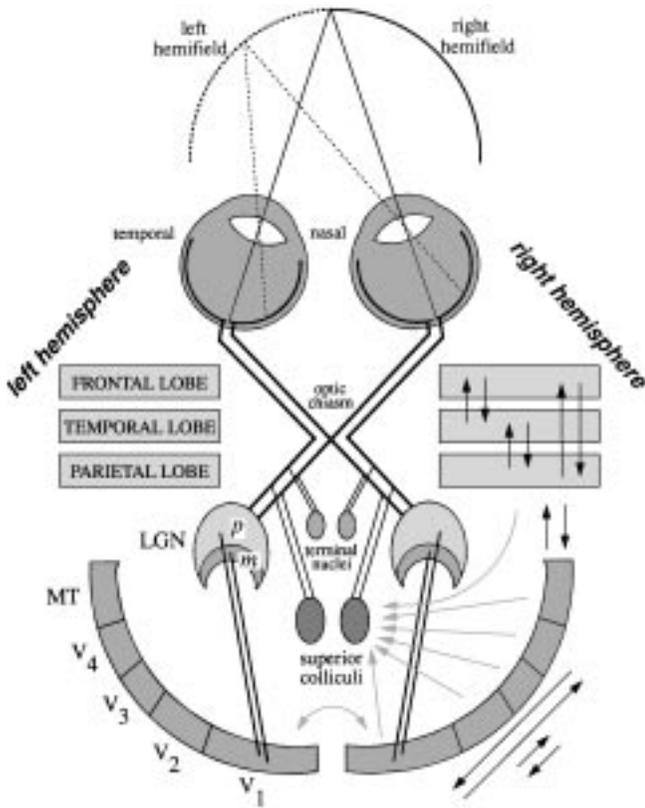
Higher cortical areas: In the primate posterior cortex more than thirty distinct visual areas that make more than 300 interconnections have been identified. These include areas V2, V3, V4, the middle temporal (MT), the medial superior temporal (MST), the ventral interparietal (VIP), and the inferior temporal (IT) areas. Most of these areas are also modular, as is area V1. Physiological studies have shown that the modules perform a great variety of analyses. The receptive fields of single cells become larger in size the further the area is removed from V1; this goes along with a gradual loss in the topographic order with which the visual field is laid out in each area. The occipitoparietal areas are believed to play an important role in the analysis of spatial relationships and motion, whereas the occipito-temporal areas are believed to play a role in object recognition and color vision. Lesion studies suggest that there is considerable redundancy in processing as selective removal of single extrastriate areas such as V3, V4, and MT does not produce highly specific or long-lasting deficits in the analysis of basic visual capacities such as motion, color, shape, and depth. However, lesions of temporal cortex produce severe


Figure 1. A schematic of the major structures and connections of the visual system as viewed from above. The temporal hemiretinae project ipsilaterally, whereas the projections from the nasal hemiretinae cross over at the optic chiasm to the contralateral hemisphere. As a consequence, corresponding retinal points in the two eyes project to the same hemisphere and to nearby regions within each target structure. Three retinal projections are depicted in the figure, which terminate in the lateral geniculate nuclei (LGN) of the thalamus, in the superior colliculi, and in the terminal nuclei. The magnocellular (*m*) and parvocellular (*p*) portions of the LGN project predominantly to primary visual cortex (V_1). The extrastriate areas shown are V_2, V_3, V_4, and MT. These areas are extensively interconnected, as indicated on the right. The temporal, parietal, and frontal lobes contain several additional visual areas that interconnect with each other as well as with the extrastriate areas. Most of these visual areas send projections to the superior colliculi as well as other subcortical visual centers.

deficits in object recognition and lesions of the parietal cortex, shorter-term deficits in spatial vision. At this stage of the research it is still not clearly understood why so many cortical visual areas have evolved in primates.

The superior colliculus: The superior colliculus, located on the roof of the midbrain, is a laminated structure. In the upper layers the visual field is represented in an orderly fashion. Most cells have relatively small receptive fields and give both ON and OFF responses to stimuli; little selectivity has been reported for color and shape. In some species, like the cat for example, cells having directionally selective attributes are common. In the primates so far studied the percentage of such cells in the superior colliculus is low.

In the deeper layers of the primate superior colliculus single cells that respond in association with eye movements

are common. Each cell discharges optimally when an eye movement of a certain direction and amplitude is executed; each region in the colliculus represents different directions and amplitudes of eye movements arranged in an orderly fashion. Electrical stimulation elicits saccadic eye movements with very low currents. The superior colliculus plays a central role in the generation of saccadic eye movements. However, several other structures, including regions in the occipital and parietal lobes, the frontal eye fields, and the medial eye fields in the frontal lobe also contribute to eye movement generation. Electrical stimulation in these areas also produces eye movements. Removal of the superior colliculus causes moderate deficits in eye movements, most notable being the inability to execute saccades to visual targets with very short latencies (the so-called express saccades). After colliculus removal, electrical stimulation of the occipital and parietal lobes no longer produces eye movements, although stimulation-elicited eye movements from the frontal areas remain unaffected. Removal of the frontal eye fields and the medial eye fields produces only minor deficits in eye movements. However, when both the frontal eye fields and the superior colliculi are removed, visually guided saccadic eye movements can no longer be generated. These findings suggest that there are two major systems for saccadic eye movement control: the posterior, which involves the occipital and parietal lobes that pass through the colliculus to reach the brain stem, and the anterior, which involves the frontal lobe that reaches the brain stem directly.

The accessory optic system: The AOS, extensively studied in the rabbit, arises from a special class of ganglion cells, the cells of Dogiel, that are directionally selective and respond best to slow rates of movement. They project to the terminal nuclei which in turn project to the dorsal cap of Kooy of the inferior olive. The climbing fibers from the olive project to the flocculo-nodular lobe of the cerebellum from where the brain stem oculomotor centers are reached through the vestibular nuclei.

The prime function of the accessory optic system appears to be to stabilize the retinal image by counterrotating the eyes when either the organism or the visual field is set in motion at slow velocities. At higher velocities retinal slip is prevented by the vestibular system which also sends its signals to the brain stem for eye movement generation via the vestibular nuclei.

Visual Cortex, Cell Types and Connections in

Like all parts of the CEREBRAL CORTEX, the function of visual cortex is dependent on the organization of its connections, the types of synapses they form, and how postsynaptic neurons respond to and integrate synaptic inputs. The various neurons within the cerebral cortex can be classified based on differences in any of these traits and their unique relationships to cortical circuits.

Numerous neuronal types are found in visual cortex as well as other cortical areas. The actual categorization of individual cells is, of course, highly dependent on the definitions used to distinguish them. Among many possibilities, cells can be defined in terms of the functional influence of their synapses (excitatory or inhibitory, strong or weak); anatomical features (spiny or aspinous dendrites, spiny stellate or pyramidal dendritic morphology; see figure 1); laminar position (the cortical layer containing the cell body; see figure 1); intrinsic membrane properties (fast-spiking, regular-spiking, bursting; see figure 1); or patterns of connectivity. In the most clear-cut cases, many of these definitions generate the same groupings. Most notably, inhibitory and excitatory neurons compose two distinct groups on the basis of several features. They release different NEUROTRANSMITTERS and their synapses therefore have different functional influences (γ-aminobutyric acid, inhibitory vs. glutamate, excitatory). Inhibitory neurons also have aspinous dendrites and are fast-spiking compared to excitatory neurons which have spiny dendrites and are regular-spiking or bursting (see figure 1 and below).

Although inhibitory cells account for only about fifteen to twenty percent of visual cortical neurons, they are a highly diverse population. They have been distinguished experimentally based primarily on morphology. By such criteria more than a dozen different types of aspinous neurons can be identified. In a few cases, important functional implications can be inferred from the anatomy. For example, "chandelier" cells form inhibitory synapses onto the axon initial segments (where the axon leaves the cell body; see figure 1) of spiny neurons and can therefore veto their output. But most inhibitory connections probably have more subtle influences via connections onto dendrites, where they interact with nearby excitatory connections. A better understanding of the functional importance of most of the morphological distinctions awaits further study.

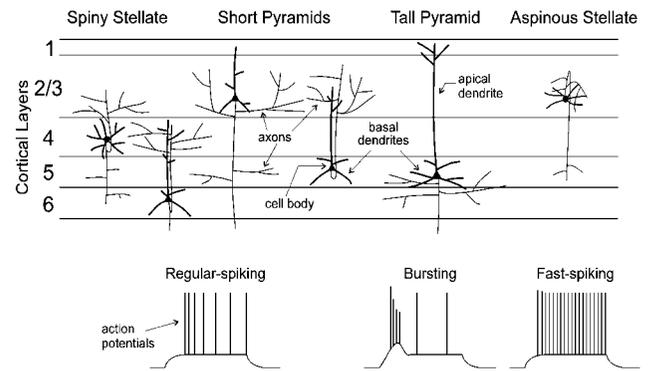
The great majority of visual cortical neurons (about 80–85 percent) are spiny and therefore excitatory. Outside of primary visual cortex (V1), virtually all of these have a pyramidal dendritic morphology (see figure 1). Such cells have a long apical dendrite extending from the cell body "up" toward more superficial layers (i.e., layer 1), as well as more numerous, shorter basal dendrites extending down-


Figure 1.

ward and obliquely. Thus, the top of the apical dendrite and bottoms of the most lateral basal dendrites define the corners of the "pyramid." Pyramidal neurons can be further distinguished by variations in their patterns of dendritic branching. Such differences are often correlated with different intrinsic physiological properties or patterns of connectivity. For example "tall" pyramids have long apical dendrites and often fire action potentials in bursts (see figure 1 and below). A second type of spiny neuron, the spiny stellate, is found in layer 4 of V1. These lack a prominent apical dendrite and instead have numerous shorter dendrites, extending obliquely upward as well as downward, to define a roughly spherical volume (see figure 1).

Cortical neurons also vary and can be classified according to intrinsic physiological differences. These differences are reflected in the patterns and shapes of action potentials that are generated on the injection of electrical current into the cell body (see figure 1). Inhibitory neurons fire high-frequency trains of brief action potentials. They are thus termed fast-spiking. Spiny neurons have broader, less brief action potentials and in most cases the firing rate decreases gradually with each spike. These are regular-spiking neurons. Bursting pyramidal neurons are rarer and fire action potentials in groups rather than singly. Bursting neurons are typically found in deep cortical layers and are also distinct from regular-spiking neurons in terms of both their dendritic morphology and axonal connections (see below).

A conspicuous feature of all cortical areas is their laminar organization. Layers are apparent in cross sections through the cortical sheet as regions with varying densities and sizes of neurons. The layers are numbered 1 to 6, with layer 1 located most superficially, at the outer surface, and layer 6 the deepest (see figure 1). Grouping of cortical neurons according to laminar position is straightforward and also useful since the most prominent feature of connectivity in visual cortex is its laminar organization. The laminar specificity of connections is a consequence of the laminar stratification of axonal arbors (see figure 1 and below). Thus, the laminar position of a neuron's cell body tends to be highly correlated with its connectivity. This is particularly true of aspinous, inhibitory neurons and spiny stellate neurons since their dendrites, which receive connections from the axons of other neurons, are usually confined to a single layer. But dendritic arbors of pyramidal neurons can

span several layers, with apical dendritic branches also being highly stratified. Laminar specificity is a characteristic of both the corticocortical connections between the numerous visual cortical areas and local connections within a cortical area. And connections with subcortical structures also arise from and terminate in distinct cortical layers.

The laminar patterns of connections between visual cortical areas are closely correlated with hierarchical relationships between areas. At the bottom of the hierarchy is the primary visual area, V1. Virtually all of the visual information reaching the cortex is first channeled through this area, where it is processed before being sent on to higher areas. Corticocortical connections are made by pyramidal neurons and are therefore excitatory. Forward connections, from lower to higher areas in the hierarchy, originate in superficial layers (layers 2 and 3) and terminate in the middle layer (layer 4). (In the case of V1 the forward input to layer 4 originates from the THALAMUS.) Feedback connections originate from deep-layer (layer 5 or 6 or both) neurons, and the axons of these cells terminate in superficial and deep layers. The forward connections are strong and their organization has a dominant influence on the visual responses of recipient neurons (see SINGLE-NEURON RECORDING). Feedback connections, although generally more numerous, are functionally weaker and serve to modulate responses driven by the forward connections.

Local excitatory connections, intrinsic to a single visual cortical area, are also highly layer-specific and can be classified as forward, dominant and feedback, modulatory. This organization is most clear in V1, where the connections are understood in the greatest detail. As noted above, the dominant, forward input to a cortical area targets layer 4. Locally, these layer 4 neurons provide dominant, forward input via their axonal arbors to layers 2 and 3 (e.g., spiny stellates in layer 4 of V1, see figure 1). And these layer 2 and 3 neurons in turn provide the feedforward output to higher cortical areas (see above). Thus, there are two levels of local forward processing (layer 4 and layers 2 and 3). Each of these levels or layers also receives local, modulatory feedback from the axons of deep-layer cells (see figure 1). Layer 6 provides feedback to its partner, layer 4; and layer 5 to its partner, layers 2 and 3. The deep layers providing this feedback receive weaker forward input from the same sources as their partner plus from the partner itself (see figure 1). They therefore incorporate information about the input to and output from their partner and modulate the partner's activity with their feedback connections.

Visual cortical areas also interact extensively with subcortical areas, most notably the thalamus, superior colliculus, and visual claustrum. These connections are also layer-specific. Thalamic nuclei, including the lateral geniculate nucleus and pulvinar nucleus, are composed of anatomically and functionally distinct subdivisions, each of which connects to distinct visual cortical areas and layers (see VISUAL ANATOMY AND PHYSIOLOGY). Connections from visual cortex to subcortical targets originate from neurons in deep layers. Unlike corticocortical connections from deep layers, however, these do not necessarily constitute modulatory, feedback connections. They arise from populations of neurons different from those that make corticocortical or local

feedback connections and their input from superficial layers might be stronger. For example, in V1, connections from layer 5 to the superior colliculus or from layer 6 to the visual claustrum arise from neurons with longer apical dendrites ("tall" pyramids) and different intrinsic firing properties than those making corticocortical connections.

Since visual cortex offers many experimental advantages and has been more extensively studied than other cortical areas, it is understood in greater detail. It is expected, however, that many of the cell types and principles of connectivity that are revealed here will be applicable to the cerebral cortex as a whole.

Visual Information Sources

See STRUCTURE FROM VISUAL INFORMATION SOURCES

Visual Neglect

Visual neglect is a common neurological syndrome in which patients fail to acknowledge stimuli toward the side of space opposite to their unilateral lesion. This disability affects many aspects of their life. For example, after a right lesion, patients typically fail to eat the food located on the left side of their plate, or to shave or make up the left side of their face, and, in extreme cases, may no longer acknowledge the left side of their body as their own. In a common clinical test known as line cancellation, they fail to mark lines toward the left of the page (see figure 1A) despite often being able to detect isolated lines presented in their left visual field, demonstrating that they are not simply blind on that side.

This syndrome is observed primarily after unilateral lesions to the parieto-occipital junction, especially in the right hemisphere (Heilman, Watson, and Valenstein 1985; Bisiach 1996). Lesions to the right frontal cortex and to various subcortical sites can also trigger neglect-like symptoms, although with subtle differences from parietal neglect (Heilman et al. 1985; Guariglia et al. 1993). Here we concentrate on parietal neglect, as it is the most common form, and can be related to recent data on the parietal lobe from nonhuman primates.

Two major accounts have been proposed for neglect. Some theories posit a deficit in directing attention toward contralesional events (Posner et al. 1984; Kinsbourne 1987; see ATTENTION and ATTENTION IN THE HUMAN BRAIN). For instance, right parietal patients—who suffer from left neglect—tend to have particular difficulty in detecting stimuli in the left hemifield if their attention has previously been drawn to the right side (Posner et al. 1984). By contrast, many "preattentive" aspects of vision appear to be spared on the affected side (Driver, Baylis, and Rafal 1992; McGlinchey-Berroth et al. 1996; Mattingley, Davis, and Driver 1997).

