Domain-specificity is also apparent in the remarkable pockets of skill that people develop as a result of extensive experience. With enough practice at a task (e.g., playing chess, gathering factual knowledge about dinosaurs), an individual can develop extraordinary abilities within that task domain. For example, experts can achieve unusual feats of MEMORY, reorganize knowledge into complex hierarchical systems, and develop complex networks of causally related information (Chi, Hutchinson, and Robin 1989). These abilities are sufficiently powerful that child experts can even surpass novice adults, in contrast to the usual developmental finding of adults outperforming children (e.g., Chi 1978). Importantly, EXPERTISE skills cannot be explained as individual differences in the general processing talents of experts, because these achievements are limited to the narrow task domain. For example, a chess expert displays advanced memory for arrangements of pieces on a chessboard, but ordinary memory for digit strings.

Modular, theory-theory, and expertise views of domain-specificity differ from one another in several fundamental ways. They make different assumptions concerning what is innate, the role of input, mechanisms of development, interindividual variability in performance, and what constitutes a domain. For example, modular theories propose that mechanisms of developmental change are biological constraints, theory theories propose that the relevant mechanisms are causal-explanatory understandings, and expertise theories propose that such mechanisms are information-processing skills. Nonetheless, they converge on the proposal that cognitive abilities are specialized to handle specific types of information. For critiques of domain-specificity, see Bates, Bretherton, and Snyder (1988) and Elman et al. (1996).

Dominance in Animal Social Groups

Social dominance refers to situations in which an individual or a group controls or dictates others' behavior primarily in competitive situations. Generally, an individual or group is said to be dominant when "a prediction is being made about the course of future interactions or the outcome of competitive situations" (Rowell 1974: 133). Criteria for assessing and assigning dominance relationships can vary from one situation to another, even for studies of conspecifics (members of the same species), and the burden is on researchers to show that their methods are suitable for the situation at hand (Bekoff 1977; Chase 1980; Lehner 1996). It is difficult to summarize available data succinctly, but generally it has been found that dominant individuals, when compared to subordinate individuals, often have more freedom of movement, have priority of access to food, gain higher-quality resting spots, enjoy favorable grooming relationships, occupy more protected parts of a group, obtain higher-quality mates, command and regulate the attention of other group members, and show greater resistance to stress and disease. Despite assertions that suggest otherwise, it really is not clear how robust the relationship is between an individual's dominance status and its lifetime reproductive success (for comparative data see Dewsbury 1982; McFarland 1982; Clutton-Brock 1988; Alcock 1993; Berger and Cunningham 1994; Altmann et al. 1996; Drickamer, Vessey and Meikle 1996; Byers 1997; Frank 1997; Pusey, Williams, and Goodall 1997). There also can be costs associated with

dominance such that dominant individuals suffer because of stresses associated with the possibility of being overthrown by more subordinate individuals or because while they are defending their mates subordinates can sneak in and copulate with them (Wilson 1975; Hogstad 1987).

In practice, the concept of social dominance has proven to be ubiquitous but slippery (Rowell 1974; Bernstein 1981). Some researchers have questioned if dominance relationships are actually recognized by the animals themselves or if they are constructed by the human observers. Some also question if dominance hierarchies widely exist in nature or if they are due to the stresses associated with living in captivity (where much research is performed; see, for example, Rowell 1974). Others also feel that a lack of correlation between dominance in different contexts (for example, the possession of food, the acquisition or retention of a mate or a resting place) or in different locations argues against its conceptual utility (but see Hinde 1978). Nonetheless, many who have casually observed or carefully studied various animals agree that social dominance exists in similar forms and serves many of the same functions in widely diverse taxa, ranging from invertebrates to vertebrates including humans, and that dominance relationships among individuals are powerful organizing principles for animal social systems and population dynamics.

Based on, and expanding from, the classical studies of Schjelderup-Ebbe (1922) on dominance hierarchies in chickens, three basic types of hierarchies are usually recognized: (i) linear hierarchies (pecking-orders), usually in groups of fewer than ten individuals in which all paired relationships among individuals are transitive, such that if individual A dominates (>) individual B, and B > C, then A > C (wasps, bumblebees, chaffinches, turkeys, magpies, cows, ponies, coyotes, various nonhuman primates); (ii) nonlinear hierarchies in which there is at least one nontransitive relationship; and (iii) despotisms in which one individual (the alpha) in a group dominates all other individuals among whom dominance relationships are indistinguishable. Many papers concerned with historical aspects of social dominance in animals are reprinted in Schein (1975).

Although there has been little empirical experimental research done on cognitive aspects of, for example, how dominance status is recognized and represented in animals' minds, there are preliminary data that show that some animals have and use knowledge of other individuals' social ranks in their social interactions, and that individuals seem to agree on their ranking of others (Cheney and Seyfarth 1990; de Waal 1996; Tomasello and Call 1997). For example, when adult female vervet monkeys compete for grooming partners in their social group, individuals appear to rank one another and to agree on the rankings of the most preferred grooming partners. The understanding of dominance relationships—having and using the social knowledge needed for making evaluations and decisions—might entail constructing ordinal relationships and transitivity concerning the relationships among individuals with whom one has and has not had personal experience (Cheney and Seyfarth 1990; Tomasello and Call 1997), but the phylogenetic distribution of these skills remains to be determined. Certainly, the formation of alliances and coalitions (who to recruit, how to solicit them,

who to retaliate against, how and when to intervene, with whom to reciprocate; Tomasello and Call 1997) may involve having and using knowledge of others' social ranks, observing the outcomes of encounters between other individuals, and making deductions using this knowledge in the absence of personal experience. Social knowledge of self and others (in the absence of personal experience) may also be important in reconciliation, but detailed comparative data are scant (de Waal 1988, 1989; Harcourt and de Waal 1992; Silk, Cheney, and Seyfarth 1996).

All in all, insight and foresight (planning) seem to be important skills that are shown by a variety of nonhuman primates and nonprimates in their social encounters, but the comparative database is too small to support any general conclusions about whether individuals really do use insight and planning in their social interactions with others. Thus, broadly comparative and detailed research on the cognitive aspects of social dominance is sorely needed. These efforts will also inform other areas in the cognitive arena, including general questions about whether individuals have a theory of mind—whether they make attributions about the mental states of others and use this information in their own social encounters.

Dreaming

Mental activity does not cease at the onset of sleep. Current scientific evidence suggests instead that it is virtually continuous throughout sleep but that its level of intensity and its formal characteristics change as the brain changes its state with the periodic recurrence of rapid eye movement (REM) and non-REM (NREM) sleep phases.

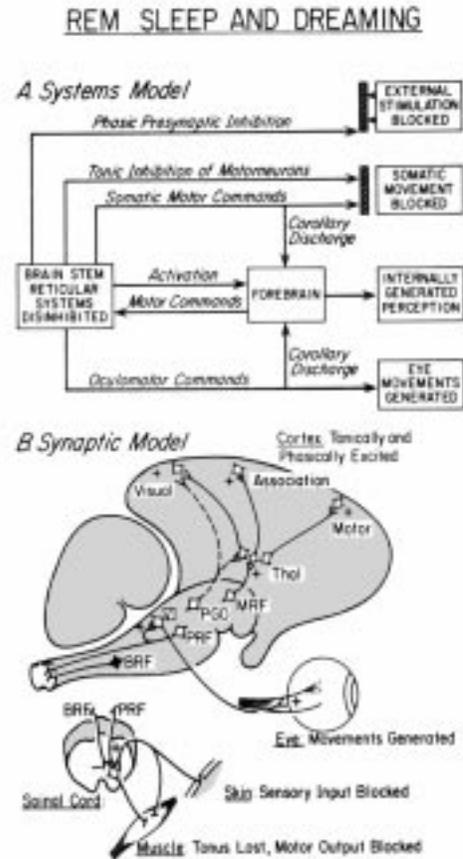
Until the discovery of REM sleep by Eugene Aserinsky and Nathaniel Kleitman in 1953, interest in the psychology of dreaming was restricted to speculative accounts of its distinctive phenomenology that were linked to schematic efforts to interpret dream content. The best known example of this kind of theorizing is the psychoanalytic model of Sigmund FREUD, which held that dream bizarreness was the result of the mind's effort to disguise and censor unconscious wishes released in sleep that in their unaltered form would over-


Figure 1. The Activation-Synthesis model. Systems and synaptic model. As a result of disinhibition caused by cessation of aminergic neuronal firing, brainstem reticular systems autoactivate. Their outputs have effects including depolarization of afferent terminals causing phasic presynaptic inhibition and blockade of external stimuli, especially during the bursts of REM, and postsynaptic hyperpolarization causing tonic inhibition of motorneurons that effectively counteract concomitant motor commands so that somatic movement is blocked. Only the oculomotor commands are read out as eye movements because these motorneurons are not inhibited. The forebrain, activated by the reticular formation and also aminergically disinhibited, receives efferent copy or corollary discharge information about somatic motor and oculomotor commands from which it may synthesize such internally generated perceptions as visual imagery and the sensation of movement, both of which typify dream mentation. The forebrain may, in turn, generate its own motor commands that help to perpetuate the process via positive feedback to the reticular formation.

whelm the mind and cause awakening. The discovery of the association of dreaming with REM sleep allowed a quite different approach. Emphasis suddenly shifted from the attempt to analyze the content to an attempt to explain the formal aspects of the distinctive phenomenology in terms of underlying brain activity.

This article gives a summary of how the cellular and molecular changes in the brain which distinguish waking, NREM and REM sleep can be used to account for the concomitant shifts in mental state that result in the shift in con-

sciousness from waking to dreaming. (See also SLEEP for relevant background information.)

Whether subjects are aroused from sleep in a laboratory setting or awaken spontaneously at home, they give reports of preawakening mental experience that are quite different if their brain state is REM than if it is non-REM. REM-sleep dream reports are seven times longer and are far more likely to describe formed sensory perceptions and vivid visual images than are the reports of NREM dreams, which tend to be more thoughtlike and dull. REM sleep reports are also far more likely to be animated, with descriptions of walking, running, playing sports, or even flying. Finally, the REM-sleep dream scenarios are accompanied by strong emotions such as anxiety, elation, and anger, all of which bear a close relationship to details of the plot.

These formal features of dreaming correlate well with changes in the activation level of the brain as measured by the degree of low-voltage, high-frequency power in the sleep electroencephalogram, and they are negatively correlated with high voltage, slow EEG patterns. Because the high-voltage, slow-wave activity of NREM sleep is most intense and prolonged in the first half of the night, reports from awakenings performed then are more likely to show differences from REM reports than are those from the second half of the night. Brain activation is therefore an easily understandable determinant of dream length and visual intensity. Dreamlike mentation may also emerge at sleep onset when the brain activation level is just beginning to fall. Sleep-onset dreaming is likely to be evanescent and fragmentary, with less vivid imagery, less strong emotion, and a less well developed story line than in REM-sleep dreaming.

Collaborating with the still high activation level to produce sleep-onset dreaming is the rapidly rising threshold to external sensory stimulation. This factor allows internal stimuli to dominate the brain. In REM sleep internal stimuli also protect the brain from external sensory influence. If the stimulus level is raised to sufficiently high levels, external information can be incorporated into dream plots, but the critical window for such incorporation is narrow and external stimuli more commonly interrupt dreaming by causing awakening. When dreams are interrupted in this way, recall of dreaming is markedly enhanced to levels as high as 95 percent if the subject is aroused from REM sleep during a cluster of rapid eye movements.

The strong correlation between dreaming and REM sleep has encouraged attempts to model the brain basis of dreaming at the cellular and molecular level. The activation-synthesis hypothesis, first put forward in 1977, ascribed dreaming to activation of the brain in REM sleep by a well-specified pontine brain stem mechanism.

Such distinctive aspects of dream mentation as vivid visual hallucinations, a constant sense of movement, and strong emotion were ascribed to internal stimulation of visual, motor, and limbic regions of the upper brain by signals of brain stem origin. The bizarreness of dream cognition, with its characteristic instability of time, place, and person, was thought to be due to the chaotic nature of the autoactivation process and to the failure of short-term memory caused by the chemical changes in REM described by

the reciprocal interaction model of brain state control first advanced in 1975.

Using microelectrode recording techniques to sample individual cell activity during natural sleep and waking in animal models, it has been possible to show that the neuromodulatory systems of the brain stem behave very differently in waking and REM sleep. These differences help to account for the distinctive psychological features of dreaming, especially the bizarreness and recent memory loss. During waking, cells of the noradrenergic locus coeruleus and the serotonergic raphe nuclei are tonically active, but in REM they are shut off. This means that the activated brain of REM is aminergically demodulated so that it cannot process information in the same way as it does in waking. Dream bizarreness and dream amnesia are both the result of this neuromodulatory defect. Compounding this difference, the pontine cholinergic neurones become reciprocally activated in REM, and their intense phasic activity conveys eye movement-related information to the visual sensory and motor areas of the brain (accounting for hallucinated dream vision and movement) and to the amygdala (accounting for the emotion of dreams).

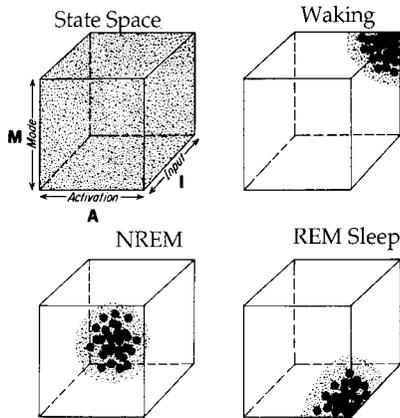
The specification of these neurochemical differences enables a three-dimensional state space model to be constructed that integrates activation level (A), input-output gating (I) with the brain modulatory factor (M). This hybrid psychophysiological construct thus updates both activation synthesis and reciprocal interaction by representing the energy level (A) information source (I) and processing mode (M) of the brain mind as a single point that continuously moves through the state space as a function of the values of A, I, and M.

According to AIM, dreaming is most likely to occur when activation is high, when the information source shifts from external to internal, and when the neuromodulatory balance shifts from aminergic to cholinergic. Because these shifts may occur gradually or suddenly, it is not surprising that the correlation of physiology with psychology is also statistical. REM is the most highly conducive to dreaming, but it can also occur at sleep onset and NREM sleep, both of which fulfill some of the necessary physiological conditions.

Our natural skepticism about the relevance of animal model data for human psychophysiology has been partially dispelled by recent POSITRON EMISSION TOMOGRAPHY (PET) studies of the human brain, which reveal significant regional changes in activation level during REM sleep compared to waking. The subjects of these studies all reported dreams after awakening from REM-sleep in the scanner. First and foremost is activation of the pontine brain stem, the presumed organizer of the REM-sleep brain. Second is the selective activation of the limbic forebrain and paralimbic cortex, the supposed mediator of dream emotion. Third is the selective inactivation of the dorsal prefrontal cortex, a brain region essential to self-reflective awareness and to executively guided thought, judgment, and action. Both of these cognitive functions are markedly deficient in dreaming.

Unfortunately, imaging techniques do not have the spatial or molecular resolution necessary to confirm the neuromodulatory hypothesis of AIM. But an extensive body of

AIM: A THREE DIMENSIONAL STATE SPACE MODEL

2A


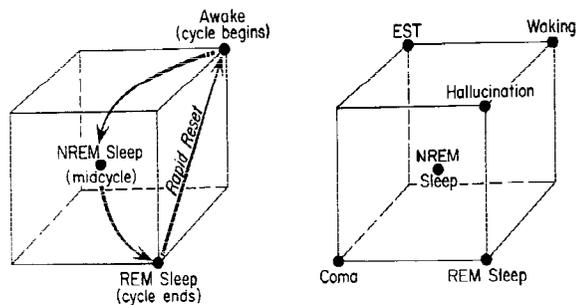
2B


Figure 2a. Three-dimensional state space defined by the values for brain activation (A), input source and strength (I), and mode of processing (M). It is theoretically possible for the system to be at any point in the state space, and an infinite number of state conditions is conceivable. In practice the system is normally constrained to a boomerang-like path from the back upper right in waking (high A, I, and M), through the center in NREM (intermediate A, I, and M) to the front lower right in REM sleep

Figure 2b. (A) Movement through the state space during the sleep cycle. (B) Segments of the state space associated with some normal, pathological, and artificial conditions of the brain.

human psychopharmacological data is consonant with the basic assumptions of the model. Drugs that act as aminergic agonists (or reuptake blockers) first suppress REM and REM-sleep dreaming. When they are later withdrawn, a marked and unpleasant intensification of dreaming and even psychosis may occur. If those drugs also possess anticholinergic actions, the effects on dreaming are even more pronounced. Finally, and most significantly, human REM-sleep dreaming is potentiated by some of the same cholinergic agonist drugs that experimentally enhance REM sleep in animals.

Dynamic Approaches to Cognition

The dynamical approach to cognition is a confederation of research efforts bound together by the idea that natural cognition is a dynamical phenomenon and best understood in dynamical terms. This contrasts with the "law of qualitative structure" (Newell and Simon 1976) governing orthodox or "classical" cognitive science, which holds that cognition is a form of digital COMPUTATION.

The idea of mind as dynamical can be traced as far back as David HUME, and it permeates the work of psychologists such as Lewin and Tolman. The contemporary dynamical approach, however, is conveniently dated from the early cybernetics era (e.g., Ashby 1952). In subsequent decades dynamical work was carried out within programs as diverse as ECOLOGICAL PSYCHOLOGY, synergetics, morphodynamics, and neural net research. In the 1980s, three factors—growing dissatisfaction with the classical approach, developments in the pure mathematics of nonlinear dynamics, and increasing availability of computer hardware and software for simulation—contributed to a flowering of dynamical research, particularly in connectionist form (Smolensky 1988). By the 1990s, it was apparent that the dynamical approach has sufficient power, scope, and cohesion to count as a research paradigm in its own right (Port and van Gelder 1995).

In the prototypical case, the dynamicist focuses on some particular aspect of cognition and proposes an abstract dynamical system as a model of the processes involved. The behavior of the model is investigated using dynamical systems theory, often aided by simulation on digital computers. A close match between the behavior of the model and empirical data on the target phenomenon confirms the hypothe-

sis that the target is itself dynamical in nature, and that it can be understood in the same dynamical terms.

Consider, for example, how we make decisions. One possibility is that in our heads there are symbols representing various options and the probabilities and values of their outcomes; our brains then crank through an ALGORITHM for determining a choice (see RATIONAL DECISION-MAKING). But this classical approach has difficulty accounting for the empirical data, partly because it cannot accommodate temporal issues and other relevant factors such as affect and context. Dynamical models treat the process of DECISION-MAKING as one in which numerical variables evolve interactively over time. Such models, it is claimed, can explain a wider range of data and do so more accurately (see, e.g., Busemeyer and Townsend 1993; Leven and Levine 1996).

A better understanding of dynamical work can be gained by highlighting some of its many differences with classical cognitive science. Most obviously, dynamicists take cognitive agents to be dynamical systems as opposed to digital computers. A dynamical system for current purposes is a set of quantitative variables changing continually, concurrently, and interdependently over quantitative time in accordance with dynamical laws described by some set of equations. Hand in hand with this first commitment goes the belief that dynamics provides the right tools for understanding cognitive processes. Dynamics in this sense includes the traditional practice of dynamical modeling, in which scientists attempt to understand natural phenomena via abstract dynamical models; such modeling makes heavy use of calculus and differential or difference equations. It also includes dynamical systems theory, a set of concepts, proofs, and methods for understanding the behavior of systems in general and dynamical systems in particular. A central insight of dynamical systems theory is that behavior can be understood geometrically, that is, as a matter of position and change of position in a space of possible overall states of the system. The behavior can then be described in terms of attractors, transients, stability, coupling, bifurcations, chaos, and so forth—features largely invisible from a classical perspective.

Dynamicists and classicists also diverge over the general nature of cognition and cognitive agents. The pivotal issue here is probably the role of time. Although all cognitive scientists understand cognition as something that happens *over* time, dynamicists see cognition as being *in* time, that is, as an essentially temporal phenomenon. This is manifested in many ways. The time variable in dynamical models is not a mere discrete order, but a quantitative, sometimes continuous approximation to the real time of natural events. Details of timing (durations, rates, synchronies, etc.) are taken to be essential to cognition itself rather than incidental details. Cognition is seen not as having a sequential cyclic (sense-think-act) structure, but rather as a matter of continuous and continual coevolution. The subtlety and complexity of cognition is found not *at* a time in elaborate static structures, but rather *in* time in the flux of change itself.

Dynamicists also emphasize SITUATEDNESS/EMBEDDEDNESS. Natural cognition is always environmentally embedded, corporeally embodied, and neurally "embrained." Clas-

sicists typically set such considerations aside (Clark 1997). Dynamicists, by contrast, tend to see cognitive processes as collective achievements of brains in bodies in contexts. Their language—dynamics—can be used to describe change in the environment, bodily movements, and neurobiological processes (e.g., Bingham 1995; Wright and Liley 1996). This enables them to offer integrated accounts of cognition as a dynamical phenomenon in a dynamical world.

In classical cognitive science, symbolic representations and their algorithmic manipulations are the basic building blocks. Dynamical models usually also incorporate representations, but reconceive them as dynamical entities (e.g., system states, or trajectories shaped by attractor landscapes). Representations tend to be seen as transient, context-dependent stabilities in the midst of change, rather than as static, context-free, permanent units. Interestingly, some dynamicists claim to have developed wholly representation-free models, and they conjecture that representation will turn out to play much less of a role in cognition than has traditionally been supposed (e.g., Skarda 1986; Wheeler forthcoming).

The differences between the dynamical and classical approaches should not be exaggerated. The dynamical approach stands opposed to what John Haugeland has called "Good Old Fashioned AI" (Haugeland 1985). However, dynamical systems may well be performing computation in some other sense (e.g., analog computation or "real" computation; Blum, Shub, and Smale 1989; Siegelmann and Sontag 1994). Also, dynamical systems are generally effectively computable. (Note that something can be *computable* without being a digital *computer.*) Thus, there is considerable middle ground between pure GOFAI and an equally extreme dynamicism (van Gelder 1998).

How does the dynamical approach relate to connectionism? In a word, they overlap. Connectionist networks are generally dynamical systems, and much of the best dynamical research is connectionist in form (e.g., Beer 1995). However, the way many connectionists structure and interpret their systems is dominated by broadly computational preconceptions (e.g., Rosenberg and Sejnowski 1987). Conversely, many dynamical models of cognition are not connectionist networks. Connectionism is best seen as straddling a more fundamental opposition between dynamical and classical cognitive science.

Chaotic systems are a special sort of dynamical system, and chaos theory is just one branch of dynamics. So far, only a small proportion of work in dynamical cognitive science has made any serious use of chaos theory. Therefore the dynamical approach should not be identified with the use of chaos theory or related notions such as fractals. Still, chaotic dynamics surely represents a frontier of fascinating possibilities for cognitive science (Garson 1996).

The dynamical approach stands or falls on its ability to deliver the best models of particular aspects of cognition. In any given case its ability to do this is a matter for debate among the relevant specialists. Currently, many aspects of cognition—e.g., story comprehension—are well beyond the reach of dynamical treatment. Nevertheless, a provisional consensus seems to be emerging that some significant range of cognitive phenomena will turn out to be dynamical, and

that a dynamical perspective enriches our understanding of cognition more generally.

Dynamic Programming

Some problems can be structured into a collection of small problems, each of which can be solved on the basis of the solution of some of the others. The process of working a solution back through the subproblems in order to reach a final answer is called dynamic programming. This general algorithmic technique is applied in a wide variety of areas, from optimizing airline schedules to allocating cell-phone bandwidth to justifying typeset text. Its most common and relevant use, however, is for PLANNING optimal paths through state-space graphs, in order, for example, to find the best routes between cities in a map.

In the simplest case, consider a directed, weighted graph < *S, A, T, L*>, where *S* is the set of nodes or "states" of the graph, and *A* is a set of arcs or "actions" that may be taken from each state. The state that is reached by taking action *a* in state *s* is described as *T(s,a)*; the positive length of the *a* arc from state *s* is written *L(s,a)*. Let *g* ∈ *S* be a desired goal state. Given such a structure, we might want to find the shortest path from a particular state to the goal state, or even to find the shortest paths from each of the states to the goal.

In order to make it easy to follow shortest paths, we will use dynamic programming to compute a distance function, *D(s)*, that gives the distance from each state to the goal state. The ALGORITHM is as follows:

```
D(s): = large
D(g): = 0
Loop |S| times
    Loop for s in S
        D(s): = min_{a ∈ A} L(s,a) + D(T(s,a))
    end loop
end loop
```

We start by initializing *D(s)* = *large* to be an overestimate of the distance between *s* and *g* (except in the case of *D(g)*, for which it is exact). Now, we want to improve iteratively the estimates of *D(s)*. The inner loop updates the value for each state *s* to be the minimum over the outgoing arcs of *L(s,a)* + *D(T(s,a))*; the first term is the known distance of the first arc

and the second term is the estimated distance from the resulting state to the goal. The outer loop is executed as many times as there are states.