Other accounts argue that the patient's lesion simply disrupts the neuronal coding of contralesional space, at relatively high levels of representation (Bisiach and Luzzatti 1978; Bisiach, Luzzati, and Perani 1979; Rizzolatti and Berti 1990; Halligan and Marshall 1991; Karnath, Schenkel, and Fischer 1991). This perspective has drawn support from the finding that even mental IMAGERY can be impaired in some left-neglect patients (Bisiach and Luzzatti 1978), such that they fail to report what would appear on their left when retrieving from memory the view of a familiar visual scene.

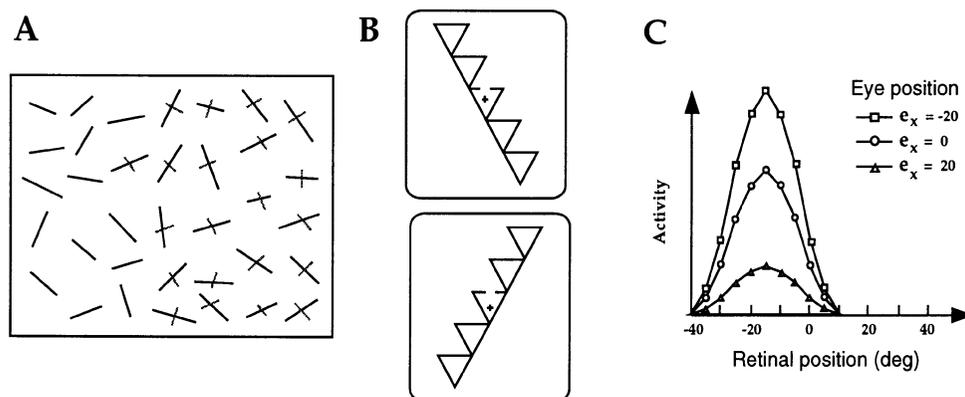
The dichotomy between attentional and representational accounts has recently been challenged by several authors using neural network models in which attentional and representational functions are interwoven (Mozer and Behrmann 1990; Cohen et al. 1994; Pouget and Sejnowski 1997a). This work suggests a compromise view, whereby neglect results from damage to cortical areas that are located at the interface between sensory and motor systems, and which are responsible for both the representation of the position of objects and the selective control of spatial action, that is to say, "attention."


Figure 1. *A*. Left items neglected in a cancellation task. *B*. Visual displays from the Driver et al. (1994) experiment. The cross indicates the fixation point. Left-neglect patients performed better for the bottom configuration than the top one, even though the gap to be detected was at the same retinal location. This pattern is consistent with left object-centered neglect. *C*. Visual receptive field of a typical monkey parietal neuron, for three different eye positions. The retinotopic position of the receptive field is invariant across eye positions but the gain of the response changes. (Adapted from Andersen, Issick, and Siegel 1985.)

Frames of reference: In principle, "left" neglect might refer to the left of the visual field, or the left of the head, or the trunk, or even of the surrounding environment. To determine the frame of reference for hemineglect, one can test patients in various postures, so that a stimulus location changes in one frame of reference while remaining constant in the others. For instance, one might test a patient looking straight ahead vs. with the gaze deviated twenty degrees to the right, while keeping all stimuli at the same position with respect to the RETINA. If neglect were purely retinotopic, these conditions should not differ, whereas if it were head- or body-centered, performance should change accordingly. Such experiments have typically revealed that neglect affects a mixture of frames of reference concurrently, rather than just one single frame. Thus, the probability that a patient will neglect a particular visual stimulus is typically a function of its position in various egocentric frames of reference, such as eye-, head- or trunk-centered, as well as showing influences from cues in the environment, for example, as regards the gravitational upright (Bisiach, Capitani, and Porta 1985; Ladavas 1987; Ladavas, Pesce, and Provincial, 1989; Calvanio, Petrone, and Levine 1987; Farah et al. 1990; Karnath et al. 1991; Behrmann and Moscovitch 1994).

A few experiments suggest that visual neglect can also be "object-centered," that is, patients tend to neglect the left side of an object regardless of its position or orientation (Driver et al. 1994; Tipper and Behrmann 1996). For example, Driver et al. (1994) devised a situation in which left-neglect patients could detect a gap in part of a triangle when this gap was perceived to be on the right side of an object, but missed the same gap when it was seen as belonging to the left side, even though it still fell at the same location relative to the patient (figure 1B). Such results seem consistent with the existence of object-centered representations in the parietal cortex.

Many other studies claim to have found evidence for object-centered neglect (Driver and Halligan 1991; Arguin and Bub 1993; Halligan and Marshall 1994), but as pointed out by Driver et al. (1994), their results could be explained instead by what we will call *relative* neglect in strictly egocentric coordinates (see also Kinsbourne 1987; Mozer and Behrmann 1990; Desimone and Duncan 1995; and Pouget and Sejnowski 1997a for variations on this idea). When confronted with two competing objects, patients may neglect the one farther to the left even if both fall in the right hemispace egocentrically, and likewise for the subparts of a single object (Driver and Halligan 1991; Driver et al. 1992; Driver et al. 1994; Halligan and Marshall 1994). Thus, it appears that the *relative* position of objects or their subparts is just as important as their *absolute* position with respect to the patient. This phenomenon can be explained if the lesion induces a *gradient* of neglect with increasing severity in the egocentric contralesional direction (Kinsbourne 1987; Driver et al. 1994; Pouget and Sejnowski 1997a).

Neural basis: There have been several attempts to relate neglect to what is known of the response properties of parietal neurons from single-cell recordings in monkeys (Mozer and Behrmann 1990; Duhamel et al. 1992; Anderson 1996; Mozer, Halligan, and Marshall 1997; Pouget and Sejnowski 1997a; see also MODELING NEUROPSYCHOLOGICAL DEFICITS

and SPATIAL PERCEPTION). Such models generally rely on cells in the parietal cortex having retinotopic receptive fields, with each hemisphere tending to overrepresent the contralateral visual field (see, however, Duhamel et al. 1992 for a different approach). Consequently, a right lesion leads to a neuronal gradient in which the left side of the retina is less strongly represented than the right side, producing left neglect. In such models, there is no particular dividing midline such that any stimulus to the left of it is invariably neglected. Instead, neglect depends only on the *relative* position of competing stimuli, as discussed above, with objects or object parts that are farther toward the retinal left than their competitors being neglected. These models readily capture the behavior of patients in tasks such as line bisection, line cancellation, and in some of the paradigms discussed above that have revealed relative neglect.

Parietal neurons, however, do not simply respond to visual stimulation, but also integrate sensory responses with posture signals such as eye and head position. Andersen and colleagues have shown that the retinotopic receptive fields of parietal cells are *gain-modulated* by such posture signals (Andersen, Essick, and Siegel 1985; Andersen et al. 1997; see figure 1C for an example in which the visual receptive field of a cell is modulated by eye position). These response properties can be modeled as *basis functions* of the inputs, a type of function which is particularly well-suited to the computational demand of sensorimotor transformations (Pouget and Sejnowski 1997b).

A simulated unilateral lesion in such a basis-function representation produces an impairment that resembles clinical neglect, in that the deficit affects a mixture of egocentric frames of reference as found in patients (Pouget and Sejnowski 1997a). This approach can also be generalized to encompass object-centered neglect, as in the Driver et al. (1994) experiment depicted in figure 1B, by considering the perceived orientation of the object as providing a signal analogous to the posture signals integrated by the basis functions (Deneve and Pouget in press). This basis-function framework can explain why neglect may be influenced by stimulus position relative to the retina, head, body, other objects, and other parts of the same object, all at the same time, without requiring cells in the parietal cortex to have visual receptive fields explicitly defined in any single one of these frames of reference.

Neglect remains a fascinating but disabling disorder, which still poses a major challenge to rehabilitation. Its further study will hopefully lead to more effective treatments, as well as reveal more about how the brain represents space, and allows for selective spatial attention.

Visual Object Recognition, AI

Visual object recognition, a subdiscipline of machine vision, addresses the problem of finding and identifying objects in images. Research in this area primarily focuses on techniques that use models of specific objects, based on properties such as shape and appearance. Such techniques are referred to as *model-based recognition* methods, because of the strong reliance on prior models of specific objects. In contrast, human visual recognition is characterized by an ability to recognize novel objects for which the observer has no specific prior model. Such generic recognition involves the ability to perform CATEGORIZATION on the basis of abstract reasoning about objects, such as inferring their form from how they function. While there has been some study of generic object recognition in MACHINE VISION, the primary focus has been on model-based recognition.

Most approaches to model-based object recognition involve comparing an unknown image against stored object models, in order to determine whether any of the models are present in the image. Many techniques perform both recognition and localization, both identifying what objects are present in the image and recovering their locations in the

image or in the world. Object recognition is often phrased as a search problem, involving several kinds of search, including search over possible locations of the object in the image, search over possible viewpoints of the observer with respect to the object, and search over possible object models. Not all recognition tasks involve all of these kinds of search. For example, recognizing faces in a database of mug shots need not involve search over possible viewpoints because the pictures are all frontal views.

A number of factors contribute to the difficulty of OBJECT RECOGNITION tasks. One factor is the complexity of the scene. This includes the number of objects in the image, the presence of objects that are touching and partly occluding one another, backgrounds that are highly textured or cluttered, and poor lighting conditions. Another factor is the generality of the object models. Objects that are composed of rigidly connected subparts, such as a pair of scissors, are harder to recognize than rigid objects such as a car. Nonrigid objects, such as a cat, are even more difficult to recognize. A third factor is the number of object models that a recognition system must consider. Many systems can only handle a small number of objects, in effect considering each model separately. A fourth factor is the complexity of the viewing transformation that maps the model coordinate frame to the image coordinate frame. For example, if an object can be viewed from an arbitrary 3-D position, then the different views of the object may look very different.

There is a trade-off in current approaches to object recognition: either it is possible to recognize objects from a small set of models appearing in complex scenes (with clutter and unknown viewpoints), or it is possible to recognize objects from a large set of models appearing in simple scenes (with a uniform background and known viewpoint). The remainder of this article will provide a brief overview of some of the major approaches used in object recognition. First, we consider search-based techniques, which operate by comparing local features of the model and image. These kinds of techniques are generally limited to a small set of object models, but handle complex images. Then we consider indexing approaches, which operate by computing a key which is used as an index into a large table or database of models. These techniques are generally limited to simple scenes.

Feature-based approaches to object recognition generally operate by recovering a correspondence between local attributes, or features, of an image and an object model. The features are usually geometrical, and are often based on detecting intensity edges in the image (places where there is a large change in image brightness). Brightness changes often correspond to the boundaries of objects or to surface markings on the objects. Local geometrical features can be simple, like corners, or involve more complex fitting of geometrical primitives, such as quadratic curves. The 2-D geometrical descriptions extracted from an image are compared with geometrical models, which may be either 2-D or 3-D.

Three major classes of feature-matching recognition methods can be identified, based on how the search for possible matches between model and image features is performed: (1) *correspondence methods* consider the space of possible corresponding features; (2) *transformation space methods* consider the space of possible transformations mapping the model to the image; and (3) *hypothesize and test* methods consider k-tuples of model and data features. A more detailed treatment of geometrical search methods can be found in Grimson (1990). In addition there are geometrical matching methods which make use of more global shape descriptors, such as entire silhouettes of objects (e.g., Kriegman and Ponce 1990).

Indexing-based approaches to object recognition are based on computing numerical descriptors of an image or portion of an image. These descriptors are then used as keys to index (or hash) into a table of object models. The most effective such methods are based on storing many 2-D views of each object. Such approaches are generally referred to as view-based because they explicitly store images or keys corresponding to each viewpoint from which an object could be seen. Another kind of indexing-based approach to recognition is based on computing *invariant descriptions* of objects that do not change as the viewpoint changes. The invariant properties of objects are generally geometrical. More information about invariant-based recognition methods can be found in Mundy and Zisserman (1992).

The most successful view-based approaches to object recognition are based on subspace techniques, which use principal components (or eigenvector) analysis to produce keys that form a concise description of a given set of images (e.g., Murase and Nayar, 1995). The main advantage of such methods is that they are useful for tasks in which there is a large database of objects to be searched. The main disadvantage is that in general they do not work well with occlusion or with complex scenes and cluttered backgrounds, because the measure of similarity is sensitive to such variation. A different view-based approach is taken in Huttenlocher, Klanderman, and Rucklidge (1993), which is based on computing distances between point sets using a measure of image similarity based on the Hausdorff distance. This similarity measure is designed to allow for partial occlusion and the presence of background clutter.

Visual Processing Streams

Vision, more than any other sense, provides us with information about the world beyond our bodies. The importance of vision in our daily lives, and the lives of our primate cousins, is reflected in the fact that we have large and highly mobile eyes. But our reliance on vision is also evident in the large amount of brain devoted to visual processing. It has been estimated, for example, that more than half of the CEREBRAL CORTEX in the macaque monkey is involved in processing visual signals.

Although the RETINA projects to a number of different nuclei in the primate brain, one of the most prominent projections is to the dorsal part of the lateral geniculate nucleus (LGNd), a multilayered structure in the THALAMUS. New projections arise from the LGNd and project in turn to an area in the occipital lobe of the cerebral cortex known variously as striate cortex, area 17, primary visual cortex, or V1. Beyond V1, visual information is conveyed to a bewildering number of extrastriate areas (for review, see Zeki 1993). Despite the complexity of the interconnections between these different areas, two broad "streams" of projections from V1 have been identified in the macaque monkey brain: a ventral stream projecting eventually to the inferotemporal cortex and a dorsal stream projecting to the posterior parietal cortex (Ungerleider and Mishkin 1982). Of course, these regions also receive differential inputs from a number of other subcortical visual structures, such as the superior colliculus (via the thalamus). Although some caution must be exercised in generalizing from monkey to human, it seems likely that the visual projections from primary VISUAL CORTEX to the temporal and parietal lobes in the human brain may involve a separation into ventral and dorsal streams similar to that seen in the monkey.

In 1982, Ungerleider and Mishkin argued that the two streams of visual processing play different but complementary roles in the processing of incoming visual information. According to their original account, the ventral stream plays a critical role in the identification and recognition of objects, while the dorsal stream mediates the localization of those same objects. Some have referred to this distinction in visual processing as one between object vision and spatial vision—"what" vs. "where." Support for this idea came from work with monkeys. Lesions of inferotemporal cortex in monkeys produced deficits in their ability to discriminate between objects on the basis of their visual features, but did not affect their performance on a spatially demanding "landmark" task. Conversely, lesions of the posterior parietal cortex produced deficits in performance on the landmark task but did not affect object discrimination learning. Although the evidence for the original Ungerleider and Mishkin proposal initially seemed quite compelling, recent findings from a broad range of studies in both humans and monkeys has forced a reinterpretation of the division of labor between the two streams (for review, see Jeannerod 1997; Milner and Goodale 1995).

Some of the most telling evidence against a simple "what" vs. "where" distinction has come from studies with neurologically damaged patients. It has been known for a long time that patients with damage to the human homologue of the dorsal stream have difficulty reaching in the correct direction to objects placed in different positions in the visual field contralateral to their lesion (even though they have no difficulty reaching out and grasping different parts of their own body indicated by the experimenter). Although this deficit in visually guided behavior, know clinically as optic ataxia, has often been interpreted as a failure of spatial vision, two other sets of observations in these patients suggest a rather different interpretation. First, patients with damage to this region of cortex often show an inability to rotate their hand or open their fingers properly to grasp an object placed in front of them, even when it is always placed in the same location. Second, these same patients are able to describe the orientation, size, shape, and even the relative spatial location of the very objects they are unable to grasp correctly (Perenin and Vighetto 1988). Clearly, this pattern of deficits and spared abilities cannot be explained by appealing to a general deficit in SPATIAL PERCEPTION.

Other patients, in whom the brain damage appears to involve ventral rather than dorsal stream structures, show the complementary pattern of deficits and spared visual abilities. Such patients have great difficulty recognizing common objects on the basis of their visual appearance (visual agnosia), but have no problem grasping objects placed in front of them or moving through the world without bumping into things. Consider, for example, patient D.F., a young woman who suffered damage to her ventral stream pathways as a result of anoxia from carbon monoxide poisoning. Even though D.F. is unable to indicate the size, shape, and orientation of an object, either verbally or manually, she shows normal preshaping and rotation of her hand when reaching out to grasp it (Goodale et al. 1991). Appealing to a general deficit in "object vision" does not help us to understand her problem. In her case, she is able to use visual information about the location, size, shape, and orientation of objects to control her grasping movements (and other visually guided movements) despite the fact that she is unable to perceive those same object features.