The character of this algorithm is as follows: Initially, only $D(g)$ is correct. After the first iteration, $D(s)$ is correct for all states whose shortest path to the goal is one step long. After $|S|$ iterations, it is correct for all states. Note that if L was uniformly 1, then all the states that are i steps from the goal would have correct D values after the ith iteration; however, it may be possible for some state s to be one step from g with a very long arc, but have a much shorter path with more steps, in which case the D value after the iteration would still be an overestimate.

Once D has been computed, then the optimal path can be described by, at any state s, choosing the action a that minimizes $D(a,s)$. Rather than just a single plan, or trajectory of states, we actually have a *policy,* mapping every state to its optimal action.

A generalization of the shortest-paths problem is the problem of finding optimal policies for Markov decision processes (MDPs). An MDP is a tuple $< S, A, T, R>$, where S and A are state and action sets, as before; $T(s,a)$ is a stochastic state-transition function, mapping a state and action into a *probability distribution* over next states (we will write $T(s,a,s')$ as the probability of landing in state s' as a result of taking action a in state s); and $R(s,a)$ is a *reward* function, describing the expected immediate utility resulting from taking action a in state s. In the simplest case, we seek a policy π that will gain the maximum expected total reward over some finite number of steps of execution, k.

In the shortest-paths problem, we computed a distance function D that allowed us to derive an optimal policy cheaply. In MDPs, we seek a value function $V^k(s)$, which is the expected utility (sum of rewards) of being in state s and executing the optimal policy for k steps. This value function can be derived using dynamic programming, first solving the problem for the situation when there are t steps remaining, then using that solution to solve the problem for the situation when there are $t + 1$ steps remaining. If there are no steps remaining, then clearly $V^0(s) = 0$ for all s. If we know V^{t-1}, then we can express $V(t)$ as

$$V^t(s) = \max_{a \in A} R(s, a) + \sum s' \in S T(s, a, s') V^{t-1}(s')$$

The t-step value of state s is the maximum over all actions (we get to choose the best one) of the immediate value of the action plus the expected $t - 1$-step value of the next state. Once V has been computed, then the optimal action for state s with t steps to go is the action that was responsible for the maximum value of $V^t(s)$.

Solving MDPs is a kind of planning problem, because it is assumed that a model of the world, in the form of the T and R functions, is known. When the world model is not known, the solution of MDPs becomes the problem of REINFORCEMENT LEARNING, which can be thought of as stochastic dynamic programming.

The theory of dynamic programming, especially as applied to MDPs, was developed by Bellman (1957) and Howard (1960). More recent extensions and developments are described in excellent recent texts by Puterman (1994) and Bertsekas (1995).

Dynamic Semantics

The term *dynamic interpretation* refers to a number of approaches in formal semantics of natural language that arose in the 1980s and that distinguish themselves from the preceding paradigm by viewing interpretation as an inherently dynamic concept. The phrase *dynamic semantics* is used to denote a specific implementation of this idea, which locates the dynamic aspect in the concept of linguistic meaning proper.

The dominant view on meaning from the origins of logically oriented semantics at the beginning of the twentieth century until well into the 1980s is aptly summarized in the slogan "Meaning equals truth conditions." This formulates a static view on what MEANING is: it characterizes the meaning relation between sentences and the world as a descriptive relation, which is static in the sense that, although the meaning relation itself may change over time, it does not bring about a change itself. The slogan focuses on sentences, but derivatively the same holds for subsentential expressions: their meanings consist in the contribution they make to the truth conditions of sentences, a contribution that is usually formalized in terms of a static relation of reference. Interpretation is the recovery of the meaning of an utterance, and is essentially sentence-based. This static view on meaning and interpretation derives from the development of formal LOGIC, and lies at the basis of the framework of Montague grammar, the first attempt to apply systematically formal semantics to natural language.

Although dominant, the static view did not go unchallenged. The development of speech act theory (Austin, Searle) and work on PRESUPPOSITION (Stalnaker) and IMPLICATURE (GRICE) stressed the dynamic nature of interpretation. However, at first this just led to a division of labor between SEMANTICS and PRAGMATICS, the latter being viewed as something that works on top of the results of the former. This situation began to change in the beginning of the 1980s when people started to realize that certain empirical problems could be solved only by viewing meaning as an integrated notion that accounts for the dynamic aspects of interpretation right from the start and that is essentially concerned with DISCOURSE (or texts), and not with sentences.

A simple but illustrative example is provided by cross-sentential ANAPHORA. In a discourse such as "A man walked into the bar. He was wearing a black velvet hat," the pronoun "he" is naturally interpreted as bound by the indefinite noun phrase "a man." If interpretation proceeds on a sentence-by-sentence basis, this can not be accounted for. And "delayed" interpretation, that is, linking quantified noun phrases and pronouns only when the discourse is finished, makes empirically wrong predictions in other cases, such as: "One man was sitting in the bar. He was wearing a black velvet hat." Such examples rather suggest that interpretation has to be viewed as a dynamic process, which takes place incrementally as a discourse or text proceeds.

Further development of this idea received both an internal and an external stimulus. The main external influence came from natural language research within the context of artificial intelligence, which favored a definitely procedural view and was oriented toward units larger than sentences. The interpretation of utterances is modeled as the execution of procedures that change the state of a system as it proceeds. It took some time before this idea caught on, mainly because it seemed hard to reconcile with the core goal of formal semantics, viz., to account for logical relationships. However, the emergence of formal models within the AI paradigm, in particular the development of NONMONOTONIC LOGICS, provided the necessary link. Also, work on the semantics of programming languages turned out to be concerned with a conceptual machinery that could be applied successfully to natural language.

In the beginning of the 1980s the dynamic view on interpretation was formulated explicitly in discourse representation theory (Kamp 1981; see also Kamp and Reyle 1993) and file change semantics (Heim 1982). The work of Kamp and Heim constitutes an extension and transformation of the framework of Montague grammar. In his original paper Kamp explicitly describes his theory as an attempt to wed the static approach of the logical tradition to the procedural view of the AI paradigm. Within different settings similar ideas developed, for example within the theory of semantic syntax (Seuren 1985), and that of game theoretical semantics (Hintikka 1983).

Discourse representation theory is a dynamic theory of interpretation, not of meaning. The dynamics is located in the process of building up representational structures, so-called discourse representations. These structures are initiated by incoming utterances and added to or modified by subsequent utterances. The structures themselves are interpreted in a static way by evaluating them with respect to a suitable model. For example, anaphoric relations across sentence boundaries are analyzed as follows. A sentence containing a referential expression (such as a proper name, or a quantified term; see QUANTIFIERS) introduces a so-called discourse referent along with restrictions on its interpretation. A subsequent sentence containing an anaphoric expression (such as a pronoun) can "pick up" this referent if certain descriptive and structural conditions are met, and thus be linked to the antecedent referential expression. The semantics of the discourse representation then takes care of the coreference.

Dynamic semantics (Groenendijk and Stokhof 1991; Groenendijk, Stokhof, and Veltman 1996) takes the idea of dynamic interpretation one step further and locates the dynamics in the concept of meaning itself. The basic starting point of dynamic semantics can be formulated in a slogan: "Meaning is context-change potential." In other words, the meaning of a sentence is the change that an utterance of it brings about. And the meanings of subsentential expressions consist in their contribution to the context-change potential of the sentences in which they occur. Unlike discourse representation theory, it tries to do away with semantic representations but assigns various expressions, such as the existential quantifier associated with indefinite noun phrases, a dynamic meaning, which allows it to extend its binding force beyond its ordinary syntactic scope.

The slogan "Meaning is context-change potential" is general in at least two respects: it does not tell us what it is that is changed, and it does not say how the change is brought about. The latter question is answered by giving analyses of concrete linguistic structures. As to the former issue, it is commonly assumed that one of the primary functions of language use is that of information exchange and that, hence, information is what is changed by an utterance. Primary focus is the information state of the hearer, but in dialogical situations that of the speaker also has to be taken into account. Depending on the empirical domain, information concerns different kinds of entities. If the subject is anaphoric relations, information is about entities which are introduced and their properties; for temporal expressions one needs information about events and their location on a time axis; in the case of default reasoning expectation patterns become relevant. In other cases (question-answer dialogues, presuppositions) "higher order" information of the speech participants about each other is also at stake.

A change in the notion of meaning brings along a change in other semantic concepts, such as entailment. In static semantics truth plays a key role in defining meaning and entailment. In dynamic semantics it becomes a limit case. The central notion here is that of support: roughly, an information state s supports a sentence Φ iff an utterance of Φ does not bring about a change in s. Entailment can then be defined as follows (alternative definitions are possible as well): $\Phi_1 \ldots \Phi_n$ entails Ψ iff for every state s it holds that updating s with $\Phi_1 \ldots \Phi_n$ consecutively leads to a state that supports Ψ. (Cf. van Benthem 1996 for discussion of various alternatives.)

Dynamic semantics of natural language can be seen as part of a larger enterprise: the study of how information in general is structured and exchanged. Such a study brings together results from diverse fields such as computer science, cognitive psychology, logic, linguistics, and artificial intelligence. Language is one particular means to structure and exchange information, along with others such as visual representations, databases, and so on. The dynamic viewpoint has considerable merit here, and, conversely, draws on results that have been developed with an eye to other applications.

Dyslexia

Dyslexia is a developmental disorder of READING that is based on abnormal brain development. The brain changes exist from before birth and persist throughout life, although they do not usually manifest themselves clinically until the early school years, and many sufferers of this disorder compensate significantly by the time they reach adult life. The etiology of dyslexia remains unknown, but it is clear that both genetic and environmental factors play a role in its clinical manifestations.

The term *dyslexia* is used in the United States to refer to a developmental disorder of reading, whereas in the United Kingdom acquired disorders of reading may also be called *dyslexias*. Whereas *dyslexia* appears as an entry in *ICD-9-CM for Neurologists* (Neurology 1994) to represent either developmental or acquired disorders of reading, *DSM-IV* (Association 1994) does not have an entry for dyslexia altogether and instead has one for *reading disorder*. In this article only the developmental form is considered.

Some researchers have been unhappy with the term *dyslexia* and prefer to use *developmental reading disorder* instead, even though the term *dyslexia* means reading disorder. In *DSM-IV* the definition for *reading disorder* includes reading achievement (accuracy, speed, and/or comprehension as measured by individually administered standardized tests) that falls substantially below that expected given the individual's chronological age, measured intelligence, and age-appropriate education. Sensory-perceptual, cognitive, psychiatric, or neurological problems may coexist with the reading disorder, but should not be sufficient to explain the reading underachievement.

Other researchers (see Shaywitz et al. 1992) do not consider that intelligence should be a factor in the diagnosis, and prefer to include all individuals with reading difficulties, even those who are frankly mentally retarded. Still others insist that the reading disorder should be the consequence of disturbances of language function (see Vellutino 1987), specifically phonological processing (see PHONOLOGY), and that a reading disorder resulting from other mechanisms not be included.

It is generally accepted that the reading disorder is often accompanied by problems with writing, arithmetic, verbal memory, and subtle motor dysfunction. Sometimes there is also coexistence of anomalous HEMISPHERIC SPECIALIZATION, ATTENTION deficits, and emotional and personality disorders. Subtle problems with oral language are also commonly seen, but the presence of more severe disturbances in oral communication gives rise to the diagnosis of developmental language impairment, albeit with associated disturbances in reading and writing.

Dyslexia is the most commonly recognized form of learning disorder. The prevalence of dyslexia is accepted by most to be in the order of 4–5 percent of the school-age population. Depending on how the condition is defined, the prevalence figures range between 1 percent and 35 percent. Although problems may persist into adulthood, no clear figures about clinical prevalence in adult age groups exist. Most studies have shown a male prevalence in excess of that for females in the range of three to four males to one female. Some of this discrepancy may relate to reporting bias (the argument is that dyslexic girls are better behaved and go unnoticed). However, even when this is taken into consideration, a significant male preponderance still remains. As with other complex behaviors, normal and abnormal, that have their origin in a genetic background with added environmental influences, the prevalence of dyslexia depends in part on its definition, severity, and sociocultural attitudes.

The most common form of dyslexia is associated with deficits in phonological processing (Morais, Luytens, and Alegria 1984; Shankweiler et al. 1995), but other varieties, some based on disturbances affecting the visual system, have also been identified (Lovegrove 1991; Stein 1994). A difficulty with processing rapidly changing stimuli, affecting at least visual and auditory functions has also been implicated, which blurs the distinction between perceptual and cognitive mechanisms in the etiology of dyslexia (Merzenich et al. 1996a, 1996b; Tallal et al. 1995). The temporal processing hypothesis states that sensory-perceptual temporal processing deficits impede the development of normal phonological representations in the brain, which in turn produce the reading disorder. The main idea is that reading requires knowledge of the normal sound structure of the language before appropriate sound-sight associations can be made. Sensory-perceptual temporal processing deficits may lead to difficulties representing some language sounds that require rapid processing, which in turn leads to an incomplete or ambiguous sound repertoire and consequently difficulty with reading. The main objection to this theory is based on observations such as the presence of normal reading in many deaf people, and the counterargument is that the reading disorder rather reflects a deficit in semiconscious parsing (metalinguistic) of the sound stream into phonemes, as a prerequisite for mapping the parsed elements onto visual words.