Goodale and Milner (1992) have suggested that one way to understand what is happening in these patients is to think about the dorsal stream not as a system for spatial vision per se, but rather as a system for the visual control of skilled action. To pick up a coffee cup, for example, not only must we have information about the spatial location of the cup with respect to our hand, but we must also have information about its size, shape, and orientation so that we can pick it up efficiently. The evidence from patients, and from studies with subjects with normal vision, suggests that the visual processing involved in the control of this kind of skilled behavior may take place quite independently of the visual processing mediating what we normally think of as visual perception. Indeed, Goodale and Milner have suggested that our visual experience of the world and the objects within it depends on visual processing in the ventral stream. In short, both streams process information about the orientation, size, and shape of objects, and about their spatial relations; both streams are also subject to modulation by ATTENTION. Each stream, however, deals with the incoming visual information in different ways. The ventral stream transforms visual information into perceptual

representations that embody the enduring characteristics of objects and their spatial relations with each other. The visual transformations carried out in the dorsal stream, which utilize moment-to-moment information about the disposition of objects within egocentric frames of reference, mediate the control of goal-directed acts. Such a division of labor not only accounts for the behavioral dissociations observed in neurological patients with damage to different regions of the cerebral cortex but it is also supported by a wealth of anatomical, electrophysiological, and behavioral studies in the monkey (for review, see Milner and Goodale 1995).

Adaptive goal-directed behavior in humans and other primates depends on the integrated function of both these streams of visual processing. The execution of a goal-directed action might depend on dedicated control systems in the dorsal stream, but the selection of appropriate goal objects and the action to be performed depends on the perceptual machinery of the ventral stream. One of the important questions that remains to be answered is how the two streams interact both with each other and with other brain regions in the production of purposive behavior.

Visual Word Recognition

The goal of research on visual word recognition is to understand the kinds of capacities that underlie the rapid and almost effortless comprehension of words in READING, how these capacities are acquired, and the impairments that occur developmentally and following brain injury (DYSLEXIA). Visual word recognition has also provided a domain in which to explore broader theoretical issues concerning knowledge representation, learning, perception, and memory; for example, it played a significant role in the development of both modular (MODULARITY OF MIND) and connectionist (COGNITIVE MODELING, CONNECTIONIST) approaches to cognition.

Studies of EYE MOVEMENTS in reading indicate that most words are fixated once for durations ranging from 50 to 250 ms. Short function words are sometimes skipped and longer words may be fixated more than once. Word recognition speeds vary depending on reading skill, the type of text, and how carefully it is being read; large increases in reading speed can only be achieved with significant loss of comprehension, as in skimming. The main bottleneck is perceptual: the perceptual span is approximately four letters to the left of fixation and fifteen to the right when reading from left-to-right (it is asymmetrical to the left in reading languages such as Hebrew). Letter identities can be determined only over a smaller range, approximately five to six letters; further from fixation only letter shape and length are perceived (Pollatsek and Rayner 1990).

A long-standing issue for reading researchers and educators is whether words are recognized on a visual basis or by first computing a phonological representation (see PHONOLOGY). Using visual information might seem to be more efficient because it involves a direct mapping from spelling to meaning; using phonology (translating from orthography to phonology to meaning) involves an extra step. However, a compelling body of research suggests that skilled readers compute phonological information as part of the recognition process (e.g., Van Orden 1987). Studies of learning to read have also highlighted the important role of phonological information (Wagner and Torgesen 1987). The quality of prereading children's knowledge of the structure of spoken language is a good predictor of later reading skill; children who are good readers are better able to translate from spelling to sound; and many dyslexic persons exhibit minor deviations in their representation of spoken language that disrupt reading acquisition (e.g., Bradley and Bryant 1983). Despite this evidence, reading education in most English-speaking countries attempts to discourage children from using phonological information on the mistaken view that it discourages reading efficiency. There is also strong evidence that learning to read an orthography has a reciprocal impact on phonological representation (Morais et al. 1986).

One barrier to using phonology in reading English and many other writing systems would seem to be the quasi-regular (Seidenberg and McClelland 1989) character of orthographic-phonological correspondences: most words can be pronounced "by rule" (e.g., *gave, mint*) but there are many exceptions that deviate from the rules in differing degrees (e.g., *have, pint*). This observation led to the development of "dual-route" models in which there are separate mechanisms for reading rule-governed words and exceptions (Coltheart 1978). Connectionist models provide an alternative approach in which a single network consisting of distributed representations of spelling, sound, and meaning is used for all words. Such networks can encode both "rule-governed" forms and "exceptions," while capturing the overlap between them. Whereas the older models involved parallel, independent visual and phonological recognition pathways, connectionist models permit continuous pooling of information from both sources until a word's meaning has been computed.

Research on WRITING SYSTEMS organized along different principles (see papers in Frost and Katz 1992) suggests that there may be more commonalities in how they are read than the differences among them might otherwise suggest. One major difference among writing systems is in how transparently they represent phonological information. For example, whereas the pronunciations of orthographic patterns in Finnish and Serbo-Croatian are highly predictable, many English words are irregularly pronounced, and the nonalphabetic Chinese writing system provides only partial cues to pronunciation. These differences have often led to suggestions that one or another writing system is optimal for learning to read. Writing systems exhibit trade-offs among other design features, however, that tend to level the playing field (Seidenberg 1992). For example, English has many irregularly pronounced words but they tend to be very short and to cluster among the highest-frequency words in the language; hence they are likely to be easy to learn and process. Serbo-Croatian is more transparent at the level of letters and phonemes but there are few monosyllabic words and there is also a complex system governing syllabic stress. The pronunciations of words in Hebrew can be reliably predicted from their spellings except that the vowels are normally omitted. Studies of reading acquisition in different writing systems do not suggest large differences in the average rate at which children learn to read.

A major unresolved issue concerns the role of subword units such as syllables and morphemes (see MORPHOLOGY) in word recognition. Does reading a word such as *farmer* involve parsing it into the morphemes [farm] + [er] or merely using orthographic and phonological information? Although several studies have provided evidence for lexical decomposition, the extent to which it occurs in reading is not known. Any decomposition scheme runs up against what to do with cases like *corner* or *display,* which appear to be morphologically complex but are not. Connectionist models have also begun to provide an alternative account in which morphological structure reflects an emergent, interlevel representation mediating correlations among orthography, phonology, SEMANTICS, and aspects of grammar.

Other research has addressed how readers determine the meanings of words and integrate them with the contexts in which they occur. Words in texts tend not to be very predictable, which makes using context to guess them an inefficient strategy. The computation of a word's meaning is nonetheless constrained by context, as is clearly the case for ambiguous words such as *rose* and *plane* but also relatively unambiguous words such as *cat.* For example, in a sentence

about petting, the word *cat* may activate the feature <fur>; in a context about getting scratched, *cat* will activate <claws> (Merrill, Sperber, and MacCauley 1981).

Impairments in word recognition are characteristic of developmental dyslexia. Dyslexia is often associated with phonological impairments that interfere with learning the relationship between the written and spoken forms of language (Liberman and Shankweiler 1985). In other cases, dyslexic persons have normal phonology but are developmentally delayed: they read like much younger children. This delay may reflect impoverished experience or other deficits in perception or learning (Manis et al. 1996).

Dyslexia also occurs as a consequence of neuropathologic discorders such as Alzheimer's disease or herpes encephalitis. Three major subtypes have been identified: phonological dyslexia, in which the main impairment is in pronouncing novel letter strings such as *nust;* surface dyslexia, in which the main impairment is in reading irregularly pronounced words such as *pint;* and deep dyslexia, in which the patient makes semantic paraphasias such as pronouncing *sympathy* "orchestra" (Shallice 1988). Current research focuses on using computational models of normal word recognition to explain how these patterns of impairment could arise (see MODELING NEUROPSYCHOLOGICAL DEFICITS). For example, connectionist models of normal performance can be "lesioned" to create the reading impairments seen in several types of patients (Plaut et al. 1996). A growing body of neuroimaging evidence is beginning to clarify how the representations and processes specified in these models are realized in the brain.

von Neumann, John

John von Neumann was born in Hungary in 1903 and died in the United States in 1957. He was without doubt one of the great intellects of the century, and one of its most distinguished mathematicians. At the time of his death he was a member of the Institute for Advanced Study, at Princeton, New Jersey.

Von Neumann's scientific interests were very broad, ranging through mathematical logic, automata theory and computer science, pure mathematics—analysis, algebra and geometry, applied mathematics—hydrodynamics, meteorology, astrophysics, numerical computation, game theory, quantum and statistical mechanics, and finally to brain mechanisms and information processing. In addition von Neumann was heavily involved in the Manhattan Project both at the University of Chicago and at Los Alamos. After World War II he became a member of the Atomic Energy Commission, and of course he was a key figure in the early U.S. development of general purpose digital computers.

So far as the cognitive sciences are concerned, von Neumann's main contributions were somewhat indirect. Together with Oscar Morgenstern he developed a mathematical model for GAME THEORY that has many implications for human cognitive behavior. He also published two papers

and one short monograph on AUTOMATA theory and related topics.

The first paper, published in the 1951 proceedings of the Hixon Symposium, was entitled "The General and Logical Theory of Automata." In it von Neumann introduced what are now known as cellular automata, and discussed in some detail the problem of designing a self-reproducing automaton. In some ways this is a remarkable paper in that it seems to anticipate the mechanism by which information is transmitted from DNA via messenger RNA to the ribosomal machinery underlying protein synthesis in all pro- and eukaryotes. Of more relevance for cognitive science was von Neumann's analysis of the logic of self-reproduction, which he showed to be closely related to Gödel's work on metamathematics and logic (see GÖDEL'S THEOREMS and SELF-ORGANIZING SYSTEMS). His starting point was MCCULLOCH and PITTS's ground-breaking work on the mathematical representation of neurons and neural nets.

The McCulloch-Pitts neuron is an extremely simplified representation of the properties of real neurons. It was introduced in 1943, and was based simply on the existence of a threshold for the activation of a neuron. Let $u_i(t)$ denote the state of the ith neuron at time t. Suppose $u_i = 1$ if the neuron is active, 0 otherwise. Let $\varnothing$ [v] be the Heaviside step function, $= 1$ if $v \geq 0$, 0 if $v < 0$. Let time be measured in quantal units Δt, so that $u(t + \Delta t) = u(n\Delta t + \Delta t) = u(n + 1)$. Then the activation of a McCulloch-Pitts neuron can be expressed by the equation:

$$u_i(n + 1) = \varnothing[\Sigma_j w_{ij} u_j(n) - v_{TH}]$$

where w_{ij} is the strength or "weight" of the ($j \to i$)th connection, and where v_{TH} is the voltage threshold. Evidently activation occurs iff the total excitation $v = S_j w_{ij} u_j(n) - v_{TH}$ reaches or exceeds 0.

What McCulloch and Pitts discovered was that nets comprising their simplified neural units could represent the logical functions AND, OR, NOT and the quantifiers $\forall$ and $\exists$. These elements are sufficient to express most logical and mathematical concepts and formulas. Thus, in von Neumann's words, "anything that you can describe in words can also be done with the neuron method." However von Neumann also cautioned that "it does not follow that there is not a considerable problem left just in saying what you think is to be described." He conjectured that there exists a certain level of *complexity* associated with an automaton, below which its

description and embodiment in terms of McCulloch-Pitts nets is simpler than the original automaton, and above which it is more complicated. He suggested, for example, that "it is absolutely not clear a priori that there is any simpler description of what constitutes a visual analogy than a description of the visual brain." The implications of this work for an understanding of the nature of human perception, language, and cognition have never been analyzed in any detail.

In his second paper, "Probabilistic Logics and the Synthesis of Reliable Organisms from Unreliable Components," published in 1956 (but based on notes taken at a lecture von Neumann gave at CalTech in 1952), von Neumann took up another problem raised by McCulloch, of how to build *fault tolerant* automata.

Von Neumann solved the reliability problem in two different ways. His first solution was to make use of the error-correcting properties of majority logic elements. Such an element executes the logical function m(a,b,c) = (a AND b) OR (b AND c) OR (c AND a). The procedure is to triplicate each logical function to be executed, that is, execute each logical function three times in parallel, and then feed the outputs through majority logic elements.

Von Neumann's second solution to the reliability problem was to multiplex, that is, use N McCulloch-Pitts circuits to do the job of one. In such nets one bit of information (the choice between "1" and "0") is signaled not by the activation of one neuron, but instead by the synchronous activation of many neurons. Let Δ be a number between 0 and 1. Then "1" is signaled if ξ, the fraction of activated neurons involved in any job, exceeds Δ; otherwise "0" is signaled. Evidently a multiplexed net will function reliably only if is close to either 0 or 1. Von Neumann achieved this as follows. Consider nets made up entirely of NAND logic functions, as shown in figure 2.

Von Neumann subsequently proved that if circuits are built from such elements, then for N large, $\Delta = 0.07$ and the probability of an element malfunctioning, $\varepsilon < 0.0107$, the probability of circuit malfunction can be made to decrease with increasing N. With $\varepsilon = 0.005$, von Neumann showed that for logical computations of large depth the method of multiplexing is superior to majority logic decoding.

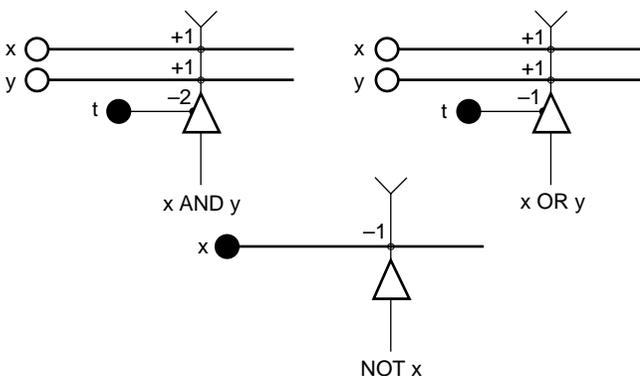
McCulloch was aware of the fact that the central nervous system (CNS) seems to function reliably in many cases, even in the presence of brain damage, or of fluctuations in baseline activity. It was therefore natural to look at how neural networks could be designed to achieve such performance.


Figure 1. McCulloch-Pitts neurons. Each unit is activated iff its total excitation reaches or exceeds 0. For example, the first unit is activated iff both the units x and y are activated, for only then does the total excitation, $(+1)x + (+1)y$ balance the threshold bias of –2 set by the threshold unit, t, whenever both x and y equal +1 (activated). The t-unit is always active. The numbers (±1), etc. shown above are called "weights." Positive weights denote "excitatory" synapses, negative weights "inhibitory" ones. Similarly, open circles denote excitatory neurons; filled circles, inhibitory ones.

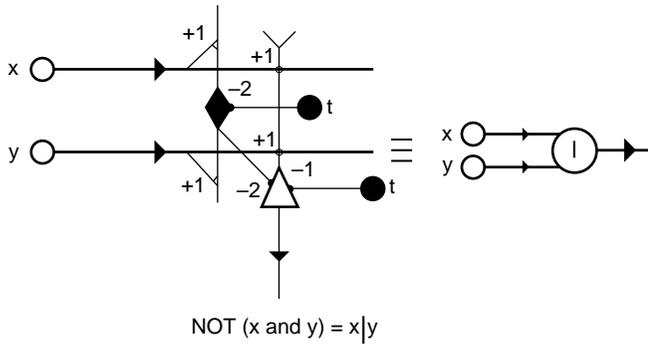
NOT (x and y) = x|y


Figure 2. NAND logic function implemented by a McCulloch-Pitts net comprising two units.

Von Neumann's work triggered a number of efforts to improve on his results, and led directly to the introduction of parallel distributed processing (Winograd and Cowan 1963), and indirectly to work on perceptrons and adalines, and associative memories.

Von Neumann's last publication in this area was the monograph "The Computer and the Brain," published posthumously in 1958, and based on his 1956 manuscript prepared for the Silliman Lectures at Yale University. In this monograph von Neumann outlined his view that computations in the brain are reliable but not precise, statistical and not deterministic, and essentially parallel rather than serial (see also COMPUTATION AND THE BRAIN). Had he lived he would have undoubtedly developed these themes into a detailed theory of brain-like computing. One can see in the many developments in artificial NEURAL NETWORKS since 1957 many echoes of von Neumann's ideas and insights.

Vygotsky, Lev Semenovich

Lev Semenovich Vygotsky (1896–1934) grew up in Gomel', a provincial town in Belorussia. From 1913 to 1917 he studied history, philosophy, and law at universities in Moscow, and he returned to Gomel' from 1917 to 1924, where he taught literature and psychology at several schools and colleges. He also wrote extensively about language, pedagogy, drama, and poetry during this period.

After a brilliant presentation at a psychoneurological conference in 1924, Vygotsky was invited to join the staff of the Moscow Psychological Institute, and he continued to live and work primarily in Moscow until he died of tuberculosis in 1934. During the final decade of his life Vygotsky helped found several research and teaching institutions in the Soviet Union; he conducted extensive empirical studies on the history and ontogenesis of language and thought (Vygotsky 1987; Vygotsky and LURIA 1993); and he wrote about philosophy, pedagogy, and psychology (Vygotsky 1997), including the psychology of disabilities (Vygotsky 1993).

Throughout his career Vygotsky's fundamental concern was with how human mental functioning is shaped by its historical, cultural, and institutional context. The theoretical framework he developed for dealing with this problem can be summarized in a few basic themes. The first of these was his commitment to a genetic, or developmental, method. From this perspective mental functioning is understood by examining its origins and the transformations it undergoes in development. Vygotsky's formulation of this theme went well beyond the focus of contemporary accounts of child and lifespan psychology, seeking to address how mental functioning is shaped by phylogenetic, historical, and microgenetic, as well as ontogenetic, forces.

The second theme that runs throughout Vygotsky's writings is the claim that higher, uniquely human mental functioning in an individual has its origins in social processes and retains a "quasi-social" nature (Vygotsky 1981a). This claim led him to criticize psychological accounts that attempt to derive social from individual processes. In contrast to such approaches he argued that higher mental functions appear first on the social, or "intermental" plane— often in the form of joint, adult-child problem-solving activity—and only then emerge on the intramental, individual plane. The nature of intermental functioning and its role in shaping intramental processes has been the focus of recent research on the "zone of proximal development" (Vygotsky 1978) and related notions such as "scaffolding."

Vygotsky's claims about the social origins of individual mental functioning have some striking implications that run counter to widely held assumptions in psychology. Because he viewed terms such as "memory" and "thinking" as apply-

ing to social as well as individual processes, he argued for the need to identify an analytic unit that is not tied to the individual. His candidate for this unit was word meaning— a unit that mediates both intermental and intramental functioning. Furthermore, he argued that the particular form that mental processes take on the intramental plane derives largely from their intermental precursors. This points to the importance of examining linguistic and social interactional dimensions of intermental functioning as a means for understanding mental processes in the individual.

The third theme that runs throughout Vygotsky's writings is that higher mental processes are mediated by socio-culturally evolved tools and signs (Vygotsky 1981b). Under the heading of mediation by signs, or semiotic mediation, Vygotsky included items such as maps, mathematical formulas, and charts, but he was particularly interested in human language. His claims about mediation lie at the center of his approach, something that is reflected in the analytic primacy he gave to this, over the two other themes. Vygotsky identified major turning points, or "revolutions" in development by the appearance of new forms of sign use, and he formulated intermental and intramental functioning in terms of semiotic mediation. The developmental relationship that he saw between these two planes existed precisely because language and other sign systems mediate both and hence serve to link them.

Vygotsky (1986) developed his theoretical claims in several empirical studies. For example, he conducted investigations on the emergence of abstract concepts and their relationship to language development, and he examined the relationship between external, social speech and inner speech in the individual. In the latter connection he analyzed a form of speech used by children in which they speak to themselves as they engage in problem-solving or fantasy play. Because such speech does not appear to take listeners into account, Piaget (1955) had labeled it "egocentric." Though not disputing many of Piaget's basic observations, Vygotsky disagreed with his interpretation. Instead of viewing such speech as a manifestation of children's egocentricity, a symptom that dies away with the increasing ability to understand others' perspectives, Vygotsky argued that egocentric speech plays an essential role in the transition from social speech to inner speech on the intramental plane. He concluded that instead of simply disappearing with age, this speech form "goes underground" to become inner speech, thereby shaping mental functioning in a uniquely human way.

Walking and Running Machines

Humans have built aircraft, submarines, and other machines that imitate or improve upon animal locomotion, but the design and construction of feasible walking and running machines remains a challenge. From a practical perspective, legged robots offer several potential advantages over wheeled vehicles. They can traverse rough terrain by stepping across or jumping over obstacles using isolated ground contacts rather than the continuous path of support required by wheels. This agility is important in difficult environments with few suitable footholds. Unlike wheeled vehicles, legged robots have an active suspension system that can decouple variations in the terrain from the motion of the body and provide a steady platform for a sensor or payload. From a scientific perspective, researchers would like to construct legged vehicles with the capabilities of animals to

Figure 1. The Adaptive Suspension Vehicle crossing uneven terrain. Photograph reprinted by permission of The Ohio State University.

better understand the principles of locomotion in biological systems. Over the past hundred years, researchers have combined innovative engineering with scientific observations of the agility and efficiency of legged animals to construct many types of legged mechanisms.

Walking and running machines are divided into two categories based on the stability of their motion: passively stable and dynamically stable. The vertical projection of the center of gravity of a *passively stable system* always remains within the convex region formed by the contact points of the feet on the ground. This region is called the *support polygon*. Statically stable machines can stop moving at any time in the locomotion cycle and maintain balance. They typically have four or six legs but may be bipeds with large feet. In contrast, *dynamically stable systems* utilize dynamic forces and feedback to maintain control and are stable in a limit cycle that repeats once each stride. Dynamically stable machines have been built with one, two, and four legs. Because dynamically stable systems are more difficult to design and analyze, the early development of legged robots focused on statically stable machines.

The earliest walking machines used gears to produce fixed patterns of leg motion for walking. The fixed patterns prevented these machines from responding in a flexible fashion to variations in terrain. Nevertheless, their construction initiated the study of leg mechanisms and gait patterns and they remain useful comparisons for the evaluation of current robots. A more agile walking machine was built in 1968 by Ralph Mosher at General Electric (Liston and Mosher 1968). An eleven-foot-tall, three-thousand-pound machine with twelve degrees of freedom, the walking truck was hydraulically powered and capable of climbing over obstacles, pushing large objects, and walking steadily at five miles per hour. The machine was controlled by a human driver who used his arms to control the front legs and his legs to control the rear legs of the machine. Force feedback allowed the driver to sense the balance of the system, but the machine was difficult and tiring to control even after substantial training. Because the machine was human controlled, it was not an autonomous legged vehicle, but it provided a convincing demonstration of the agility possible with a mechanical legged system.

Digital computers provided the numerical computation necessary to develop automatically controlled walking robots in the 1970s. Computers were used to determine footholds that maintained stability, to solve the kinematic equations for positioning the legs, to provide feedback control based on the body orientation and leg positions, and to plan paths through the environment (see PLANNING). Several of these early machines were hexapods because six-leg designs allow walking with a stable, alternating tripod gait. The Ohio State University Hexapod was built in 1977 by Robert McGhee using electric drill motors (Bucket 1977; McGhee 1983). A second hexapod from OSU, the Adaptive Suspension Vehicle, was a three-ton vehicle with a human driver but automatic positioning of the legs under most terrain conditions (Song and Waldron 1989) as shown in figure 1. The first computer-controlled, self-contained walking robot was a hexapod, built by Sutherland in 1983 (Raibert and Sutherland 1983). The first commercially available legged robot was the ODEX 1 "Functionoid" built by Odetics in 1983 (Russell 1983).

Research in legged locomotion has proceeded primarily along two lines: leg design and control. Design considers the geometries of leg arrangements and mechanisms to increase motion, strength, speed, or reliability, decrease energy requirements or weight, or simplify control. For example, Shigeo Hirose's 1980 PV II quadruped used a pantograph leg mechanism that allowed actuators independently to control each degree of freedom in Cartesian space, considerably simplifying the kinematic equations (Hirose and Umetani

Figure 2. The planar biped running right to left, up and down a short flight of stairs. Photograph reprinted by permission of the MIT Leg Laboratory.

1980). The Ambler, a thirty-foot-tall, hexapod planetary explorer built at Carnegie Mellon University, used an orthogonal leg design to simplify the kinematic equations (Simmons et al. 1992). The design kept the outer segments of the legs vertical while positioning them with inner segments that rotated in a horizontal plane. Dante, also built at CMU, used sets of legs mounted on sliding frames. After one frame's legs lifted, the frame slid forward and then lowered the legs for the next step. In 1994, Dante II successfully descended into an active volcano in Alaska and analyzed high temperature gases (Wettergreen, Pangels, and Bares 1995).

Issues of control have been explored most often in bipedal walking and running robots. Computer-controlled bipeds that used large feet to allow static stability were built in 1972 (Kato and Tsuiki 1972). These were followed by quasi-static walkers that included a dynamic phase during which the machine fell forward onto the next stance foot (Kato et al. 1983). The first dynamically stable walking bipeds were designed by Miura and Shimoyama (1984). These machines used stiff legs that were raised by rotating the hip and produced motion that resembled walking on stilts.

In the early and mid-1980s, Raibert and colleagues at MIT and CMU designed dynamically stable running monopods, bipeds, and quadrupeds. These machines used springs in the legs to provide a passive rebound during the stance phase and hydraulic actuators to provide thrust and to control the leg angle (Raibert 1986). The control systems for these machines divided the complex system dynamics into three largely decoupled problems: hopping height, forward speed, and body attitude. Hopping height was maintained by extending the actuator in series with the leg spring. Body attitude was controlled by applying a torque at the hip while the foot was in contact with the ground. Forward running speed was controlled by positioning the foot at touchdown. A finite state machine determined the active control laws at any given moment. In addition to running, these machines also used a variety of gaits (Raibert, Chepponis, and Brown

1986), ran fast (Koechling and Raibert 1988), performed flips (Hodgins and Raibert 1990), and ran up and down stairs (Hodgins and Raibert 1991), as shown in figure 2.

Further exploration of control for legged robots has led to the discovery of an elegant class of legged robots with no computer control at all. Called *passive walkers,* these machines walk down an inclined slope but have no internal source of energy. The length of the legs and mass distribution are chosen so that the legs swing forward and the knees straighten for touchdown without actuation (McGeer 1990a, 1990b). Controllers for passive running have also been proposed (McGeer 1989; Ringrose 1997; Ahmadi and Buehler 1995). Recently, several researchers have begun to build a formal theoretical framework for analyzing the stability of dynamic running machines. This approach models dynamic robots as simpler systems such as spring/mass systems and then proves stability of the model given a particular set of control laws (Koditschek and Buehler 1991; Schwind and Koditschek 1997).

Although the dream of an artificial legged creature such as C-3PO from the movie *Star Wars* has not been realized, research into running and walking machines has furthered our understanding of legged locomotion in machines and animals. Researchers have explored a variety of geometries, mechanisms, control techniques, gaits, and motion styles for legged machines, and the resulting insights have enabled new applications and designs, as well as a growing theoretical foundation for legged locomotion and control.

Wh-Movement

A characteristic feature of natural languages is the fact that certain syntactic categories are systematically found "out of place." Normally, in English, a direct object follows the verb on which it depends (one says *I had seen it* rather than *I had it seen* or *It I had seen*). Nonetheless, if the object is interrogated, a *wh*-word (so called because most interrogative words in English begin with the letters *wh—who, what, which, when, where, why,* etc.) is used and "displaced" to first position in (root or subordinate) interrogative sentences (*What had you seen? I asked what you had seen*).

Such *wh*-movement is found in other contructions as well (relatives, exclamatives, concessives, etc.: *The film which you had seen . . .* ; *What a nice house you have! Whatever you do, . . .* , etc.) and is but an instance of a more general movement operation which "displaces" syntactic categories other than *wh*-phrases: for instance, nominal phrases and verbs (on the latter, see HEAD MOVEMENT).

After Chomsky 1977, 1986, 1995, and the references cited there, a better understanding is available of many of the properties of *wh*-movement; for example, (a) the nature of the position the *wh*-phrase moves to; (b) the rationale for such a movement; and (c) the conditions under which such movement is permitted or blocked.

Modern linguistic theory considers sentence structure as characterized by the alternation of a head (a syntactic atom such as a verb, noun, adjective, determiner, complementizer—that is, a subordinating conjunction—etc.) and a phrase (a larger syntactic unit built around a head), which can serve as a complement or as a specifier of another head (see X-BAR THEORY, Chomsky 1970; Kayne 1994). The simplified structure is thus:

(1)   [Phrase *Complementizer* [Phrase *Agreement* [Phrase *Tense* [Phrase (subject) *Verb* Phrase (object)]]]]

(The phrase to the immediate left of each (italicized) head is its *specifier*).

An object *wh*-phrase is displaced from the complement position on the right of the verb to the specifier position on the left of the complementizer. This, for example, accounts for its occupying the first position of the (interrogative) sentence (as no other head precedes the complementizer), as well as for the fact that in certain languages the *wh*-phrase co-occurs with (and precedes) the complementizer itself (e.g., Middle English: *This bok which that I make mencioun of . . .*). In root interrogatives (in English and other languages), the finite verb (a head) is necessarily in second position, immediately after the *wh*-phrase (*What have you seen?*). This can be made sense of if it too is displaced to the complementizer head. The rationale for the movement of a wh-phrase appears to be related to the way a

wh-phrase is interpreted. A question like *Which persons have you met?* means roughly "Tell me which is the value of *x*, where *x* ranges over the class of persons such that you have met *x*." In other terms, *which* is a sort of quantifier extracted from the object and binding a variable in the object position, much as in the (Polish) notation of standard predicate logic (see QUANTIFIERS). The displacement of a *wh*-phrase can thus be seen as a way of partially building in the syntax a representation of the LOGICAL FORM of the sentence, although not all languages displace their *wh*-phrases overtly in the syntax or have a special morphological way that distinguishes them from indefinite phrases (see Cheng 1991).

The displacement of *wh*-phrases is severely constrained. Although *wh*-movement gives the impression of taking place over an unbounded number of sentences (*How do you think that they said that they wanted to repair it?*, where *how* is moved from the sentence containing the verb *repair*), there is evidence that it proceeds stepwise through the specifier of each complementizer (at least in the case of phrases other than subjects and complements). This is shown by the fact that whenever the specifier of some intermediate complementizer is filled by another *wh*-phrase, such movement becomes impossible (**How do you wonder why he repaired it?*). Only subjects and complements can (marginally) skip over one such intermediate specifier (cf. ??*Which one of his brothers did you wonder why they invited?*).

Such stepwise movement of *wh*-phrases is constrained in another fashion. In essence, it can apply only when the subordinate sentence is a complement of the next higher verb (for refinements, see Rizzi 1990 and Cinque 1990). As witnessed by the fact that they seem to involve a quantifier/variable interpretation, and that they are subject to the same constraints as overt *wh*-movement constructions, a number of other constructions have been analyzed as containing a covert type of *wh*-movement (see Chomsky 1977). These comprise comparative (*He buys more books than his father used to buy*), topicalized (*This film, I think that they saw*), "easy-to-please" (*John is easy for everybody to succeed in convincing*), and other constructions.

What-It's-Like

One of the most distinctive features of conscious mental states is that there is "something it is like" to have them. There is something it is like *for me* to smell a rose, daydream about my vacation, or stub my toe, but presumably *for the rose* there is nothing it is like to have an odor, and *for the table leg* there is nothing it is like to be kicked by my toe. Many philosophers feel that it is this feature of mentality, its subjectivity, that presents the most difficult challenge to a materialist theory of the mind.

There are two issues involved here. First, we want to know what distinguishes those states that there is something it is like to be in from those there is nothing it is like to be in; those states that have a subjective character from those that do not. Second, there is the more specific question concerning just what it is like to be in particular types of mental states. The qualitative character of smelling a rose is quite distinct from seeing it. What determines, for a state there is something it is like to be in, exactly what it is like?