Neurophysiological and psychophysical studies have shown abnormalities in visual perception and eye movements in dyslexics (Cornelissen et al. 1991). These findings are consistent with dysfunction of the magnocellular pathway of the visual system, which among other functions deals with rapid temporal processing (Greatrex and Drasdo 1995; Livingstone et al. 1991). Psychophysical evidence indicated that language-impaired children exhibit slow processing in the auditory system, too (Tallal and Piercy 1975). More recently studies employing functional MAGNETIC RESONANCE IMAGING showed that the area involved in motion perception, MT, does not activate normally in dyslexics, an area that forms part of the magnocellular system (Eden et al. 1996). In sum, therefore, there is increasing evidence to suggest that rapid processing is impaired in dyslexics, which may help account for the phonological disorder and hence the reading disorder. The ongoing debate has to do with the question of whether the type and degree of temporal processing perceptual difficulty seen in dyslexics is sufficient for explaining their language problems (for instance, see Paulesu et al. 1996).

Dyslexia is associated with anatomic changes in the brain. The normal human brain often shows asymmetry in the planum temporale, a region concerned with language function. Normal brains that are not asymmetric in the planum temporale show two large planums, rather than two small ones or two medium-sized ones. Dyslexic brains fail to show the standard asymmetric or symmetric pattern in the planum temporale (Galaburda 1993), presumably indicating a disturbance in the development of hemispheric specialization for language (see Annett, Eglinton, and Smythe 1996).

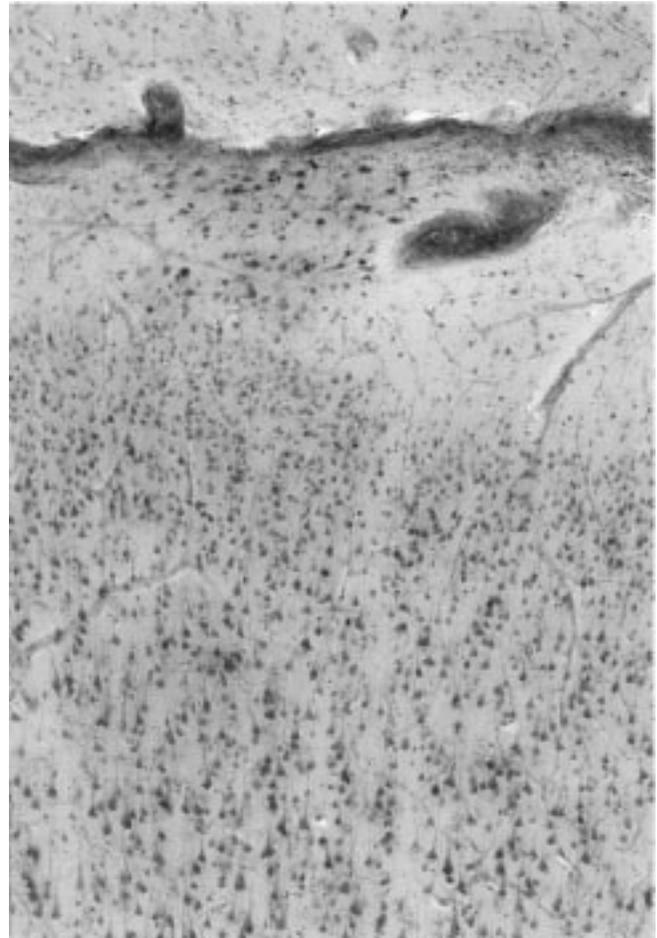
There are also subtle changes in the lamination of the CEREBRAL CORTEX, which are focal in nature and affect the left cerebral hemisphere more than the right in most cases (Galaburda 1994). They consist mostly of displaced nests of


Figure 1. Example of an ectopia found in the brain of a dyslexic. In the upper part of the photomicrograph there is an extrusion of neurons and glia into the molecular layer (uppermost layer of the cortex). This is one example of a neuronal migration anomaly.

neurons and glia in the frontal, parietal, and temporal cortex. These anomalies, called *ectopias* (see figure 1), reflect disturbances in neuronal migration to the cerebral cortex during fetal brain development. The fundamental cause of the migration disturbance, though suspected to be genetic, is not known (for a review of recent work on the genetics of dyslexia, see Pennington 1995).

Associated with the ectopias in the cerebral cortex are changes in the sizes of neurons of some thalamic sensory nuclei, including the visually linked lateral geniculate nucleus (LGN) (Livingstone et al. 1991) and the auditory medial geniculate nucleus (MGN; Galaburda, Menard, and Rosen 1994). These are structures close to the input channels for visual and auditory experience and are not involved in cognitive functions but rather in sensory perceptual functions. In the LGN, the neurons comprising the magnocellular layers are smaller in dyslexic than in control brains, and in the MGN there is a shift toward an excess of small neurons and a paucity of large neurons in the left hemisphere.

Ectopias have been induced in newborn rats, and the displaced neurons exhibit abnormal connections with neurons in the THALAMUS as well as with other cortical areas in the

ipsilateral and contralateral cerebral hemispheres (Rosen and Galaburda 1996). This provides a possible conduit for the propagation of changes from the ectopias to the thalamus and/or vice versa. Additional research has shown that induction of cortical malformations related to ectopias lead to secondary changes in the thalamus, namely the appearance of excessive numbers of small neurons and a paucity of large neurons (Herman et al. 1997). The animals with the induced malformations also exhibit slow temporal processing involving rapidly changing sounds. There are sex differences in these findings, such that induction of cortical malformations produce both behavioral changes and changes in thalamic neuronal sizes only in treated males. Females demonstrate the anatomic changes in the cortex, but no changes in the thalamus and no abnormal slowing in auditory processing. Moreover, administration of testosterone to pregnant rat mothers in the perinatal period produces masculinization of the female offspring complete with thalamic neuronal changes (Rosen, Herman, and Galaburda 1997).

In summary, animal models for the brain changes seen in association with developmental dyslexia indicate that abnormal cortical development can lead to abnormal development of the thalamus, and that it is likely that brain areas that deal with cognitive tasks and brain areas that deal with sensory-perceptual tasks are both affected in dyslexia. Moreover, the research indicates that multiple modalities, as well as multiple stages of processing, are involved, which may limit the ability of the developing brain to compensate. On the other hand, because of the relative discreteness of the neural connections even during development, not all cortical and thalamic areas are affected, setting up the possibility for a relatively delimited form of learning disorder.

Ebbinghaus, Hermann

Hermann Ebbinghaus (1850–1909) was the first psychologist to apply experimental methods to the study of human MEMORY. His groundbreaking book summarizing his experimental work, *Über das Gedächtnis,* was published in 1885.

The English translation appeared in 1913 as *Memory: A Contribution to Experimental Psychology* and is still in print and well worth reading today.

Ebbinghaus was born in Barmen, Germany, studied at the University of Bonn, and began his pioneering research on memory in Berlin in 1878. His work is notable for its many original features. In addition to performing the first experiments on memory, he provided an authoritative review of probability and statistics, an elegant command of experimental design, a mathematical model of the forgetting function, an enlightened discussion of problems of experimenter bias and demand characteristics in research, and a set of experimental results that has stood the test of time. All the experiments reported by Ebbinghaus have been replicated.

No one knows how he created his ingenious methods, although historians have speculated that his purchase of a copy of Fechner's book (in English) (1860/1966) and his reading about psychophysical methods may have been the source of his own clever methodology (see PSYCHOPHYSICS). Ebbinghaus solved the three problems faced by all cognitive/experimental psychologists in their work: to convert unobservable mental processes into observable behavior; to measure the behavior reliably; and to show how the behavior is systematically affected by relevant factors and conditions.

Ebbinghaus solved these problems by creating long lists of nonsense syllables (ZOK, VAM, etc.) to be memorized. He hoped that using these materials would permit him to study formation of new associations with relatively homogeneous materials. He learned the lists by reciting them in time to a metronome and measuring the amount of time or the number of repetitions taken until he could recite a list perfectly. He discovered quickly that the longer the list, the more repetitions were required to effect a perfect recitation. Although this was hardly a surprising finding, Ebbinghaus plotted the exact relation between the length of the series and the amount of time (or number of repetitions) to recall it once perfectly, a measure known as *trials to criterion*. He then had to determine how to measure retention of the series at some later point in time. Ebbinghaus's clever idea was to have himself relearn the list to the same criterion (of one perfect recitation); he could then obtain the savings (in time or repetitions) in relearning the series and use it as his measure of list retention. The greater the savings (the fewer trials to relearn the series), the greater is retention; conversely, if the same number of trials is needed to relearn the series as was originally required to learn it, then its forgetting was complete.

The beauty of Ebbinghaus's relearning and savings method is that measures of retention could be obtained even when recall of the list items was absent. This is one reason Ebbinghaus preferred his objective savings technique over what he called introspective techniques, such as recall or recognition. In a sense, ten years before FREUD proposed his ideas of unconscious mentation, Ebbinghaus had already devised a method whereby they could be studied. Even if someone failed to bring information to mind consciously, the unconscious residue could be examined through his relearning and savings technique.

Ebbinghaus made many discoveries with his new methods. He obtained a relatively precise relation between number of repetitions and forgetting: For every three repetitions of a list, he saved one repetition in relearning it a week later. He also discovered the logarithmic nature of the forgetting function; great forgetting occurred soon after learning, with the rate of forgetting slowing over time. In addition, he fitted an equation to the forgetting function. He also discovered the advantage of spaced repetitions of lists to massed repetition, when he found that "38 repetitions, distributed in a certain way over the three preceding days, has just as favorable an effect as 68 repetitions made on the day just previous" (page 89).

Ebbinghaus asked the question of whether associations were only formed directly, between adjacent nonsense syllables, or whether in addition remote associations were formed between syllables that were not adjacent. Using the symbols A, B, C, D, E, F, G, and H to represent syllables in a list to be learned, he asked whether there are only associations between A and B, B and C, and so on, or whether there are also associations (albeit presumably weaker ones) between A and C, A and D, and so on. Ebbinghaus developed a clever transfer of training design to answer the question. He derived lists for relearning that had associations of varying remoteness, which can be symbolized as ACEG . . . BDFH (for one degree of remoteness) or ADG . . . BEH . . . CF for two degrees of remoteness, and so on. He discovered that he did show savings in relearning these derived lists relative to control lists (that had no associations), and he concluded that the savings were the result of remote associations. In reviewing Ebbinghaus's work, William JAMES (1890) noted that "Dr. Ebbinghaus's attempt is as successful as it is original, in bringing two views, which seem at first sight inaccessible to proof, to a direct and practical test, and giving the victory to one of them" (page 677). The derived list experiments might be the first case of competitive hypothesis testing between two theories in experimental psychology.

Ebbinghaus was the only subject in all of his experiments, and this fact might give rise to doubt about the results. But he was a meticulous scientist, employing LOGIC, controls, and precise techniques far ahead of this time. All his results have stood the test of time. His particular methods of studying memory were rather quickly supplanted by other techniques—the introspective techniques of recall and recognition that he had wished to avoid—but his great achievements live on. He was the pioneer in showing how complex and unconscious mental processes could be studied through objective means by careful, systematic observation. As such, he helped pave the way for modern cognitive/experimental psychology.

Echolocation

Echolocation, a term first coined by Donald Griffin in 1944, refers to the use of sound reflections to localize objects and orient in the environment (Griffin 1958). Echolocating animals transmit acoustic signals and process information contained in the reflected signals, permitting the detection, localization and identification of objects. The use of echolocation has been documented in bats (e.g., Griffin 1958), marine mammals (e.g., Norris et al. 1961; Au 1993), some species of nocturnal birds (e.g., Griffin 1953) and to a limited extent in blind or blindfolded humans (e.g., Rice 1967). Only in bats and dolphins have specialized perceptual and neural processes for echolocation been detailed.

Acoustic signals for echolocation in bats and marine mammals are primarily in the ultrasonic range, above 20 kHz and the upper limit of human hearing. The short wavelengths of these ultrasound signals permit reflections from small objects in the environment. All bat species of the suborder Microchiroptera produce echolocation calls, either through the open mouth or through a nose-leaf, depending on the species. The signal types used by different bat species vary widely, but all contain some frequency modulated (FM) components, which are well suited to carry information about the arrival time of target echoes. Constant frequency (CF) signal components are sometimes combined with FM components, and these signals are well suited to carry information about target movement through Doppler shifts in the returning echoes. There is evidence that species using both FM and CF signals show individual variations in signal structure that could facilitate identification of self-produced echoes (see Suga et al. 1987; Masters, Jacobs, and Simmons 1991). One species of echolocating bat of the suborder Megachiropetera, *Rosettus aegyptiacus,* produces clicklike sounds with the tongue for echolocation (Novick 1958). The most widely studied echolocating marine mammal, the bottlenose dolphin (*Tursiops truncatus*), emits brief clicks, typically less than 50 μs in duration, with spectral energy from 20 kHz to over 100 kHz, depending on the acoustic environment in which the sounds are produced (Au 1993).

In echolocating animals, detection of a sonar target depends on the strength of the returning echo (Griffin 1958). Large sonar targets reflecting strong echoes are detected at greater distances than small sonar targets (Kick 1982; Au 1993). Psychophysical studies of echo detection in bats and dolphins indicate a strong dependence of performance on the acoustic environment. Forward and backward masking, background noise level, and reverberation can all influence sonar target detection (Au 1993; Moss and Schnitzler 1995).

Once an animal detects a sonar target, it must localize the object in three-dimensional space. In bats, the horizontal location of the target influences the features of the echo at the two ears, and these interaural cues permit calculation of a target's azimuthal position in space (Shimozowa et al. 1974). Laboratory studies of target tracking along the horizontal axis in bats suggest an accuracy of approximately 1 deg (Masters et al. 1985). The vertical location of a target results in a distinctive travel path of the echo into the bat's external ear, producing spectral changes in the returning sound that can be used to code target elevation (Grinnell and Grinnell 1965). Accuracy of vertical localization in bats is approximately 3 deg (Lawrence and Simmons 1982). The third dimension, target distance, depends on the time delay between the outgoing sound and returning echo (Hartridge 1945; Simmons 1973). Psychophysical studies of distance discrimination in FM bats report thresholds of about 1 cm, corresponding to a difference in echo arrival time of approximately 60 microseconds. Experiments that require the bat to detect a change in the distance (echo delay) of a jittering target report thresholds of less than 0.1 mm, corresponding to a temporal jitter in echo arrival time of less than 1 microsecond. Successful interception of insect prey by bats requires accuracy of only 1–2 cm (summarized in Moss and Schnitzler 1995). In marine mammals, psychophysical data show that the dolphin can discriminate a target range difference of approximately 1 cm, performance similar to that of the echolocating bat (Murchison 1980).

Many bats that use CF-FM signals are specialized to detect and process frequency and amplitude modulations in the returning echoes that are produced by fluttering insect prey. The CF components of these signals are relatively long in duration (up to 100 ms), sufficient to encode target movement from a fluttering insect over one or more wingbeat cycles. The CF-FM greater horseshoe bat, *Rhinolophus ferrumequinum*, can discriminate frequency modulations in the returning echo of approximately 30 Hz (less than 0.5% of the bat's 83 kHz CF signal component), and can discriminate fluttering insect species with different echo signatures (von der Emde and Schnitzler 1990). Several bat species that use CF-FM signals for echolocation exhibit Doppler shift compensation behavior: the bat adjusts the frequency of its sonar transmission to offset a Doppler shift in the returning echo, the magnitude of which depends on the bat's flight velocity (Schnitzler and Henson 1980). Doppler shift compensation allows the bat to isolate small amplitude and frequency modulations in sonar echoes that are produced by fluttering insects.

High-level perception by sonar has been examined in some bat species. Early work by Griffin et al. (1965) demonstrated that FM-bats can discriminate between mealworms and disks tossed into the air. Both mealworms and disks presented changing surface areas as they tumbled through the air, and this study suggested that FM-bats use complex echo features to discriminate target shape. The acoustic basis for target shape discrimination by FM-bats has been considered in detail by Simmons and Chen (1989); however, researchers have not yet determined whether FM bat species develop three-dimensional representations of objects using sonar (see Moss and Schnitzler 1995). Three-dimensional recognition

of fluttering insects has been reported in the greater horse-shoe bat, a species that uses a CF-FM signal for echolocation (von der Emde and Schnitzler 1990).

Successful echolocation depends on specializations in the auditory receiver to detect and process echoes of the transmitted sonar signals. Central to the conclusive demonstration of echolocation in bats was data on hearing sensitivity in the ultrasonic range of the biological sonar signals (Griffin 1958), and subsequent research has detailed many interesting specializations for the processing of sonar echoes in the auditory receiver of bats. In dolphins, studies of the central auditory system have been limited, but early work clearly documents high frequency hearing in the ultrasonic range of echolocation calls (e.g., Bullock et al. 1968).

In some CF-FM bat species, there are specializations in the peripheral and central auditory systems for processing echoes in the frequency range of the CF sonar component. The greater horseshoe bat, for example, adjusts the frequency of its sonar emissions to receive echoes at a reference frequency of approximately 83 kHz. The auditory system of this species shows a large proportion of neurons devoted to processing this reference frequency, and this expanded representation of 83 kHz can be traced to mechanical specializations of this bat's cochlea (Kössl and Vater 1995).

There are other specializations in the bat central auditory system for echo processing that may play a role in the perception of target distance. In bat species that utilize CF-FM signals and those that utilize FM sonar components alone, there are neurons in the midbrain, THALAMUS and cortex that respond selectively to pairs of FM sounds separated by a delay (e.g., Yan and Suga 1996). The pairs of FM sounds simulate the bat's sonar transmissions and returning echoes, and the time delay separating the two corresponds to a particular target distance. The pulse-echo delay evoking the largest facilitated response, referred to as the best delay (BD), is in some CF-FM bat species topographically organized (Suga and O'Neill 1979). Neural BD's fall into a biologically relevant range of 2–40 ms, corresponding to target distances of approximately 34 to 690 cm. Such topography has not been demonstrated in FM-bat species (e.g., Dear et al. 1993).

Many specializations in behavior and central auditory processing appear in echolocating animals; however, research findings suggest that echolocation builds on the neural and perceptual systems that evolved for hearing in less specialized animals.

Ecological Psychology

The term *ecological* has been used to characterize several theoretical positions in psychology, but only one—that of James J. GIBSON (1966, 1979) and his successors—is clearly relevant to cognitive science. (The others are Barker's descriptions of social behavior settings and Bronfenbrenner's analysis of the many contexts that influence the developing child; see ECOLOGICAL VALIDITY.) Gibson's views—and their subsequent development by other theorists—are the focus of the *International Society for Ecological Psychology*. The Society's journal *Ecological Psychology* has been published since 1989; the ecologically oriented *International Conference on Event Perception and Action* has met every two years since 1981.

The ecological approach rejects the cognitivist assumption of the poverty of the stimulus, that is, that perceivers must rely on MENTAL REPRESENTATIONS because they have access only to fragmentary and fallible sense-data. It also rejects many of the conventional variables that are usually regarded as the objects of perception: (absolute) distance, (absolute) size, (two-dimensional) form, etc. What people and animals actually perceive includes the *layout of the environment* (the arrangement of objects and surfaces, relative to one another and to the ground), the *shapes* of objects, the *self* (the perceiver's own situation in and motion through the layout), *events* (various types of movement and change),

and especially AFFORDANCES, possibilities for effective action. These things are perceivable because they are specified by information available to appropriately tuned perceptual systems. The task of ecological psychology is to analyze that information, and to understand how animals regulate their encounters with the environment by taking advantage of it.

The ecological analysis of vision begins not with the retinal image but with the *optic array*. At any point of observation to which an eye might come there is already an optical structure, formed by ambient light reflected to the point from all directions. Even a static array of such points is rich in information, but the transformations generated by observer motion are richer still: they specify the layout of the environment and the perceiver's path of motion uniquely. The *visual system* that evolved to take advantage of this information consists of a hierarchy of active organs: a pair of movable eyes, each with its lens and chamber and retina, stabilized in their orbits by the ocular muscles and set in a mobile head on a moving body (Gibson 1966). Note that the brain does not appear in this definition: the specialized neural mechanisms essential to vision have been of relatively little interest to ecological psychologists. Vision would be impossible without the brain, but it would be equally impossible without the optic array and the mobile organs of vision.

Much of the early research in ecological psychology focused on movement-produced information, which had been largely neglected in other approaches to perception. Kinetic *occlusion*, for example, occurs when nearby objects hide (or reveal) others beyond them as a result of observer or object motion. In occlusion, visible elements of surface texture are systematically deleted at one side of the occluding edge but not at the other. The result is a compelling impression of relative depth as well as a perceptual form of object permanence: one sees that the occluded object is going out of sight without going out of existence (see also DEPTH PERCEPTION). Movement-produced information (including deformations of shading, highlights, etc.) also plays a significant role in the perception of object shape (Norman, Todd, and Phillips 1995).

Another form of kinetic structure is *optic flow*, the characteristic streaming of the array produced by observer motion. Such flows have powerful effects on posture and can create vivid illusions of self-motion. Optic flow also enables perceivers to determine their heading (i.e., the direction in which they are moving), but the details of this process are presently controversial (Cutting 1996; Warren 1995). For more on optic flow, see MID-LEVEL VISION.

Looming is the rapid magnification of a sector of the array that occurs when an object approaches the eye or the eye approaches a surface. Looming specifies impending collision, and animals of many different species—humans, monkeys, chickens, crabs—respond appropriately. The time remaining before collision (assuming unchanged velocity) is optically specified by a variable called *tau* (Lee 1980). (If X is the visual angle subtended by the approaching object or any of its parts, the tau-function is $\tau(X) = X/[dX/dt]$.) A considerable body of evidence suggests that humans and other animals use tau-related information in

the control of action (e.g., Lee 1993), although the issue is not closed.

Given their focus on information structures rather than stimuli, ecological psychologists have been especially interested in *amodal invariants* available to more than one perceptual system. It is easy, for example, to match the shapes of seen objects with shapes felt with the hand (Gibson 1962)—easy not just for humans but for chimpanzees (Davenport, Rogers, and Russell 1973). Runeson and Frykholm (1981) have shown that one can judge the weight of a box just as well by watching someone else lift it as by lifting it oneself, even if one's view of the lifter is just a "point-light" display. Even infants can pick up many types of tactile-visual and audiovisual invariants, matching what they see to what they hear or feel. At any age, the perceived unity of environmental events—a person seen and heard as she walks by, the breaking of a glass that falls on the floor—depends on our sensitivity to amodal invariants.

Ecological psychologists have been among the leaders in the study of infant perception and PERCEPTUAL DEVELOPMENT. A case in point is the discovery, cited above, that infants are sensitive to amodal invariants. Another example concerns infant locomotion: reinterpreting her classical studies of the "visual cliff," E. J. Gibson has shown that babies' willingness to venture onto a surface depends on their perception of its affordances. A sharp dropoff affords falling but not crawling; an undulating waterbed affords crawling but not walking (Gibson et al. 1987); sloping surfaces afford various modes of exploration and locomotion (Adolph, Eppler, and Gibson 1993).

J. J. Gibson's (1966) concept of a *perceptual system* (as opposed to a sensory modality) is particularly useful in the study of HAPTIC PERCEPTION and dynamic touch. (The older term *tactile perception* suggests a more passive form of experience.) The haptic system includes a rich complex of afferent and efferent nerves as well as the skin, underlying tissues, muscles, digits, and joints. This system is capable of remarkable feats: one can, for example, determine a great deal about the length, shape, and other properties of an (unseen) rigid rod simply by wielding it with one hand. Michael Turvey (1996) and his associates have shown that the rotational/mechanical invariants on which this form of perception is based can be summarized in the inertia tensor I_{ij}, which represents the moments of inertia specific to a given object rotated around a fixed point. Because we "wield" our own limbs in much the same sense, the inertia tensor may provide a partial basis for self-perception as well. "Simply put, moving one's limbs can be considered a case of dynamic touch" (Pagano and Turvey 1995: 1081).

Ecological psychologists have also made substantial contributions to the study of motor control. Effective action requires the coordination of many simultaneously moving body parts, each with its own inertia and other physical attributes. That coordination must be matched to the specific affordances of the immediate environment, and hence cannot be achieved by any centrally programmed pattern of impulses. This problem has been widely recognized (see MOTOR CONTROL); part of the solution may be the formation of task-specific *coordinative structures*. "A group of muscles spanning several different joints, and capable of contracting independently of each other, can become functionally linked so as to perform as a single task-specific unit" (Turvey 1990: 940). Turvey and his collaborators have developed this concept in a series of studies of coordinated movements.