Nagel (1974) poses the second question quite forcefully with the following example. Bats navigate by echolocation, a sensory system unlike any possessed by human beings. They emit high-pitched sounds and determine the spatial layout of their environment by the nature of the echoes they detect. To the question how this system performs its function of providing spatial information to the bat, a computational theory is the answer. If we can determine the function from sensory input to informational output, and see how the bat's neurophysiology implements that function, then the strictly computational question is answered. But there seems to be another question we want answered; namely, what is it like for the bat to perceive the world in this way? To this question, it does not seem as if the computational theory can provide even the beginning of an answer.

Another very influential thought experiment that illustrates the subjectivity of conscious mental states is Frank Jackson's (1982) story of Mary, the neuroscientist brought up in a black-and-white environment. Though she knows all there is to know about the physical mechanisms underlying color perception, it seems that she would not know what it is like to see red until she actually sees it for herself. Again, it seems as if one has to undergo conscious experiences to know what they are like. But why should that be?

Nagel's diagnosis of the problem is that conscious states essentially involve a "subjective point of view," whereas physicalist and computationalist theories involve adopting an objective point of view. Thus to know what it's like to have a certain conscious experience one must be capable of taking up the relevant point of view—that is, one must be capable of having this sort of experience. The puzzle for materialism is to explain just how the physical mechanisms underlying conscious experience could give rise to subjective points of view at all, and to particular facts concerning

what it's like that are accessible only from certain points of view. How objectively describable physical processes result in subjective points of view is central to the problem known as the EXPLANATORY GAP.

Two of the most influential responses to the problem are the "knowledge how" strategy and the "indexical" strategy. The idea behind the first strategy (see Lewis 1990 and Nemirow 1990) is that knowledge of what it is like to have an experience is not factual knowledge, therefore not susceptible to explanation. Rather, to know what it's like to see red is to have the ability to recognize seeing red when it occurs. If this is right, then of course one has to actually undergo the relevant experience in order to manifest the ability. Many philosophers reject this solution, however. They do not find it plausible that knowing what it's like is merely "knowledge how," an ability, and not "knowledge that," factual knowledge. It seems clear to them that there is a fact involved here, and in certain cases, such as the bat's perception via echolocation, one that is inaccessible to us.

The idea behind the second strategy is to deflate the mystery by showing that the subjectivity of conscious experience is just another manifestation of the phenomenon of indexicality (see Lycan 1996; Rey 1996; Tye 1995). Though many people can describe me—my physical appearance, my behavior, and even many of my thoughts—they cannot do it in a first-person way. That is, they cannot capture what I am thinking or doing by saying "I am writing an essay"; only I can do that. So, in a sense, certain ways of thinking about me are inaccessible to them. Yet, no one finds this mysterious; it is just the way the "I"-concept works. Similarly, that there is a subjective point of view is not mysterious. What accounts for subjectivity is that the subject herself has a means of representing her own experience, that is, by the mere fact that it is her experience, inaccessible to others.

This solution has its problems as well (see Levine 1997). It is true that both phenomena, knowing what it's like and employing the first-person concept, involve adopting a perspective. But it is plausible that the first-person concept is purely a matter of perspective, and that is why it generates no mystery. When one considers what it is like to see red, however, it doesn't seem that one is merely apprehending from a different perspective the same fact as that which is captured by a graph of the spectral reflectance of the object observed; rather, it seems as if something completely new is revealed, a substantive fact that is not capturable in any way by a graph or verbal description.

How seriously one treats the problem of subjectivity in the end is largely a matter of one's attitude toward philosophical intuitions. Many philosophers (see Akins 1993; Churchland 1985; Dennett 1991) are willing to dismiss the intuitions driving the worries about what it's like in the hopes that enough scientific progress will render them impotent. Other philosophers continue to engage the problem directly, convinced that the intuitions Nagel and others express reveal a deep philosophical problem that demands a solution.

Wiener, Norbert

Norbert Wiener (1894–1964) worked in pure mathematics, but also used mathematics to pioneer statistical communication theory, and in collaboration with engineers and neurobiologists originated and elaborated the field of "cybernetics" (the study of "control and communication in the animal and the machine"). Wiener's work in the 1940s,

related to cybernetics, constitutes one of the roots of modern "cognitive science." After World War II, anticipating the social and philosophical significance of cybernetic technologies, Wiener developed an important prescient philosophy of technology incorporating humane values. Nearly all his work shows the mark of a highly original mind.

Son of a Russian Jewish immigrant professor of Slavic languages and literature at Harvard, Norbert Wiener was a child prodigy who received his doctorate in philosophy from Harvard at the age of eighteen. His postdoctoral mentors included Bertrand Russell and G. H. Hardy in Cambridge. From 1919 until his death he was a member of the faculty of mathematics (during the last five years a freewheeling "institute professor") at the Massachusetts Institute of Technology.

Within pure mathematics Wiener worked on potential theory, generalizations of harmonic analysis, proving Tauberian theorems, proving theorems concerning Fourier transforms in the complex plane, studies of chaos, ergodic theory, and other topics. One of Wiener's major mathematical innovations, developed when he was still in his twenties, was the invention of what has come to be known as the "Wiener process" or the "Wiener measure," extending the Lebesgue theory of measure, and combining it with probability theory to describe Brownian motion. This mathematical development, which offered a new way of thinking about many problems, has found subsequent application also in quantum field theory and other branches of science.

It was his collaboration in the early 1940s with the Mexican physiologist Arturo Rosenblueth, on the one hand, and with engineer Julian Bigelow, on the other, which led to the fundamental ideas of cybernetics. These fruitful collaborations were evidence of Wiener's capacity for bringing his own discipline to bear on other fields and transforming them. Application of sophisticated mathematics to wartime engineering problems led Wiener to create general statistical theories of communication, prediction, and filtering. "Information," rigorously defined, became a concept as precise as the concepts describing matter within the field of physics. Also, the concept of a "goal," and that of "feedback" of information indicating how far one is from reaching the goal, and the engineering task of building an automatic mechanism for computing a correction, and acting on the information so as to come closer to the goal, were part and parcel of the Wiener-Bigelow design work. Wiener's collaboration with Rosenblueth was based on the shared philosophical premise that the formal structures of mechanical or electrical systems are often isomorphic to the formal structures involving organisms, and can be described by mathematics. It led to joint work in analyzing human or animal heart flutter, heart fibrillations, muscle clonus, and detailed local electrical fluctuations in the central nervous system.

Wiener, Rosenblueth, and Bigelow presented a paradigm for a new, as yet unnamed area of interdisciplinary research in their 1943 article, "Behavior, Purpose, and Teleology." It dealt with the analysis of purposive action, whether in an animal or in a machine, although the notion of "purpose" had been largely excluded by the then-dominant behaviorist psychology. The ubiquitous process of achieving a "purpose" or goal, they suggested, entailed continuous or repeated negative feedback to guide action, and a circuit encompassing physical action as well as information. That feedback loop to implement purpose meant a circular causality, A effects B which in turn effects A, and so on, in contrast to traditional one-way cause-and-effect relations. When the war was over, Wiener made common cause with Warren McCulloch, Walter Pitts, and John VON NEUMANN, whose work on formal-logical modeling of the central nervous system and general-purpose computers suggested strong structural similarities between brains and computers. In a series of small conferences that became known as the Macy conferences on cybernetics, they discussed their ideas and presented them to an interdisciplinary group which included psychologists of diverse persuasions, psychiatrists, biologists, and anthropologists. A controversy at the meetings concerned the discrepant premises of the older GESTALT PSYCHOLOGY, on the one hand, and those of the emerging cognitive science (using electronic computer and information-processing models of the mind) on the other. Some of the group came to shift their research programs when they incorporated the new ideas into their own discipline. In 1948 Wiener presented his own synthesis of the new field, which had come to include what he learned from other Macy conferees, in a book titled *Cybernetics*. It brought the ideas to the attention of a large scientific audience worldwide.

After the war Wiener eschewed work likely to be useful to weapons development, and, using insights from cybernetics, turned his attention to topics such as analysis of electroencephalograms, and the principles of prosthetic devices for people who are blind, deaf, or have lost a limb. His criteria for sophisticated prosthetic devices have proved to be valid guiding principles for their design.

Wiener came to view the ideas of cybernetics as a theory of messages. He saw himself as an adherent of what he called the "Gibbsian point of view," the primacy of the contingent, not only within science but in life generally. Furthermore he took it upon himself to place engineering and technical innovation within a framework of ethics, using the legend of the golem as a metaphor. He described his outlook in various books for the general reader.

Word Meaning, Acquisition of

The acquisition of word meaning involves, at minimum, the process of mapping concepts onto sounds or signs. These mappings differ across languages—*siy* is the phonological string associated with the meaning "if" in French, "yes" in Spanish, and "apprehend visually" in English—and hence cannot be innate. Since antiquity, scholars interested in word learning have assumed that the source of information for acquiring the meaning of new words is the child's observation of the linguistic and extralinguistic contexts of their use. Recent theorizing, as we shall describe, contributes new insights and findings that argue that the process is dramatically more complex than thought in the past.

Children understand a few words starting at about 9 months, with first spoken words typically appearing at about 12–14 months. These milestones are identical for spoken and signed languages (Petitto 1992; see SIGN LANGUAGES and SIGN LANGUAGE AND THE BRAIN). The acquisition of new words is at first quite slow, averaging about 0.3 words per day, but this rate gradually increases, eventually to about 15 new words per day in the school years (Anglin 1993). Some children show a sudden spurt in vocabulary growth between about 20 to 30 months, and there is in general a high correlation between syntactic and lexical development (Fenson et al. 1994). The onset of SYNTAX also coincides with a change in the character of the vocabulary: Earliest words, even in very different linguistic communities, are mainly animal sounds, "routines" like *bye-bye,* and common nouns, with a relatively high proportion of object names. Verbs, adjectives, and function words are rare (compared to their proportions in maternal usage; Fenson et al. 1994; Gentner 1982).

The vocabulary of a monolingual high school graduate is in the neighborhood of 80,000 words (Miller 1996). This number is impressive—80,000 arbitrary sound/meaning pairings is a lot to learn and store in memory—but word learning is impressive for other reasons as well. Quine (1960) gives the example of hearing a word, "gavagai," in an unknown language under the most transparent of circumstances; let us say, only and always while viewing a rabbit. A first thought is that the listener would be warranted in supposing that this word means "rabbit." But Quine points out that *gavagai* has a logical infinity of possible meanings, including rabbit tails or legs, rabbit shapes, colors, or motions, temporal rabbit-slices, and even undetached rabbit parts. Because all of these conjectures for the meaning are consistent with the listener's experience, how can he or she zoom in on the single interpretation "rabbit"? (See RADICAL INTERPRETATION.) In actual fact, real children are apparently faced with just this problem, yet they seem to converge just about unerringly on the adult interpretation—that the word refers to the whole animal. But so saying leaves the problem raised by Quine unanswered.

Matters get worse. Contrary to what is often assumed, words are typically not presented in such "transparent circumstances." Adult speech to young children even in middle-class American homes is frequently about the past or the future, when the word's referents often are not in view (Beckwith, Tinker, and Bloom 1989). In some cultures, there is no explicit labeling of objects, and yet children have no problem learning object names (Schieffelin 1985). Blind children, whose observational opportunities are limited compared to the normal case, acquire word meanings—even the meanings of color words and verbs of perception—at about the same rate as sighted children (Landau and Gleitman 1985). And philosophers such as Plato have noted the puzzles that arise for the learning of abstract terms, such as those for numbers or ideal geometrical forms. (Consider also terms that describe mental states, such as "idea" and "know.") In sum, the sorts of words that children must learn and the conditions under which they must learn them suggest that word learning cannot succeed solely by raw observation of the co-occurring world.

The solution to these puzzles must involve attributing certain powers to very young children. Some of these are conceptual. Surely children enter the language-learning situation equipped with natural ways of interpreting many things, properties, and events in the world around them. These "natural ways" include perceiving objects and even rabbits, but it is likely that they do not include perceiving undetached rabbit parts. In consequence, the task of early word learning ordinarily comes down to connecting these preexisting conceptions with phonetic sequences. In support of this, consider the speed and effectiveness of early word learning. Children grasp aspects of the meanings of new words with very few exposures, without training or feedback and without ostensive naming. This process has been dubbed "fast mapping" (Carey 1978). For instance, if a 3-year-old hears one object out of ten being referred to casually as "a koba," over a month later she will know that this object is a koba (Markson and Bloom 1997). Children under the age of two can fast map new nouns (Waxman and Markow 1995), and the meanings of these early acquired words seem to be the same as they are for adults (Huttenlocher and Smiley 1987). This suggests that word learning is indeed supported by a preexisting conceptual repertoire. This position is bolstered by research with prelinguistic infants that shows that they possess a rich understanding of objects, actions, and other ontological kinds (e.g., Spelke 1994).

But even if children have the required conceptual structure for word-meaning acquisition, making the mappings to the

right phonetic sequences remains to be explained. For example, very often in the child's immediate environment "open" is uttered when nothing is opening, and often there is no utterance of "open" when something is saliently opening. How then do children make the connection between "open" and opening? Quite surprisingly, part of the solution is that even infants under two years of age will not passively associate all and only new sounds with all and only newly observed objects or actions. Rather, they regularly inspect the situation co-occurring with a new word to find out what the speaker intended to refer to when he or she used that word. For example, if 18-month-olds hear a novel word while they are playing with a novel toy, they will assume that the word names that toy only if the speaker is also attending to it: if the speaker is looking at a different object, children will spontaneously follow her line-of-regard and assume that the object she is looking at is the referent of the new word (Baldwin 1991). This pragmatic understanding might also underlie certain expectations about how the LEXICON works, such as the assumption that different words should not have the same meaning (Clark 1985; though see Woodward and Markman 1997 for a different perspective). And children's understanding of the actual meanings of many words—particularly for artifacts, such as "toy" or "clock," but also for certain collections such as "family" and "army"—might require an appreciation of the goals and motivations of others (Bloom 1996).

Finally, much of word learning results from the child's emerging appreciation of properties of language itself. As noted above, there is a strong relationship between the onset of syntax and the nature and development of word learning. In many regards (see SYNTAX, ACQUISITION OF), young children understand certain properties of language-specific grammar and balk when these are violated by adult speakers (Shipley, Smith, and Gleitman 1969). The ability to take into account more than one word in the adult sentence offers significant new clues to the word-learning child. One important cue comes from identification of a word's grammatical category, a process called "syntactic bootstrapping." For example, children who hear "This is ZAV" expect the word to refer to a specific individual, as with a proper name like "Fred" (Katz, Baker, and Macnamara 1974). Children who hear "a ZAV" expect it to refer to a kind of individual, such as "dog"; those who hear "some ZAV" expect it to refer to a substance name such as "water" (Brown 1957; Bloom and Kelemen 1995). And children hearing "John ZAVS Bill" expect the word to have a meaning similar to that of "hit," whereas those who hear "John and Bill ZAV" expect it to have a meaning similar to that of "stand" (Gleitman 1990; Naigles 1990)—that is, they can make inferences about the number and type of arguments that a new predicate encodes for. Ultimately, the view that structure can be informative for word learning is one that commits theorists to the view that there are links between syntax and semantics to which young learners are privy very early in their language development (e.g., Gleitman 1990; Pinker 1989).

This brings us back to a finding mentioned earlier—the large proportion of object names in children's very early vocabularies. One explanation that has been offered for this property of early lexicons is that object categories are conceptually simpler than categories such as parts and actions (Gentner 1982). Another proposed solution is that there are special default biases in word learning that guide children towards an object-kind interpretation of new words (Woodward and Markman 1997). A focus on syntactic development suggests a third possibility: no matter how conceptually sophisticated they are, learners who have no access to syntactic cues may be able to acquire only words whose referents are relatively "concrete," those whose referents can be directly observed in the extralinguistic environment. In support of this, Gillette et al. (1997) found that adults shown videotaped mother-child interactions with the audio turned off and with beeps used in place of words (that is, adults who were deprived of syntactic support) acquired only "concrete" terms, typically object names—just like presyntactic infants.