Other perceptual systems have been studied as well: as a first step toward an ecological analysis of hearing, Gaver (1993) has recently outlined a descriptive framework for the sounds of everyday events. Fowler (1986) has advanced an ecological approach to SPEECH PERCEPTION, which can be regarded as a special case of the perception of events (specifically, the movements of the articulatory organs). Stoffregen and Riccio (1988) have proposed an ecological analysis of the vestibular system and related phenomena such as motion sickness.

Since J. J. Gibson's death in 1979, theory development in ecological psychology has taken two principal forms. On the one hand is the development of increasingly sophisticated formal descriptions of environmental structure and the information that specifies it (e.g., Bingham 1995); more generally, of animal/environment mutuality (Turvey and Shaw 1995). On the other hand are various attempts to broaden the enterprise, using ecological concepts to address a range of classical psychological issues. In this vein are Eleanor Gibson's (1994) elaboration of her theory of development, Walker-Andrews's (1997) account of the perception of emotion, my own analysis of self-perception (Neisser 1993), and the wide-ranging theoretical work of Edward Reed. Reed's book *The Necessity of Experience* (1996b) is a philosophical and political critique of the assumptions underlying standard cognitive science; its companion volume *Encountering the World* (1996a) presents ecological analyses of many topics in psychology. "Cognition," says Reed, "is neither copying nor constructing the world. Cognition is, instead, the process that keeps us active, changing creatures in touch with an eventful, changing world" (1996a: 13).

Ecological Validity

The term *ecological validity* refers to the extent to which behavior indicative of cognitive functioning sampled in one environment can be taken as characteristic of an individual's cognitive processes in a range of other environments. Consequently, it is a central concern of cognitive scientists who seek to generalize their findings to questions about "how the mind works" on the basis of behavior exhibited in specially designed experimental or diagnostic settings. This concern was provocatively expressed by Urie Bronfenbrenner (1979), who complained that too much of the study of child development depended on the study of children in strange circumstances for short periods of time, in contrast with the ecologies of their everyday lives.

Discussions of the problem of ecological validity first came to prominence in cognitive research in the United States owing to the work of Egon Brunswik and Kurt Lewin, two German scholars who emigrated to the United States in the 1930s. Other important sources of ideas about ecological validity include Roger Barker (1978), whose work on the influence of social setting on behavior retains its influence to the present day, and J. J. GIBSON (1979), who argued that the crucial questions in the study of perception are to be resolved not so much by an attention to the perceiver as by the description of how the environment in particular everyday life arrangements "affords" a person perceptual information; the issue was given further prominence in Ulric Neisser's influential *Cognition and Reality* in 1976.

Brunswik (1943) proposed an ECOLOGICAL PSYCHOLOGY in which psychological observations would be made by sampling widely the environments within which particular "proximal" tasks are embedded. Brunswik's overall goal was to prevent psychology from being restricted to artificially isolated proximal or peripheral circumstances that are not representative of the "larger patterns of life." In order to avoid this problem, he suggested that situations, or tasks, rather than people, should be considered the basic units of psychological analysis. In addition, these situations or tasks must be "carefully drawn from the universe of the requirements a person happens to face in his commerce with the physical and social environment" (p. 263). To illustrate his approach, Brunswik studied size constancy by accompanying an individual who was interrupted frequently in the course of her normal daily activities and asked to estimate the size of some object she had just been looking at. This person's size estimates correlated highly with physical size of the objects and not with their retinal image size. This result, Brunswik claimed, "possesses a certain generality with regard to normal life conditions" (p. 265).

Lewin proposed a "psychological ecology," as a way of "discovering what part of the physical or social world will

determine, during a given period, the 'boundary zone' of the life space" of an individual (1943: 309). By life space, Lewin meant "the person and the psychological environment as it exists for him" (p. 306). He argued that behavior at time *t* is a function of the situation at time *t* only, and hence we must find ways to determine the properties of the lifespace "at a given time." This requirement amounts to what ethnographers refer to as "taking the subject's point of view." It seeks to unite the subjective and the objective.

If one agrees that understanding psychological processes in terms of the life space of the subject is important, following the logic of Lewin's argument, Brunswik's approach was inadequate. His experimental procedures did not allow him to observe someone fulfilling a well-specified task in a real-life environment; rather, it amounted to making experiments happen in a nonlaboratory environment. His procedures, in Lewin's terminology, changed the subject's life space to fit the requirements of his predefined set of observation conditions.

Ulric Neisser (1976) also pointed out marked discontinuities between the "spatial, temporal, and intermodal continuities of real objects and events" and the objects and events characteristic of laboratory-based research as a fundamental shortcoming of cognitive psychology, going so far as to suggest, "It is almost as if ecological *in*validity were a deliberate feature of the experimental design" (1976: 34).

Urie Bronfenbrenner's (1979, 1993) advocacy of ecologically valid research has greatly influenced the study of cognitive social development (Cole and Cole 1996). There are, he writes, three conditions that ecologically valid research must fulfill: (1) maintain the integrity of the real-life situations it is designed to investigate; (2) be faithful to the larger social and cultural contexts from which the subjects come; (3) be consistent with the participants' definition of the situation, by which he meant that the experimental manipulations and outcomes must be shown to be "perceived by the participants in a manner consistent with the conceptual definitions explicit and implicit in the research design" (1979: 35).

Note that there is a crucial difference between Lewin, Neisser, and Bronfenbrenner's interpretations of how to conduct ecologically valid research and the procedures proposed by Brunswik. Neisser, Bronfenbrenner, and others do not propose that we carry around our laboratory task and make it happen in a lot of settings. They propose that we discover and directly observe the ways that tasks occur (or don't occur) in nonlaboratory settings. Moreover, in Bronfenbrenner's version of this enterprise we must also discover the equivalent of Lewin's "life space," for example how the task and all it involves appear to the subject.

Two decades ago, the idea that such discovery procedures are possible was quite widespread among researchers who used experimental procedures and were cognizant of questions of ecological validity. Herbert Simon was echoing common opinion when he asserted that there is

a general experimental paradigm that can be used to test the commonality of cognitive processes over a wide range of task domains. The paradigm is simple. We find two tasks that have the same formal structure (e.g., they are both tasks of multi-dimensional judgment), one of which is drawn from a social situation and the other is not. If common processes are implicated in both tasks, then we should be able to produce in each task environment phenomena that give evidence of workings of the same basic cognitive mechanisms that appear in the other. (1976: 258)

However, a variety of contemporary research indicates that the requirements for establishing ecological validity place an enormous analytical burden on cognitive scientists (see Cole 1996: ch. 8–9 for an extended treatment of the associated issues). Once we move beyond the laboratory in search of representativeness, the ability to identify tasks is markedly weakened. Failure to define the parameters of the analyst's task or failure to insure that the task-as-discovered is the subject's task can vitiate the enterprise. This point was made clearly by Schwartz and Taylor (1978). Their particular interest was the representativeness of standardized achievement and IQ tests, but their specification of the issues involved has broad applicability in cognitive science. They queried, "Does the test elicit the same behavior as would the same tasks embedded in a real noncontrived situation? . . . Even to speak of the same task across contexts requires a model of the structure of the task. In the absence of such a model, one does not know where the equivalence lies (p. 54)."

As Valsiner and Benigni (1986) point out, standardized cognitive experimental procedures are meant to embody closed analytic systems (the point of the experimental/test procedures being to achieve precisely this closure). Consequently, attempting to establish task equivalence in order to generalize beyond the experimental circumstances amounts to imposing a closed system on a more open behavioral system. To the degree that behavior conforms to the prescribed analytic categories, one achieves ecological validity in Brunswik's sense. Yet a variety of research (reviewed in Cole 1996) has shown that even psychological tests and other presumably "closed system" cognitive tasks are more permeable and negotiable than analysts ordinarily take account of. Insofar as the cognitive scientist's closed system does not capture veridically the elements of the open system it is presumed to model, experimental results systematically misrepresent the life process from which they are derived. The issue of ecological validity then becomes a question of the violence done to the phenomenon of interest owing to the analytic procedures employed (Sbordone and Long 1996).

Economics and Cognitive Science

Economics is concerned with the equilibria reached by large systems, such as markets and whole economies. The units that contribute to these collective outcomes are the individual participants in the economy. Consequently, assumptions about individual behavior play an important role in economic theorizing, which has relied predominantly on a priori considerations and on normative assumptions about individuals and institutions.

In economics, it is assumed that every option has a subjective "utility" for the individual, a well-established position in his or her preference ordering (von Neumann and Morgenstern 1947; see RATIONAL DECISION MAKING). Because preferences are clear and stable they are expected to be invariant across normatively equivalent assessment methods (procedure invariance), and across logically equivalent ways of describing the options (description invariance). In addition, people are assumed to be good Bayesians (see BAYESIAN LEARNING and BAYESIAN NETWORKS), who hold coherent (and dynamically consistent) preferences through time. Economics also makes a number of secondary assumptions: economic agents are optimal learners, whose selfish focus is on tangible assets (e.g., consumer goods rather than goodwill), who ignore sunk costs, and who do not let good opportunities go unexploited.

Coinciding with the advent of cognitive science, Simon (1957) brought into focus the severe strain that the hypothesis of rationality put on the computing abilities of economic agents, and proposed instead to consider agents whose rationality was bounded (see BOUNDED RATIONALITY). Over the last three decades, psychologists, decision theorists, and, more recently, experimental and behavioral economists have explored people's economic decisions in some detail. These studies have emphasized the role of information processing in people's decisions. The evidence suggests that people often rely on intuitive heuristics that lead to non-Bayesian judgment (see JUDGMENT HEURISTICS), and that probabilities have nonlinear impact on decision (Kahneman and TVERSKY 1979; Wu and Gonzalez 1996). Preferences, moreover, appear to be formed, not merely revealed, in the elicitation process, and their formation depends on the framing of the problem, the method of elicitation, and the valuations and attitudes that these trigger.

Contrary to the assumption of utility maximization, evidence suggests that the psychological carriers of value are gains and losses, rather than final wealth (see DECISION MAKING). Because of diminishing sensitivity to greater amounts, people exhibit risk aversion for gains and risk seeking for losses (except for very low probabilities, where these can reverse). Prospects can often be framed either as gains or as losses relative to some reference point, which can trigger opposing risk attitudes and can lead to discrepant preferences with respect to the same final outcomes (Tversky and Kahneman 1986). People are also loss averse: the loss of utility associated with giving up a good is greater than the utility associated with obtaining it (Tversky and Kahneman 1991). Loss aversion yields "endowment effects," wherein the mere possession of a good can lead to higher valuation of it than if it were not in one's possession (Kahneman, Knetsch, and Thaler 1990), and also creates a general reluctance to trade or to depart from the status quo, because the disadvantages of departing from it loom larger than the advantages of the alternatives (Knetsch 1989; Samuelson and Zeckhauser 1988). In further violation of standard value maximization, decisional conflict can lead to a greater tendency to search for alternatives when better options are available but the decision is hard than when relatively inferior options are present and the decision is easy (Tversky and Shafir 1992).

When a multiattribute option is evaluated, in consumer choice for example, each attribute must be weighted in accord with its contribution to the option's attractiveness. The standard economic assumption is that such evaluation of options is stable and does not depend, for example, on the method of evaluation. Behavioral research, in contrast, has shown that the weight of an attribute is enhanced by its compatibility with a required response. Compatibility effects are well known in domains such as perception and motor performance. In line with compatibility, a gamble's potential payoff is weighted more heavily in a pricing task (where both the price and the payoff are expressed in the same monetary units) than in choice. Consistent with this is the preference reversal phenomenon (Slovic and Lichtenstein 1983), wherein subjects choose a lottery that offers a greater chance to win over another that offers a higher payoff, but then price the latter higher than the former. This pattern has been observed in numerous experiments, including one involving professional gamblers in a Las Vegas casino (Lichtenstein and Slovic 1973), and another offering the equivalent of a month's salary to respondents in the People's Republic of China (Kachelmeier and Shehata 1992).

People's representation of money also systematically departs from what is commonly assumed in economics. According to the fungibility assumption, which plays a central role in theories of consumption and savings such as the life-cycle or the permanent income hypotheses, "money has no labels"; all components of a person's wealth can be collapsed into a single sum. Contrary to this assumption, people appear to compartmentalize wealth and spending into distinct budget categories, such as savings, rent, and entertainment, and into separate mental accounts, such as current income, assets, and future income (Thaler 1985, 1992). These mental accounting schemes lead to differential marginal propensities to consume (MPC) from one's current income (where MPC is high), current assets (where MPC is intermediate), and future income (where MPC is low). Consumption functions thus end up being overly dependent on current income, and

people find themselves willing to save and borrow (at a higher interest rate) at the same time (Ausubel 1991). In addition, people often fail to ignore sunk costs (Arkes and Blumer 1985), fail to consider opportunity costs (Camerer et al. 1997), and show money illusion, wherein the nominal worth of money interferes with a representation of its real worth (Shafir, Diamond, and Tversky 1997).