In sum, there are three recent discoveries that have increased our understanding of word learning. First, a range of ontological categories, including objects, are available to very young children. Second, in addition to being conceptual creatures like us, children are intentional creatures like us: far from being at the mercy of passive associations when words occur in extralinguistic contexts, they are sensitive to subtle cues to a speaker's referential intentions. Third, two findings about the form-meaning relations that children are acquiring may help explain how they perform their pyrotechnic learning feats—the increasing linguistic understanding of the SYNTAX-SEMANTICS INTERFACE; and the growing evidence that young children use cues at this level to constrain the interpretation of novel words.

Working Memory

Working memory is the cognitive system that allows us to keep active a limited amount of information (roughly, 7 ± 2 items) for a brief period of time (roughly, a few seconds). This system has been a major research topic since the advent of the cognitive revolution in the 1950s, and was earlier referred to as "short-term memory." It was then thought to have two functions: storing material that we have to recall in a few seconds, as when we rehearse a phone number until we dial it, and providing a gateway to long-term memory (e.g., Atkinson and Shiffrin 1968). While cognitive scientists continue to believe in the simple storage purpose, their belief in the gateway function has been somewhat undermined by the existence of neurological patients who are impaired in short-term memory tasks, but perform normally on long-term memory tasks (see, e.g., Shallice 1988). Rather, cognitive scientists now assume that the major function of the system in question is to temporarily store the outcomes of intermediate computations when PROBLEM SOLVING, and to perform further computations on these temporary outcomes (e.g., Baddeley 1986). For example, when mentally multiplying two-digit numbers like 38×19, we may first compute and store the partial product $8 \times 9 = 72$, later use this partial product in further computations, and subsequently drop it when it is no longer needed. Given this role, the system in question has been renamed "working memory," and is considered critical not only for analyzing MEMORY, but for understanding thought itself.

In what follows, first we review some basic characteristics of working memory, and then consider its role in higher-level cognition. We mention empirical evidence from various human studies, including cognitive-behavioral experiments, neuropsychological (patient) studies, and neuroimaging experiments (using POSITRON EMISSION TOMOGRAPHY or functional MAGNETIC RESONANCE IMAGING).

There appear to be different working memories for different kinds of materials, particularly different systems for verbal and spatial information. In a paradigm cognitive-behavioral experiment, subjects perform a working-memory task while concurrently performing a secondary task. Any secondary task usually causes some interference with a

working-memory task, but verbal secondary tasks interfere more with verbal than with spatial working-memory tasks, whereas spatial secondary tasks interfere more with spatial than with verbal working-memory tasks (e.g., Brooks 1968). This pattern of *selective interference* supports the hypothesis of separate systems for verbal and spatial working memory. (These separate working-memory systems may be connected to separate verbal and spatial perceptual systems.)

The above results are bolstered by neuropsychological findings. There are pairs of neurological patients such that one is impaired on a standard measure of verbal working memory—digit span—but normal on a standard test of spatial working memory—Corsi blocks test—whereas the other patient shows the reverse pattern (see McCarthy and Warrington 1990). This *double-dissociation* between verbal and spatial working-memory tasks argues for two separate systems. Perhaps the most direct evidence for two systems comes from neuroimaging experiments. Subjects perform either a verbal recognition test—for example, remembering the names of four letters for 3 sec—or a spatial recognition test—for example, remembering the locations of three dots for 3 sec—while having their brains scanned. Different areas of the brain are activated in the two tasks, with almost all of the activations in the verbal task being in the left hemisphere, and most of the activations in the spatial task being in the right hemisphere (Smith, Jonides, and Koeppe 1996). (Other neuroimaging studies indicate that there might be separate working memories for spatial and visual-object information, just as the single-cell evidence shows for nonhuman primates—see WORKING MEMORY, NEURAL BASIS OF).

Within verbal and spatial working memory, there is evidence for a further subdivision, that between a passive storage process and an active rehearsal process. The evidence is strongest for the verbal system. In cognitive-behavioral studies, experimenters have argued that some effects reflect only a storage process, for example the *phonological similarity effect,* in which the short-term recall of words is poorer for phonologically similar than phonologically dissimilar ones (Conrad 1970) whereas other effects are due to rehearsal, for example, the *word-length effect,* in which the short-term recall of words declines with the time it takes to say the words (Baddeley, Thompson, and Buchanan 1975). Importantly, when subjects doing these tasks are prevented from rehearsing the words by having to articulate some irrelevant word or phrase, the word-length effect disappears but the phonological-similarity effect remains intact (Longoni, Richardson, and Aiello 1993). Presumably, the irrelevant articulation blocked rehearsal, but had no effect on the storage buffer. Further support for this interpretation comes from the study of a patient whose brain damage presumably disrupted only the rehearsal component. This patient shows a normal phonological-similarity effect, but no effect of word length or of irrelevant articulation (Basso et al. 1982).

There is converging evidence for the storage-rehearsal distinction from neuroimaging studies. Subjects are scanned while doing a short-term recognition task, which presumably involves storage plus rehearsal, or while doing a task that involves only articulation or rehearsal. Both tasks activate areas in the left-hemisphere frontal cortex that are known to be involved in the planning of speech, whereas only the memory task activates posterior-parietal regions thought to be involved in storage per se (Paulesu, Frith, and Frackowiak 1993; Awh et al. 1996). Recent neuroimaging experiments argue for a comparable storage-rehearsal distinction in spatial working memory, where spatial rehearsal appears to amount to selectively attending to particular locations (Awh and Jonides forthcoming).

Some of the best evidence for (verbal) working memory playing a role in higher-level cognition comes from cognitive-behavioral studies. One line of evidence is that there are substantial correlations between (1) a measure of a person's verbal working-memory capacity—the reading-span task—and (2) the person's performance on either a reasoning task—the Raven Progressive Matrices test—or language-understanding tasks (e.g., Carpenter, Just, and Shell 1990; Just and Carpenter 1992). A second piece of behavioral evidence is the finding that performing a working-memory task interferes with a concurrent reasoning task (solving syllogisms) more than does performing a non–working-memory task (Gilhooly et al. 1993). Again, there is converging evidence from recent neuroimaging experiments. When people engage in either a reasoning task (the Raven test again) or a complex-categorization task, many of the areas found active are those activated in standard working-memory studies (Prabhakaran et al. 1997; Smith, Patalano, and Jonides 1998).

Other persuasive evidence for working memory's role in higher-level cognition comes from computational research, specifically the use of symbolic models to simulate higher-cognitive processes. Simulations of this sort routinely give a major role to working-memory operations, and provide a detailed account of exactly how working memory can be used to regulate the flow of information processing during CATEGORIZATION, PLANNING, reasoning, PROBLEM SOLVING, and language understanding (e.g., Anderson 1983; Newell 1990; Carpenter et al. 1990).

Working Memory, Neural Basis of

Working memory, as defined by cognitive psychologists, refers to "a system for the temporary holding and manipulation of information during the performance of a range of cognitive tasks such as comprehension, learning and reasoning" (Baddeley 1986). The adjective "working" is a critical part of the definition, emphasizing as it does the *processing* of information and not its particular content. Working memory is characterized by its limited storage capacity and rapid turnover and is differentiated from the larger capacity and archival memory system traditionally defined as long-term memory. The origin of the term "working memory" is difficult to trace. It was used by Miller, Galanter, and Pribram in their 1960 book, *Plans and the Structure of Behavior*, to describe the functions of the frontal lobe: "This most forward portion of the primate frontal lobe appears to us to serve as a "working memory" where plans . . . can be retained temporarily when they are being formed, or transformed, or executed." Metaphors for working memory include "blackboard of the mind" (Reddy 1980); "mental sketch-pad" (Baddeley 1986), and "on-line memory" (Goldman-Rakic 1987). When we listen to human speech, we are using working memory to hold the segments of sentences "on-line" millisecond by millisecond. We employ working memory to carry forward, in real time, the subject of a sentence and associate it with verbs and objects in order to comprehend the sense and meaning of sentences. When we perform a mental arithmetic problem, recall a phone number, plan a hand of bridge or a chess move, or follow a verbal instruction, we use working memory. In fact it is difficult to think of a cognitive function that does not engage the working-memory systems of the brain. A number of different models have been proposed regarding the functional architecture of human cognition (see WORKING MEMORY).

The study of short-term memory in nonhuman primates can be traced at least as far back as the seminal work of Jacobsen and Fulton which showed a dependence of delayed-response performance on the dorsolateral prefrontal areas of the primate frontal lobe (Jacobsen 1936). Delayed-response tasks are those in which a brief delay is introduced between the presentation of a stimulus (usually denoting either a location or the identity of an object) and the response that is required to indicate that the stimulus has

Figure 1.

been recalled. It is important to point out, that, as studied in the 1930s and forward, delayed-response tasks were considered tests primarily of "immediate memory." This terminology denoted passive or short-term storage and did not embody the notion of processing or the linkage between storage and processing that are central concepts in the study of working memory (Baddeley 1986). For commonly used tasks of the delayed-response "family," little or no processing is in fact required. However, there is much evidence to indicate that the storage and processing functions within working memory are carried out by the same cells and circuits and that the study of the machinery for storage is an essential step in understanding the processes carried out by those cells and circuits.

Working memory is studied in humans mainly by the use of behavioral paradigms, most recently in conjunction with brain imaging. However, the physiological and circuit underpinnings of this process have come primarily from anatomical, physiological, and behavioral research in non-human primates. A cellular basis for working memory has emerged from the study of activity in single neurons recorded from the prefrontal cortex of monkeys that have been trained to perform delayed response tasks (Fuster and Alexander 1971; Kubota and Niki 1971; Goldman-Rakic, Lidow, and Gallager 1990). In the traditional type of spatial delayed-response task, a monkey observes an experimenter place a food morsel in one of two food wells, each of which is immediately covered by identical cards. A screen is lowered between the test tray to prevent the monkey from immediately displacing the card to reveal the hidden treat. After several seconds, the screen is raised and the animal is allowed to select one of the food wells. The imposed delay forces the monkey to base its choice on the memory of the location in which the food was placed before the delay, that is, the choice is memory-guided. Monkeys with lesions of

their dorsolateral prefrontal cortices are unable to make correct choices but instead respond at random (Goldman-Rakic 1987; Fuster 1989). Physiological studies have revealed that the activity of prefrontal neurons correlates with events in the delayed-response tasks, that is, some neurons respond during the placement of the food stimulus, others respond during the delay period, and still other neurons respond at the time of the response (figure 1). Many neurons are combinatorial, having cue, delay, and response-related responses. The activity profiles of prefrontal neurons are thus strikingly related to the subfunctions of sensory registration, memory, and motor control, respectively. As the cue, delay, and response-related neurons are necessarily activated in sequence rather than simultaneously, these neurons mediate the real time events in working memory.

The neurons that respond in the delay period are of particular interest because they exhibit sustained activity for many seconds in the absence of any stimulus, a property that is not observed in primary sensory areas of the brain. Using an oculomotor paradigm which requires the monkey to fixate while small stimuli are presented in various locations in the visual field, it became possible to show that these prefrontal neurons have "memory fields," defined as maximal firing of a neuron to the representation of a target in one or a few locations of the visual field (Funahashi, Bruce, and Goldman-Rakic 1989). For example, a neuron's activity may rise sharply after a stimulus is presented briefly at its "preferred" (e.g., 270°) position, then remain tonically active during a 3 to 5 sec delay (in the absence of the stimulus), and then return to baseline activation abruptly at the end of delay when the response is initiated (as displayed in figure 2). Importantly, such activation occurs *every time* the animal has to remember the same location but not when the animal is remembering targets presented at other "nonpreferred" locations (e.g., 135°, 180°, 225°). An additional important feature of many prefrontal neurons is that while their rate of firing in the delay period is enhanced for one target location, it may be inhibited during the delay on trials with target stimuli of opponent polarity; such a pattern of activity indicates that some prefrontal neurons have "opponent memory fields." This functional distinction provides a valuable clue to how the neural circuitry subserving working memory might be organized. In particular, it points to the role of neural inhibition in sculpting the memory field of these neurons. Inhibition is provided by interneurons in the immediate vicinity of the pyramidal neurons which express memory fields and with the capacity to transmit the information to other areas of the brain. Finally, neuronal activity in the delay period appears essential to correct recall of the preceding stimulus; errors are invariably made on trials in which neurons with memory fields fail to maintain their activation during the delay period (Funahashi et al. 1989).

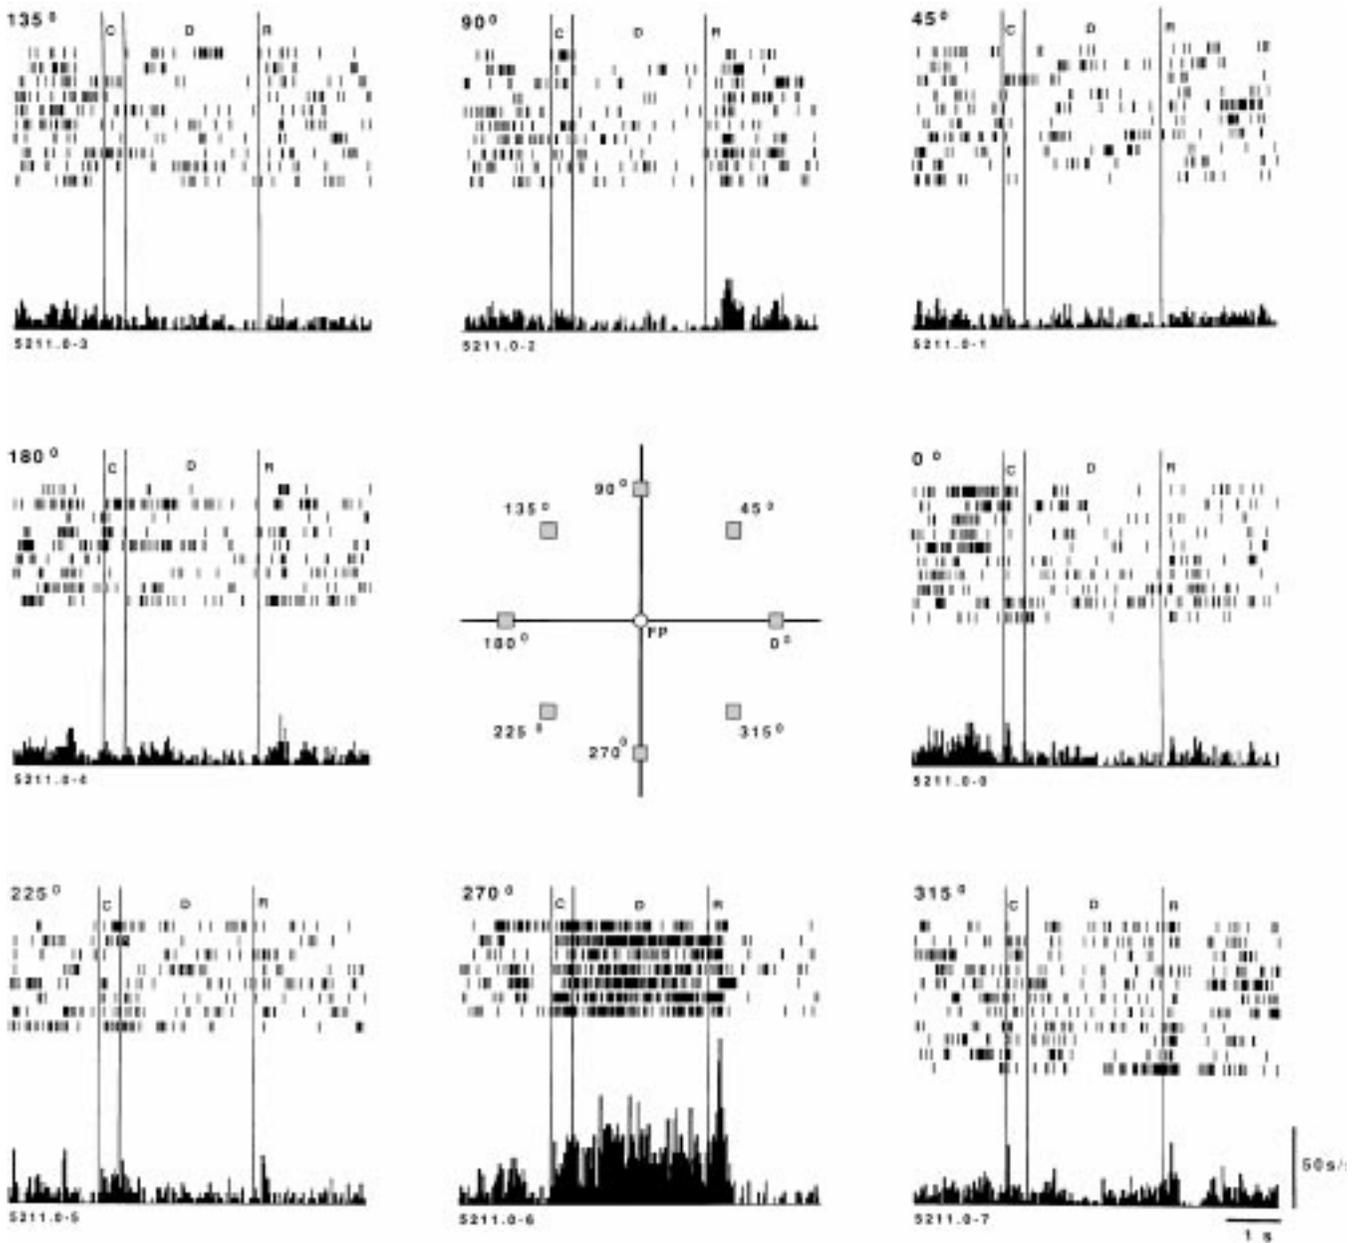
From CAJAL on, it has been appreciated that several types of interneurons populate the CEREBRAL CORTEX and interact with pyramidal cells. The overwhelming majority of interneurons utilize the inhibitory neurotransmitter, γ-aminobutyric acid (GABA), whereas pyramidal cells use the excitatory amino acid glutamate as their neurotransmitter. Recent evidence indicates that pyramidal-nonpyramidal interactions are critical to the formation of memory fields in


Figure 2.

prefrontal cortex just as they may play a role in establishing the orientation specificity of primary visual neurons. Wilson, O'Scalaidhe, and Goldman-Rakic (1994) have succeeded in classifying prefrontal neurons as interneurons or pyramidal neurons based on their firing rates *in vivo*, that is, as monkeys performed the oculomotor delayed response task. This study showed that interneurons, like pyramidal neurons, express directional preferences and the patterns of activity expressed by closely adjacent pyramidal and nonpyramidal neurons are often inverse, such that as a nonpyramidal neuron increases its rate of discharge, a nearby pyramidal neuron decreases its rate. Current studies are examining in more detail the nature of interactions between interneurons and pyramidal neurons engaged in the working

memory process. At present, it is clear that the mechanism of disinhibition is a process that plays a powerful role in the construction of a prefrontal neuron's memory field. Further, it is becoming clear that modulatory NEUROTRANSMITTERS such as dopamine and serotonin modulate the activity of and interactions between pyramidal and nonpyramidal cells.

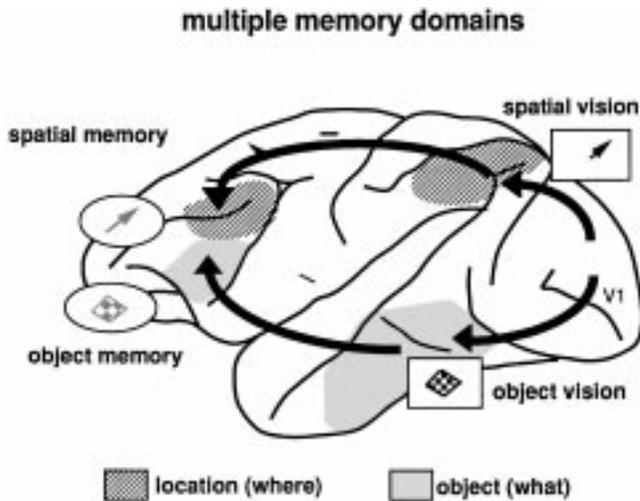
Spatial and feature working memory mechanisms of prefrontal cortex are dissociable at the behavioral, cellular, and areal levels of functional architecture (figure 3). In nonhuman primates, lesions of the dorsolateral prefrontal cortex produce deficits on spatial working-memory tasks but not on object working-memory tasks while, conversely, lesions of the inferior convexity of the prefrontal cortex produce deficits on object-memory tasks but not on spatial tasks


Figure 3.

(Goldman-Rakic 1987; Mishkin 1964). Consistent with lesion and behavior results, neurons located in dorsolateral prefrontal cortex (areas 46 and 8) code visual-spatial memoranda, while those that code simple, complex, or categorical features of stimuli are located in the inferior convexity (areas 12 and 45; Wilson, O'Scalaidhe, and Goldman-Rakic 1993; O'Scalaidhe, Wilson, and Goldman-Rakic 1997). Moreover, individual neurons that are engaged by the memory of an object rarely, if ever, code their peripheral location (Wilson et al. 1993). Physiologically guided injections of pathway tracers in the spatial and object-memory centers have shown them to be connected to the appropriate visual centers in the parietal (Cavada and Goldman-Rakic 1989) and temporal lobes, respectively (Webster, Bachevalier, and Ungerleider 1994; Bates et al. 1994).

Working memory is considered a major component of the machinery of executive function and it is not surprising that POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI) studies in human subjects have focused on this function. Recent studies in healthy human subjects, for example, have shown that the middle frontal gyrus, the region corresponding to the dorsolateral areas studied in macaque monkeys, is activated when human subjects carry out analogous spatial working-memory tasks (McCarthy et al. 1994; Jonides et al. 1993). Inferior regions of the dorsolateral prefrontal cortex are activated for verbal and other nonspatial working-memory functions (e.g., Frith et al. 1991; Courtney et al. 1996; Demb et al. 1995). All of these results speak to the modular organization of working-memory systems in the prefrontal cortex, with each working-memory "domain" associated with an informationally constrained sensory-processing stream.

Working-memory capacity in human subjects can be assessed by numerous tasks designed by cognitive psychologists using visual or auditory stimuli and verbal, spatial, and object vision. Many of these tasks are formally similar to those used with nonhuman primates, assuring the generalizability of results from the nonhuman species to humans. fMRI and PET have been used to examine changes in blood flow or metabolic activity in the cerebral cortex of normal human subjects performing a wide variety of working-memory tasks. The human prefrontal areas that are invariably activated under these behavioral conditions are dissociable from the areas activated by sensorimotor components of the tasks examined (Cohen et al. 1994; Courtney et al. 1996; Sweeney et al. 1996) as they are in nonhuman primates (for review, see Goldman-Rakic 1987; also Goldman et al. 1971).

Conversely, prefrontal areas display depressed blood flow or metabolism in patients with schizophrenia (e.g., Weinberger, Berman, and Zec 1986), depression (e.g., Buchsbaum, Debisi, and Holcomb 1984) and other conditions of impaired affect or cognition. As might be expected if working memory were essential to executive function, working-memory deficits and correlated prefrontal dysfunction have been demonstrated in schizophrenics (e.g., Weinberger et al. 1986; Fukushima et al. 1988; Park and Holzman 1992), in Parkinson patients (e.g., Gotham, Brown, and Marsden 1988; Levin, Labre, and Weiner 1989), and in age-related memory decline (e.g., Salthouse 1991)— neuropathological conditions in which impairments of higher cortical processing are expressed. Prefrontal cortical volume is reduced in schizophrenia, (e.g., Zipursky et al. 1992) and cellular changes (e.g., Benes et al. 1991; Selemon, Rajkowska, and Goldman-Rakic 1995) have also been observed in prefrontal areas in this disorder. On the strength of these and other findings, Goldman-Rakic has proposed that working memory dysfunction may be the core functional deficit underlying thought disorder in schizophrenia (Goldman-Rakic 1987, 1991). It has now become clear that schizophrenic patients are also impaired in tasks requiring working memory. Park and Holzman (1992) have demonstrated that patients with schizophrenia express delay-dependent errors on a modified spatial oculomotor delayed-response paradigm nearly identical to that used in the single-unit studies described above. Early evidence indicates that relatives of patients perform more poorly on spatial working-memory tasks than unrelated control subjects (Park, Holzman, and Goldman-Rakic 1995). Auditory working memory is also severely impaired in schizophrenic patients (Gold et al. 1997; Saykin et al. 1991). These and many other studies are laying the basis for a comprehensive analysis of psychiatric disorders in terms of working memory and the prefrontal mechanisms upon which it greatly depends.

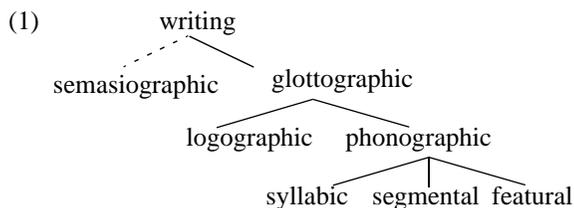
Writing Systems

Writing systems entered the purview of cognitive science only recently. Twentieth-century linguistics was anxious to

move away from prescription of "good usage" to scientific description of natural usage, so for many decades it focused almost exclusively on spoken language. Comprehensive psychological studies had to await the globalization of scholarship that has occurred since the 1970s; previously, the only Westerners knowledgeable about nonalphabetic writing systems were a handful of scholars with literary rather than cognitive-science training.

Nevertheless, there are several motives for cognitive scientists to investigate writing and writing systems. Whereas there are large controversies about how far spoken languages are products of nature rather than nurture, writing is one complex aspect of human behavior that is indisputably a cultural development rather than innate: it has come into existence recently (the earliest writing emerged in Mesopotamia perhaps five thousand years ago), and it is by no means universal either among individuals or among societies. The fundamental role of LITERACY training within all education systems means that psychologists who acquire new knowledge about reading and writing are assured of an audience. Many parents and teachers paid attention when it was reported that DYSLEXIA is rare among users of the nonalphabetic though complex Japanese script (Makita 1968).

Scientific analysis of writing requires a terminology to describe types of script; the following classification is based on Sampson 1987, which represents the relationships between script types as a tree diagram:

(1)   writing
          semasiographic   glottographic
                    logographic   phonographic
                           syllabic segmental featural


A fundamental distinction is between semasiographic and glottographic systems. *Semasiographic* systems are independent graphic languages not tied to any one spoken language; *glottographic* systems use visible marks to represent elements of a specific spoken language. Examples of semasiographic writing are the "language" of mathematics or the international system of road signs in which, for instance, triangle versus disc means warning versus command, and hollow red versus solid blue means negative versus positive. In theory one could imagine a script of this sort being expanded into a comprehensive system of communication; Otto Neurath's "Isotype" (Neurath 1936) was an attempt at such a system, although Isotype never came close to matching the expressivity of spoken languages. Archaeological evidence suggests that the earliest precursors of writing may have been semasiographic systems.

Glottographic scripts can be divided into *logographic* scripts, where the spoken elements represented by individual graphic symbols are meaningful units (words or "morphemes"), and *phonographic* scripts, where marks are assigned to the meaningless sounds from which words are built up. The leading example of logographic writing is Chinese script, in which words sounding identical will often be represented by entirely unrelated graphic characters.

Phonographic scripts in turn can be classified in terms of the "size" of the sound units symbolized. Alphabetic writing assigns a separate mark to each "phoneme" (consonant or vowel segment); but there are many *syllabic* scripts, in which for instance *pa, pe, po* would be represented by three individual and unrelated symbols. The remarkable Han'ǔl script of Korea is based on phonetic *features*: within the symbol for *t*, say, the fact of the tongue-tip touching the upper jaw and the fact of the soft palate being raised to block airflow through the nose are separately indicated.

These categories are ideal types; real scripts often mix the principles. (For an encyclopaedic survey of the world's scripts, see Daniels and Bright 1996.) English writing might be described as fundamentally phonemic but with elements of logography (to take one example among many, the spelling difference between *rain* and *reign* has nothing to do with pronunciation; it relates purely to word identity). Japanese writing is mixed in a more obvious way: it uses Chinese logographic script to represent the stems of "content words," such as nouns and verbs, and a visually distinct syllabic script for grammatical inflexions and particles.

The foregoing account of script types is not wholly uncontroversial. John DeFrancis (1989) has claimed that *all* writing systems are essentially phonographic. Against the reality of the semasiographic category he points out, correctly, that no semasiographic system with coverage as broad as a spoken language has ever existed. He adds that the crude semasiographic systems found in the archaeological record, although they may have been ancestral to writing, should not themselves be classed as writing; this seems to be a disagreement about definitions rather than facts. Some Central American peoples such as the Aztecs and Mixtecs used semasiographic systems that were far from crude and continued to do so for centuries after their neighbors developed glottographic writing (Boone and Mignolo 1994).

More surprisingly, DeFrancis argues that no true logographic scripts exist either: Chinese writing is based on pronunciation. This confuses historical origin with present-day reality. When Chinese script was developed, some three thousand years ago, its characters were based partly on the pronunciations of Chinese words at that period; it may well be true that no full-scale script could ever in practice be created without heavy use of a phonographic principle. But Chinese pronunciation has changed greatly over the millennia (and the script has evolved independently), with the consequence that Chinese writing now is far less phonographic than it once was. The suggestion that all scripts are necessarily phonographic is really untenable (Sampson 1994). Perhaps the clearest counterexample is the use of Chinese characters to write Japanese vocabulary. Japanese words are written with characters for Chinese words that mean the same, but (since the two languages are genetically unrelated) a graphic element that may still today give a hint about the pronunciation of the Chinese word will be totally uninformative about the pronunciation of the Japanese word.

Even the idea that English orthography is not perfectly phonographic has been challenged by one school, the generative phonologists. The usual explanation of (say) the odd spelling of *righteous* is that *gh* represented a velar fricative

consonant (as in Scottish *loch*) that was pronounced in Middle English; the spelling became fixed and did not adapt when the fricative sound dropped out of the spoken language about five hundred years ago. But Chomsky and Halle (1968) argued that there is evidence from English sound patterns (for instance, the vowel alternation between *vice* and *vicious* versus lack of alternation between *right* and *righteous*) which implies that the fricative consonant remains a psychological reality with respect to the "underlying" word forms in which modern speakers mentally store their vocabulary. However, this concept of abstract phonology is no longer widely accepted.

Probably the liveliest current debate within the psychology of writing concerns the question how far a mature reader's ability to retrieve a meaningful word from a string of letters depends on an intermediate step of mentally converting the letters into a pronunciation. The question has obvious resonance with the debate in the teaching profession between "phonic" and "look-and-say" methods. The consensus view has been that pronunciation is often bypassed, particularly when reading common or irregularly spelled words. P. E. Bryant and Lynette Bradley (1980) showed that unskilled readers often cannot read words that they can spell correctly, when the spelling is regular but visually nondistinctive. But a minority of researchers (e.g., Lukatela and Turvey 1994) argue that phonetic mediation is essential in all word recognition.

In the last few years, research has begun to exploit new categories of data, including MAGNETIC RESONANCE IMAGING and POSITRON EMISSION TOMOGRAPHY, which are revealing correlations between the reading process and detailed neural activity. Findings to date are surveyed by Posner et al. (1996).

A very different area of intersection between writing systems and cognitive science concerns the question whether literacy changes the nature of mental life in societies that possess it. Learning to read and write undoubtedly affects awareness of the structure of language itself; for instance, although vowels and consonants seem natural units to users of alphabetic scripts, people who do not write alphabetically do not find it easy to segment speech into phonemes. But many scholars have claimed that literacy affects thought much more broadly.

Jack Goody and Ian Watt (1963) held that Western habits of thought, such as emphasis on logic, require not merely literacy but specifically phonographic script. However, although it is historically true that the Chinese were much less interested than the Greeks in logical issues, it is very hard to see how the special nature of Chinese writing can have been relevant to that fact. Many other writers do not claim that different script types have differential consequences for human thought, but they urge that the difference between possession and lack of writing has massive consequences for the intellectual life of societies and individuals.

Because professional academics live by the written word, this is a natural view for them to hold: at an earlier period, it ranked as an unquestioned though vague truism. More recently, scholars such as Walter Ong (1982) have tried to be more specific about the cognitive consequences of literacy. At the same time, several writers have argued that literacy is less significant than commonly supposed. Elizabeth Eisenstein (1979) claimed that systematic habits of mind that have been attributed to literacy arose only with the more recent invention of printing. Sylvia Scribner and Michael Cole (1981) investigated a Liberian tribe that uses a syllabic script that is learned informally, outside a school context, and they concluded that it is the formal schooling process itself that inculcates mental disciplines that have been taken for consequences of literacy. Several writers have suggested that literacy is less advantageous to individuals than it is to states that wish to control their subjects. David Olson (1994) offers a judicious survey of these issues.