Economic agents are presumed to have a good sense of their tastes and to be consistent through time. People, however, often prove weak at predicting their future tastes or at learning from past experience (Kahneman 1994), and their intertemporal choices exhibit high discount rates for future as opposed to present outcomes, yielding dynamically inconsistent preferences (Loewenstein and Thaler 1992). In further contrast with standard economic assumptions, people show concern for fairness and cooperation, even when dealing with unknown others in limited encounters, where long-term strategy and reputation are irrelevant (see, e.g., Dawes and Thaler 1988; Kahneman, Knetsch and Thaler 1986; Rabin 1993).

The foregoing partial list of empirical observations and psychological principles does not approach a unified theory comparable to that proposed by economics. The empirical evidence suggests that *Homo sapiens* is significantly more difficult to model than *Homo economicus*. Some have argued that the descriptive adequacy of the economic assumptions is unimportant as long as the theory is able to predict observed behaviors. Friedman (1953), for example, has proposed the analogy of an expert billiards player who, without knowing the relevant rules of physics or geometry, is able to play as if he did. Nonetheless, as the preceding list suggests, the tension between economics and the cognitive sciences appears to reside in the actual predictions, not only in the assumptions. Others have argued that individual errors are less important when one is ultimately interested in explaining aggregate behavior. The observed discrepancies, however, are systematic and predictable, and if the majority errs in the same direction there is no reason to expect that the discrepancies should disappear in the aggregate (Akerlof and Yellen 1985). Cognitive scientists and experimental and behavioral economists are trying better to understand and model systematic departures from standard economic theory. The aim is to bring to economics a theory populated with psychologically more realistic agents.

Education

In its broadest sense, education spans the ways in which cultures perpetuate and develop themselves, ranging from infant-parent communications to international bureaucracies and sweeping pedagogical or maturational movements (e.g., the constructivist movement attributed to PIAGET). As a discipline of cognitive science, education is a body of theoretical and applied research that draws on most of the other cognitive science disciplines, including psychology, philosophy, computer science, linguistics, neuroscience, and anthropology. Educational research overlaps with the central part of basic cognitive psychology that considers LEARNING. Such research may be idealized as primarily either descriptive or prescriptive in nature, although many research ventures have aspects of both.

Descriptively, educational research focuses on observing *human* learning. Specific areas of study include expert-novice approaches, CONCEPTUAL CHANGE and misconception research, skill learning, and METACOGNITION. Expert-novice research typically explicitly contrasts the extremes of a skill to infer an individual's changes in processes and representations. Misconception research in domain-based education, such as NAIVE PHYSICS, NAIVE MATHEMATICS, writing, and computer programming, implicitly contrasts expert knowledge with that of nonexperts; a person's current understanding may be thought of in terms of SCHEMATA, frames, scripts, MENTAL MODELS, or analogical or metaphorical representations. Child development research often involves studying misconceptions. These constructs are used for both explanatory and predictive purposes. Research in general skill learning includes psychometric analyses of high-level aptitudes (e.g., spatial cognition), and topics such as INDUCTION, DEDUCTIVE REASONING, abduction (hypothesis generation and evaluation), experimentation, critical or coherent reasoning, CAUSAL REASONING, comprehension, and PROBLEM SOLVING. Some of these skills are analyzed into more specific skills and malskills such as heuristics, organizing principles, bugs, and reasoning fallacies (cf. JUDGMENT HEURISTICS). Increasingly, metacognition research focuses on an individual's learning style, reflections, motivation, and belief systems. Research on learning can often be readily applied predictively (i.e., a priori). For example, Case (1985) predicted specific cognitive performance in balance-beam problem solving within defined stages of development.

Prescriptive elements of education are quite diverse. Some liken such elements to the engineering, as opposed to the science, of learning. Products of prescriptive education include modest reading modules, scientific microworlds, literacy standards, and assessment-driven curricular systems (e.g., Reif and Heller 1982; Resnick and Resnick 1992). The advent of design experiments (Brown 1992; Collins 1992) represents a kind of uneasy compromise between the rigorous control of laboratory research and the potential of greater relevance from classroom interventions.

Educational proponents of situated cognition generally highlight the notion that individuals always learn and perform within rather narrow situations or contexts, but such proponents are often reticent to offer specific pedagogical recommendations. Situated cognition variably borrows pieces of activity theories, ECOLOGICAL VALIDITY, group interaction, hermeneutic philosophies, direct perception, BEHAVIORISM, distributed cognition, cognitive psychology, and social cognition. It generally focuses on naturalistic, apprentice-oriented, artifact-laden, work-based, and even culturally exotic settings. This focus is often represented as a criticism of traditional school-based learning—even though some situated studies are run in schools (which are arguably natural in our society). Situated cognition's critics see it as an unstructured, unfalsifiable melange with near-infinite degrees of explanatory freedom and generally vague prescriptions. Recent disputes between the situated and mainstream camps seem to center on the questions, "What is a symbol?", "How can we separate a learner from a social situation?", and "Is transfer of training common or rare?" (e.g., Vera and Simon 1993, and commentaries). The disputes mirror many core issues from other cognitive science disciplines, as well as questions about the goals of social science.

Several cognitive theories have descriptive, predictive, *and* prescriptive applications to education. For instance, the ACT-based computational models of cognition (Anderson 1993) attempt to account for past data, predict learning outcomes, and serve as the basis for an extended family of intelligent tutoring systems (ITSs). These sorts of models might incorporate proposition-based semantic networks, "adaptive" or "learning" production systems, economic or rational analyses, and representations of individual students' strengths and weaknesses. The contrasts among various

computer-based categories of learning-enhancement systems have not been sharp (Wenger 1987). These categories include ITSs, computer-aided instruction, interactive learning environments, computer coaches, and guided discovery environments. Some distinctions among these categories include (a) whether a model of student knowledge or skill is employed, (b) whether a relatively generative knowledge base for a chosen domain is involved, (c) whether feedback comes via hand-coded (or compiled) buggy rules (and lookup tables) or via the interpreted semantics of a knowledge base, and (d) whether a novel, more effective representation is introduced for a traditional one. Superior ITSs demonstrate great effectiveness relative to many forms of standard instruction, but currently have limited interactional sophistication compared to human tutoring (Merrill et al. 1992). Specific ITSs often spawn the following question from both within and without cognitive science: "Where is the intelligence, or the semantics, in this system?"

Distributed cognition systems also face this question, although many proponents are unconcerned about philosophical semantics-from-syntax queries. Constraint-based and connectionist models are not yet commonly employed in educational ventures (cf. Ranney, Schank, and Diehl 1995), which seems surprising, given the efforts focused on learning in parallel distributed processing models of cognition, BAYESIAN NETWORKS, artificial neural or fuzzy networks, and the like.

As with some ITSs, cognitive science approaches to education, in general, often focus on improving students' knowledge representations or on providing more generative or transparent representations. Many such representational systems have evolved with computational technology, particularly as graphical user interfaces supplant text-based, command-line interactions. Clickable, object-oriented interfaces have become the norm, although the complexity of such features sometimes overwhelms and inhibits learners.

Most recently, the Internet and World Wide Web have spawned many research ventures, for instance, involving collaborative learning environments that include the integration of technology and curricula. However, an ongoing danger to education is the proliferation of well-funded research projects developing potentially promising technologies that, relative to the vast majority of classrooms, (a) require intolerable levels of equipment upgrades or technical and systemic support, (b) are unpalatable to classroom teachers, and (c) simply do not "scale up" to populations of nontrivial size (cf. Cuban 1989).

Electric Fields

See ELECTROPHYSIOLOGY, ELECTRIC AND MAGNETIC EVOKED FIELDS

Electrophysiology, Electric and Magnetic Evoked Fields

Electric and magnetic evoked fields are generated in the brain as a consequence of the synchronized activation of neuronal networks by external stimuli. These evoked fields may be associated with sensory, motor, or cognitive events, and hence are more generally termed *event-related potentials* ERPs) and *event-related magnetic fields* (ERFs), respectively. Both ERPs and ERFs consist of precisely timed sequences of waves or components that may be recorded noninvasively from the surface of the head to provide information about spatio-temporal patterns of brain activity associated with a wide variety of cognitive processes (Heinze, Münte, and Mangun 1994; Rugg and Coles 1995).

Electric and magnetic field recordings provide complementary information about brain function with respect to other neuroimaging methods that register changes in regional brain metabolism or blood flow, such as POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI). Although PET and fMRI provide a detailed anatomical mapping of active brain regions during cognitive performance, these methods cannot track the time course of neural events with the high precision of ERP and ERF recordings. Studies that combine ERP/ERF and PET/fMRI methodologies are needed to resolve both the spatial and temporal aspects of brain activity patterns that underlie cognition.

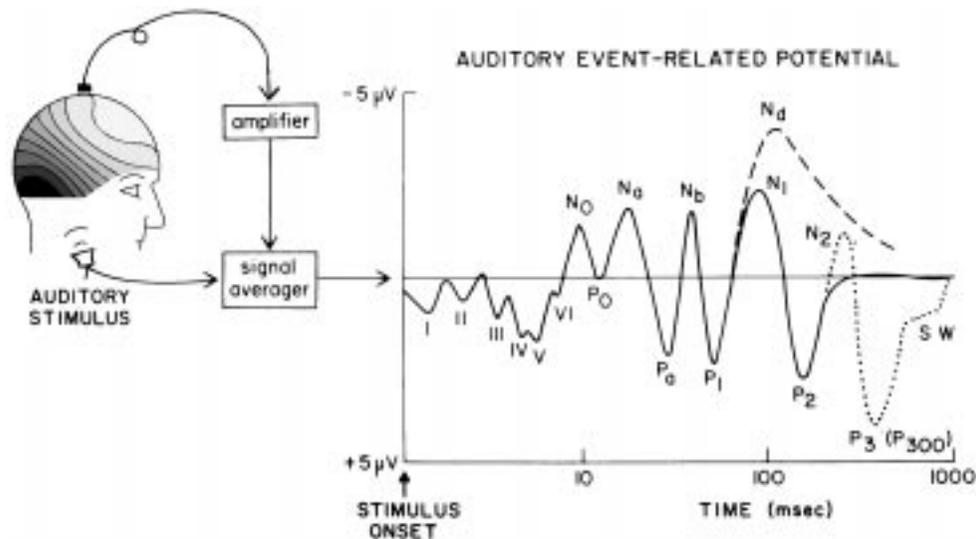
At the level of SINGLE-NEURON RECORDING, both ERPs and ERFs are generated primarily by the flow of ionic currents


Figure 1. The characteristic time-voltage waveform of the auditory ERP in response to a brief stimulus such as a click or a tone. To extract the ERP from the ongoing noise of the electroencephalogram, it is necessary to signal average the time-locked waves over many stimulus presentations. The individual waves or components of the ERP are triggered at specific time delays or latencies after the stimulus (note logarithmic time scale). The earliest waves (I–VI) are generated in the auditory brainstem pathways, while subsequent negative (N) and positive (P) waves are generated in different subregions of primary and secondary auditory cortex. (From Hillyard, S.A. (1993). Electrical and magnetic brain recordings: contributions to cognitive neuroscience. Current Opinion in Neurobiology 3: 217–224.)

across nerve cell membranes during synaptic activity. ERPs arise from summed field potentials produced by synaptic currents passing into the extracellular fluids surrounding active neurons. In contrast, ERFs are produced by the concentrated intracellular flow of synaptic currents through elongated neuronal processes such as dendrites, which gives rise to concentric magnetic fields surrounding the cells. When a sufficiently large number of neurons having a similar anatomical position and orientation are synchronously activated, their summed fields may be strong enough to be detectable as ERPs or ERFs at the surface of the head. The detailed study of scalp-recorded ERPs became possible in the 1960s following the advent of digital signal-averaging computers, whereas analysis of ERFs required the further development in the 1980s of highly sensitive, multichannel magnetic field sensors (Regan 1989).

The anatomical locations of the neuronal populations that generate ERPs and ERFs may be estimated on the basis of their surface field configurations. This requires application of algorithms and models that take into account the geometry of the generator neurons and the physical properties of the biological tissues. Active neural networks may be localized in the brain more readily by means of ERF than by surface ERP recordings, because magnetic fields pass through the brain, skull, and scalp without distortion, whereas ERPs are attenuated by the resistivity of intervening tissues. Both ERP and ERF data have been used successfully to reveal the timing of mental operations with a high degree of precision (of the order of milliseconds) and to localize brain regions that are active during sensory and perceptual processing, selective attention and discrimination, memory storage and retrieval, and language comprehension (Hillyard 1993).