Wundt, Wilhelm

Wilhelm Wundt (1832–1920) was born in Neckarau, Germany, the son of a Protestant minister. Despite a withdrawn

adolescence, he was able to enter medical school first at Tübingen (1851), and then at Heidelberg (1852–56). After a semester's research on neuroscience in Berlin he returned to Heidelberg, where he taught physiology and acted as research assistant for Hermann HELMHOLTZ; here, independently of Helmholtz, he developed the notion that "unconscious inference" can determine perception (Richards 1980). In 1862 he wrote a book on perception that included a plan for a future science of psychology based on experiment, observation of behavior, and self-observation; this future psychology would include child psychology, animal psychology, and the study of linguistic, moral, and religious differences between ethnic groups (*Völkerpsychologie*). Such a science would be free of metaphysics and speculations based on introspection. Wundt distinguished between acceptable self-observation (e.g., "press a button when the identity of a word just briefly flashed before you comes clearly to mind") and unacceptable INTROSPECTION (e.g., "What do you think went on in your mind just before you pressed the button?"), a distinction stressed by Blumenthal (1980) and Danziger (1980).

From 1864 to 1868 Wundt served as a professor of both anthropology and medical psychology at Heidelberg and also, until 1869, as a representative, in the Baden legislature, of the city of Heidelberg. In 1872 he married Sophie Mau (1844–1912); they had three children. The first edition of his authoritative *Grundzüge der physiologischen Psychologie* appeared in 1874; the sixth and final edition would appear in 1908–11. Following a year at Zürich, in 1875 he moved to Leipzig with the title of professor of philosophy.

Wundt's famous Institute of Experimental Psychology, for which funding was first received in 1879, consisted initially of the use of a classroom on the third floor of a refectory building (destroyed by bombing in World War II), but in 1883 it was expanded to nine rooms (a floor plan is provided by Bringmann, Bringmann, and Ungerer 1980: 151). Further expansions took place in 1888, 1892, and 1897, when the institute moved to the top floor of a newly built building. Wundt (1910) himself chronicled these expansions and gave a floor plan of the 1897 laboratory. In 1881 he also founded a journal, *Philosophische Studien,* for the dissemination of the research from his Institute.

Students came there not only from Germany but also from North America, the United Kingdom, Russia, Japan, and other countries. For example, the American James McKeen Cattell (1860–1944) carried out research at Leipzig on word associations, introduced Wundt to the newly invented typewriter, and wrote letters home that give a good account of life and work in Wundt's laboratory (Sokal 1981). A full list of Wundt's Ph.D. students was provided by Tinker (1932), with more details on his thirty-three American students in particular being given by Benjamin et al. (1992). Between 1879 and 1920 Wundt published prolifically; a bibliography of his scientific writings was given by Titchener and Geissler (1908, with supplements continuing to 1922). Wundt's books included works on LOGIC and ethics as well as psychology, and his final years were devoted to his multivolume *Völkerpsychologie* (The Psychology of Peoples). It was in the first volume of this work that Wundt put forward an approach to PSYCHOLINGUISTICS that stressed that a mental representation was psychologically prior to the formation of a sentence in the speaker's mind; variations in the use of grammar permitted the speaker to emphasize one or another aspect of the MENTAL REPRESENTATION (Blumenthal 1970).

Among Wundt's ideas that received extensive discussion at the turn of the century, we may note his hypothesis that all "feelings" have the tridimensional attributes of being pleasant/unpleasant, exciting/depressing, and strained/relaxed; and his belief that the frontal lobes mediated the process known since the eighteenth century as "apperception," namely, the identification and grouping by the brain of sense data so that the perceiver attained coherence in his or her interpretation of reality. In this latter opinion, he belonged to a tradition of German psychology inherited from Leibniz and KANT; and the first Ph.D. thesis awarded at Leipzig for an experiment in psychology, that of Max Friedrich (1883), attempted to measure apperception-time. Wundt also insisted that any system of psychology had to include a purposive element, that is, a component reflecting intentional, voluntary decision making. He argued that the laws of mental science differ from the laws of physical science particularly insofar as the former cannot be described without including variables concerned with "value" or "desirability." And he maintained that thinking can involve a "creative synthesis" such that genuinely new ideas can emerge from the mental fusion of two or more ideas; a combination of ideas is not necessarily a simple And-Sum. In these beliefs, he foreshadowed GESTALT PSYCHOLOGY.

Meischner and Eschler (1979: 110–112) provide a list of thirty honorary degrees and memberships of foreign societies awarded to Wundt between 1874 and 1918, as well as a photograph of his Leipzig home, where he died of natural causes.

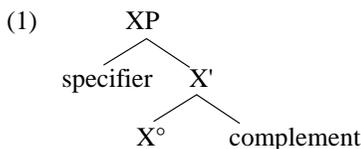
X-Bar Theory

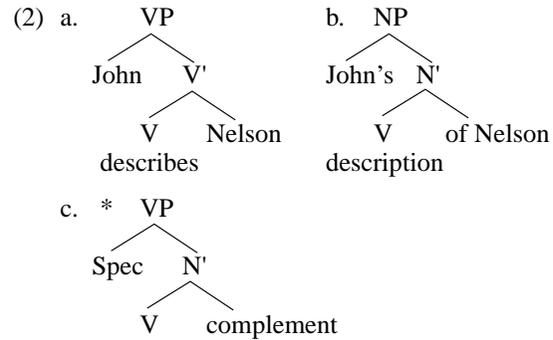
In generative SYNTAX (see GENERATIVE GRAMMAR), X-bar theory is the module of the grammar that regulates constituent structure. It aims at characterizing a possible syntactic configuration. In interaction with the other principles of the grammar, X-bar theory determines structural representations.

Syntactic structure is defined in terms of two principles: (i) constituents are endocentric, phrases are organized around a head (i.e. they are projections of heads); (ii) constituents are built up according to the schema (1).

(1)   XP
        / \
  specifier X'
            / \
          X°   complement


A head X° (a word, or a—possibly abstract—morpheme) combines with one maximal projection, its complement, to form the intermediate projection, $\overline{X}$ ("X-bar"), or X'. X' combines with another maximal projection, its spec(ifier) to form the maximal projection, represented as XP, or as $\overline{\overline{X}}$ ("X-double bar") or as X". The variable X ranges over syntactic categories of two types: lexical categories N(oun), V(erb), A(djective), P(reposition); and functional categories such as I(nflection) or C(omplementizer). Properties of the head percolate along the projection line: if the head is a V(erb), the projection will be a V(erb)P(hrase) (2a); a N(oun)head projects a N(oun)P(hrase) (2b), and so on. (2a) and (2b) are grammatical representations, but (2c) is ungrammatical:

(2) a.   VP   b.   NP
          /   \   /   \
       John   V'   John's   N'
              / \   / \
             V   Nelson   V   of Nelson
          describes   description

    c. *   VP
          /   \
        Spec   N'
               / \
              V   complement


The X-bar format makes it possible to express crosscategorial generalizations. Thus, for instance, the selectional properties of the V *describe* in (2a) are parallel to those of the N *description* in (2b).

(1) is the format of X-bar theory adopted in the principles-and-parameters approach to syntax (see MINIMALISM). There are a number of variations to the implementation of the core idea. For instance, for some approaches, X-bar theory need not be committed to the strong claim (due to Stowell 1981) that all constituents are endocentric, only that this is the default option. LEXICAL FUNCTIONAL GRAMMAR respects X-bar theory but allows for a finite set of exocentric phrases with special properties (notably S in nonconfigurational languages). In some versions of X-bar theory, it is assumed that all syntactic structure is binary branching (Kayne 1984). Other versions allow multiple complements and multiple specifiers (see Carrier and Randall 1992, for example). There is also variation with respect to the number of bar levels (see Stuurman 1985 for discussion).

Originally, the X-bar format was mainly elaborated for the projection of lexical categories (see Jackendoff 1977: 53), functional categories (inflectional morphemes such as the tense and agreement morphemes of verbs, or function words such as determiners or conjunctions) being integrated within lexical projections, typically as their specifiers. The sentence was interpreted either as an exocentric category— that is, a category without a head or as a projection of the verb (Jackendoff 1977). In the principles-and-parameters approach (Stowell 1981 and Chomsky 1986), the X-bar format is extended to all syntactic categories, functional as well as lexical. A sentence is an extended projection of a verb (Grimshaw 1991): it is a projection of V augmented with projections of inflectional morphemes. The sentence is dominated by a projection of the functional category C(omplementizer), which encodes its illocutionary force. In embedded clauses like (3a), C is filled by the complemen-

tizer (the subordinating conjunctions *that, if, for*). C takes as its complement IP, a projection of the verbal inflection (tense, agreement morphemes; Van Riemsdijk and Williams 1986; Haegeman 1994 for introductions).

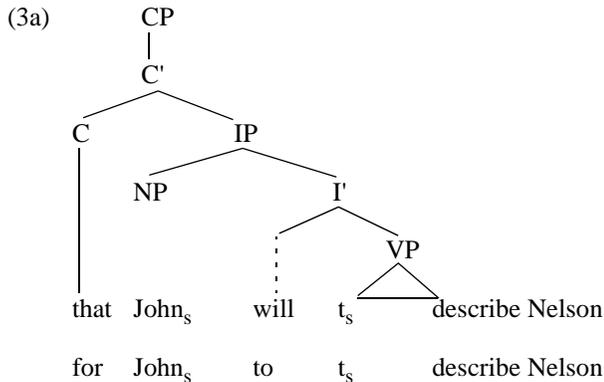
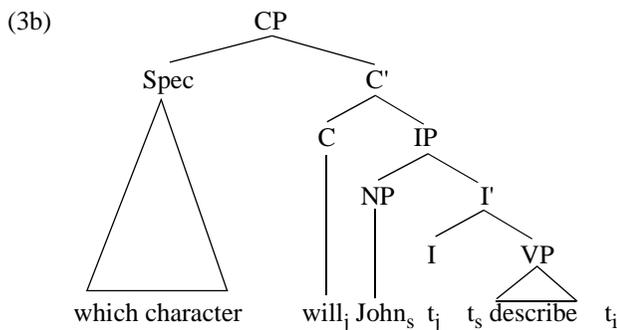
                 NP    I'
                      /  \
                    ...   VP
                         /  \
                  
    that  John_s   will   t_s    describe Nelson

    for   John_s   to     t_s    describe Nelson
```


In (3a) the subject NP, which originates in the specifier of VP (2a) (McCloskey 1997 discusses the status of subject in generative syntax; see also GRAMMATICAL RELATIONS), moves to the specifier position of IP. Movement leaves a trace (ts). (3b) illustrates the X-bar format as applied to an interrogative root clause. See also HEAD MOVEMENT and WH-MOVEMENT.

(3b)

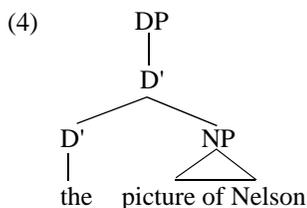
```
                  CP
                /    \
             Spec     C'
             /\      /  \
            /  \    C    IP
           /    \       /  \
          /_____\    NP    I'
                            /  \
     which character       I    VP
                                /\

  will_j  John_s  t_j  t_s describe  t_i
```


In (3b) the direct object, *which character*, has undergone *wh*-movement to the specifier of CP, and the auxiliary *will* has undergone head movement from I to C.

Abney (1987) shows that the projection of the noun (NP) must be reinterpreted as an extended projection of NP—that is, a projection of N augmented with functional projections, such as, among others, the projection of the D(eterminer), as shown in

(4)

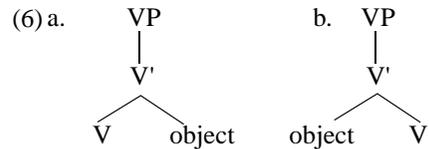
```
            DP
            |
            D'
           /  \
          D'   NP
          |   /  \
          |  /____\
         the  picture of Nelson
```


The X-bar format determines the hierarchical organization of structure but not the linear order of the constituents. English is an SVO language: in (5a) V precedes the direct object; West Flemish is an SOV language: in (5b) V follows the direct object. See also LINGUISTIC UNIVERSALS AND UNIVERSAL GRAMMAR.

(5) a. I think that John wants to buy this book.
    b. k peinzen da Valére wilt dienen boek kuopen.
       I think   that Valére wants that book buy

One option to account for the crosslinguistic variation is to postulate parametric variation in the base structure: whereas the underlying structure of the VP in (5a) is as in (6a), that of (5b) is as in (6b) (see Kayne 1984).

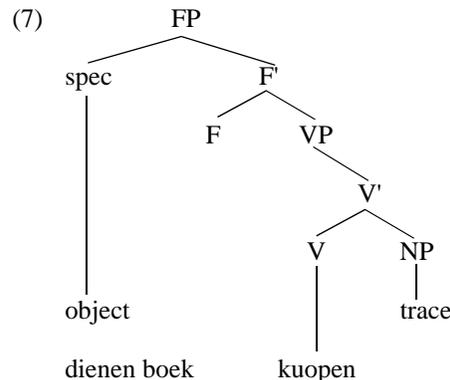
(6) a.

```
      VP                    b.    VP
      |                           |
      V'                          V'
     /  \                        /  \
    V   object            object    V'
```


An alternative option is to maintain that the base structure is invariantly head-initial, hence, the direct object always originates to the right of the head, V. Crosslinguistic word-order variation as that in (5) is derived by additional movement rules. In OV languages (see (5b), the object moves leftward to the specifier position of a functional projection dominating VP. The resulting representation (7) maps into an OV order.

(7)

```
                  FP
                /    \
             spec     F'
              |      /  \
              |     F    VP
              |          |
              |          V'
              |         /  \
              |        V    NP
              |        |    |
            object           trace

         dienen boek    kuopen
```


The mechanism of head movement, in conjunction with X-bar theory, accounts for the formation of complex verbs as found in POLYSYNTHETIC LANGUAGES (see Baker 1996).

The X-bar format is often claimed to find a predecessor in the superscripting convention of Harris (1951: chap. 6) whose aim was "to reduce the number of classes which we require when we state the composition of each utterance of the language" (1951: 262, in Stuurman 1985: 18). However, Stuurman (1985) has shown that structuralist superscripting is a lexical device and differs considerably from the generative X-bar format. The basis for the generative X-bar format was developed in Chomsky's (1970) "Remarks on Nominalization" whose aim was to capture crosscategorial generalizations without using transformations. X-bar theory is further elaborated by Emonds (1970) and Jackendoff (1974, 1977). Later developments concern the generalization to functional structure (Stowell 1981; Chomsky 1986), the binary branching format (Kayne 1984), the antisymmetry hypothesis (Kayne 1994), and the related universal base hypothesis (Kayne 1994).

Muysken (1981) interprets the concept of phrase-structure level in terms of a relational property expressed by two features [+projection], [+ maximal], where [–projection, –maximal] stands for X°, and [+projection, +maximal]

stands for XP, the maximal projection. Intermediate projections are [+projection, –maximal]. Chomsky (1995), capitalizing on Muysken's proposal, explores ways of reducing the X-bar format via the concept of bare phrase structure, in which the levels of projection are derived notions and in which nonbranching projections are eliminated (Speas 1990 is a precursor for this view). Ongoing controversies concern the status of adjunction (May 1985; Kayne 1994), the status of intermediate projections (Chomsky 1995; Kayne 1994), and the status of multiple specifiers (Chomsky 1995). For the structure of nonconfigurational languages, see Hale (1983). For investigations of the application of the X-bar format to morphology, see, among others, Aronoff (1976).

In imposing restrictions on the format for phrase structure rules, the X-bar format restricts the expressive power of the technical devices available for natural language grammars. The X-bar format imposes that a constituent is a projection of a head and that the internal structure of constituents is invariant crosscategorially. Taken as part of Universal Grammar, this constrained view of the format of phrase structure contributes towards explaining the rapidity and uniformity of the acquisition of syntactic structures.