The processing of sensory information in different modalities is associated with characteristic sequences of surface-recorded ERP/ERF components (figure 1). In each modality, components at specific latencies represent evoked activity in subcortical sensory pathways and in primary and secondary receiving areas of the CEREBRAL CORTEX. Cortical components with latencies of 50–250 msec have been associated with perception of specific classes of stimuli (Allison et al. 1994) and with short-term sensory memory processes. Altered sensory experience (e.g., congenital deafness, blindness, or limb amputation) produces marked changes in ERP/ERF configurations that reflect the NEURAL PLASTICITY and functional reorganization of cortical sensory systems (Neville 1995).

Recordings of ERPs and ERFs have revealed both the timing and anatomical substrates of selective ATTENTION operations in the human brain (Näätänen 1992; Hillyard et al. 1995). In dichotic listening tasks, paying attention to sounds in one ear while ignoring sounds in the opposite ear produces a marked enhancement of short-latency ERP/ERF components to attended-ear sounds in auditory cortex. This selective modulation of attended versus unattended inputs during AUDITORY ATTENTION begins as early as 20–50 msec poststimulus, which provides strong support for theories of attention that postulate an "early selection" of stimuli prior to full perceptual analysis. In visual attention tasks, stimuli presented at attended locations in the visual field elicit enlarged ERP/ERF components in secondary (extrastriate) cortical areas as early as 80–100 msec poststimulus. This suggests that visual attention involves a sensory gain control or amplification mechanism that selectively modulates the flow of information through extrastriate cortex. Paying

attention to nonspatial features such as color or shape is manifested by longer latency components that index the time course of feature analyses in different visual-cortical areas.

ERPs and ERFs provide a converging source of data about the timing and organization of information processing stages that intervene between a stimulus and a discriminative response. Whereas short-latency components demarcate the timing of early sensory feature analyses, longer latency components ("N200" and "P300" waves) are closely coupled with processes of perceptual discrimination, OBJECT RECOGNITION, and classification. ERP components generated in motor cortex index the timing of response selection and MOTOR CONTROL processes. Studies using these ERP measures have provided strong support for "cascade" theories that posit a continuous flow of partially analyzed information between successive processing stages during sensory-motor tasks (Coles et al. 1995).

Long-latency ERPs have been linked with MEMORY encoding, updating, and retrieval processes (Rugg 1995). ERPs elicited during LEARNING can reliably predict accuracy of recall or recognition on subsequent testing. Some components appear to index conscious recognition of previously learned items, whereas others are sensitive to contextual priming effects. These memory-related components have been recorded both from the scalp surface and from implanted electrodes in hippocampus and adjacent temporal lobe structures in neurosurgical patients.

ERP and ERF recordings are also being used effectively to investigate the NEURAL BASIS OF LANGUAGE, including phonetic, lexical, syntactic, and semantic levels of processing (Kutas and Van Petten 1994). Alterations in specific ERP/ERF components have been linked to syndromes of LANGUAGE IMPAIRMENT. A late negative ERP ("N400") provides a graded, on-line measure of word expectancy and semantic priming during sentence comprehension. Studies of N400 have contributed to understanding the organization of semantic networks in the brain (McCarthy et al. 1995).

Eliminative Materialism

Eliminative materialism, or "eliminativism" as it is sometimes called, is the claim that one or another kind of mental state invoked in commonsense psychology does not really exist. Eliminativists suggest that the mental states in question are similar to phlogiston or caloric fluid, or perhaps to the gods of ancient religions: they are the nonexistent posits of a seriously mistaken theory. The most widely discussed version of eliminativism takes as its target the intentional states of commonsense psychology, states like beliefs, thoughts and desires (P. M. Churchland 1981; Stich 1983; Christensen and Turner 1993). The existence of conscious mental states such as pains and visual perceptions has also occasionally been challenged (P. S. Churchland 1983; Dennett 1988; Rey 1983).

Though advocates of eliminativism have offered a wide variety of arguments, most of the arguments share a common structure (Stich 1996). The first premise is that beliefs, thoughts, desires, or other mental states whose existence the argument will challenge can be viewed as posits of a widely shared commonsense psychological theory, which is often called "folk psychology." FOLK PSYCHOLOGY, this premise maintains, underlies our everyday discourse about mental states and processes, and terms like "belief," "thought," and "desire" can be viewed as theoretical terms in this commonsense theory. The second premise is that folk psychology is a seriously mistaken theory because some of the central claims that it makes about the states and processes that give rise to behavior, or some of the crucial presuppositions of these claims, are false or incoherent. This second premise has been defended in many ways, some of which will be considered in the following discussion. Both premises of the eliminativist argument are controversial. Indeed, debate about the plausibility of the second premise, and thus about the tenability of commonsense psychology, has been one of the central themes in the philosophy of mind for several decades. From these two premises eliminativists typically draw a pair of conclusions. The weaker conclusion is that the cognitive sciences that ultimately give us a correct account of the workings of the human mind/brain will not refer to commonsense mental states like beliefs and desires; these states will not be part of the ontology of a mature cognitive science. The stronger conclusion is that these commonsense mental states simply do not exist. Most of the discussion of eliminativism has focused on the plausibility of the premises, but several authors have argued that even if the premises are true, they do not give us good reason to accept either conclusion (Lycan 1988; Stich 1996)

Arguments in defense of the second premise typically begin by making some claims about the sorts of states or mechanisms that folk psychology invokes, and then arguing that a mature cognitive science is unlikely to countenance states or mechanisms of that sort. One family of arguments follows Wilfrid Sellars (1956) in maintaining that folk psychology takes thoughts and other intentional states to be modeled on overt linguistic behavior. According to this Sellarsian account, common sense assumes that beliefs are quasi-linguistic states and that thoughts are quasi-linguistic

episodes. But if this is right, one eliminativist argument continues, then either nonhuman animals and prelinguistic children do not have beliefs and thoughts, or they must think in some nonpublic LANGUAGE OF THOUGHT, and both of these options are absurd (P. S. Churchland 1980). Opponents of the argument fall into two camps. Some, following Donald Davidson (1975), argue that children and nonhuman animals *do not* have beliefs or thoughts, whereas others, most notably Jerry Fodor (1975), argue that children and higher animals do indeed think in a nonpublic "language of thought." Another argument that relies on the Sellarsian account of beliefs and thoughts notes that neuroscience has thus far failed to find syntactically structured, quasi-linguistic representations in the brain and predicts that the future discovery of such quasi-linguistic states is unlikely (Van Gelder 1991).

Many authors have challenged the claim that commonsense psychology is committed to a quasi-linguistic account of intentional states (see, for example, Loar 1983; Stalnaker 1984), and a number of arguments for the eliminativist's second premise rely on less controversial claims about commonsense psychology. One of these arguments (Ramsey, Stich, and Garon 1990) maintains only that, according to commonsense psychology, a belief is a contentful state that can be causally involved in some cognitive episodes while it is causally inert in others. It is not the case that all of our beliefs are causally implicated in all of our inferences. However, there is a family of connectionist models of propositional memory in which information is encoded in a thoroughly holistic way. All of the information encoded in these models is causally implicated in every inference the model makes. Thus, it is claimed, there are *no* contentful states in these models which can be causally involved in some cognitive episodes and causally inert in others. Whether or not connectionist models of this sort will provide the best psychological account of human propositional memory is a hotly disputed question. But if they do, the eliminativist argument maintains, then folk psychology will turn out to be pretty seriously mistaken. A second argument (due to Davies 1991) that relies on connectionist models begins with the claim that commonsense psychology is committed to a kind of "conceptual modularity." It requires that there is "a single inner state which is active whenever a cognitive episode involving a given concept occurs and which can be uniquely associated with the concept concerned" (Clark 1993). In many connectionist models, by contrast, concepts are represented in a context-sensitive way. The representation of coffee in a cup is different from the representation of coffee in a pot (Smolensky 1988). Thus, there is no state of the model that is active whenever a cognitive episode involving a given concept occurs and that can be uniquely associated with the concept concerned. If these models offer the best account of how human concepts are represented, then once again we have the conclusion that folk psychology has made a serious mistake.

Still another widely discussed family of arguments aimed at showing that folk psychology is a seriously mistaken theory focus on the fact that commonsense psychology takes beliefs, desires, and other intentional states to have semantic properties—truth or satisfaction conditions—

and that commonsense psychological explanations seem to attribute causal powers to intentional states that they have in virtue of their semantic content. A number of reasons have been offered for thinking that this reliance on semantic content will prove problematic. Some authors argue that semantic content is "wide"—it depends (in part) on factors outside the head—and that this makes it unsuitable for the scientific explanation of behavior (Stich 1978; Fodor 1987). Others argue that semantic content is "holistic"—it depends on the entire set of beliefs that a person has—and that useful scientific generalizations cannot be couched in terms of such holistic properties (Stich 1983). Still others argue that semantic properties cannot be reduced to physical properties, and that properties that cannot be reduced to physical properties cannot have causal powers. If this is right, then, contrary to what folk psychology claims, semantic properties are causally irrelevant (Van Gulick 1993). Finally, some authors have urged that the deepest problem with commonsense psychology is that semantic properties cannot be "naturalized"—there appears to be no place for them in our evolving, physicalistic view of the world (Fodor 1987; Stich and Laurence 1994).

Emergentism

George Henry Lewes coined the term *emergence* (Lewes 1875). He drew a distinction between emergents and resultants, a distinction he learned from John Stuart Mill. In his *System of Logic* (1843), Mill drew a distinction between "two modes of the conjoint action of causes, the mechanical and the chemical" (p. xviii). According to Mill, when two or more causes combine in the mechanical mode to produce a certain effect, the effect is the sum of what would have been the effects of each of the causes had it acted alone. Mill's principal example of this is the effect of two or more forces acting jointly to produce a certain movement: the movement is the vector sum of what would have been the effect of each force had it acted alone. According to Mill, two or more causes combine in the chemical mode to produce a certain effect if and only if they produce the effect, but not in the mechanical mode. Mill used the term *chemical mode* because chemical agents produce effects in a nonmechanical way. Consider a chemical process such as $CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$ (methane $\rightarrow$ oxygen produces carbon dioxide + water). The product of these reactants acting jointly is not in any sense the sum of what would have been the effects of each acting alone. Mill labeled the effects of two or more causes acting in the mechanical mode "homopathic effects," and effects of two or more causes acting in the chemical mode "heteropathic effects." Lewes called heteropathic effects emergents and homopathic ones resultants (McLaughlin 1992).

Mill's work launched a tradition, British Emergentism, that flourished through the first third of the twentieth century (McLaughlin 1992). The main works in this tradition are Alexander Bain's *Logic* (1843), George Henry Lewes's *Problems of Life and Mind* (1875), Samuel Alexander's *Space, Time, and Deity* (1920), Lloyd Morgan's *Emergent Evolution* (1923), and C. D. Broad's *The Mind and Its Place in Nature* (1925). There were also prominent American emergentists: William JAMES, Arthur Lovejoy, and Roy Wood Sellars; and in France, Henri Bergson developed a brand of emergent evolution (Blitz 1992; Stephan 1992). In the 1920s in the former Soviet Union, the members of the Debron School, headed by A. M. Debron, spoke of the emergence of new forms in nature and maintained that the mechanists "neglected the specific character of the definite levels or stages of the development of matter" (Kamenka 1972: 164).

Alexander (1920) spoke of levels of qualities or properties, maintaining that "the higher-level quality emerges from the lower level of existence and has its roots therein, but it emerges therefrom, and it does not belong to that lower level, but constitutes its possessor a new order of existent with its special laws of behavior. The existence of emergent qualities thus described is something to be noted, as some would say, under the compulsion of brute empirical fact, or, as I should prefer to say in less harsh terms, to be accepted with the 'natural piety' of the investigator. It admits no explanation" (1920: 46). Morgan (1923) connected the notions of emergence and evolution and argued for an evolutionary cosmology. Morgan maintained that through a process of evolution genuinely new qualities emerge that generate new fundamental forces that effect "the go" of events in ways unanticipated by force-laws governing matter at lower levels of complexity.

Broad (1925) contrasted "the ideal of Pure Mechanism" with emergentism. Of the ideal of pure mechanism, he said: "On a purely mechanical theory all the apparently different kinds of matter would be made of the same stuff. They would differ only in the number arrangement and movements of their constituent particles. And their apparently different kinds of behaviour would not be ultimately different. For they would all be deducible from a single simple principle of composition from the mutual influences of the particles taken by pairs [he cites the Parallelogram Law]; and these mutual influences would all obey a single law which is quite independent of the configuration and surroundings in which the particles happen to find themselves" (1925: 45–46). He noted that "a set of gravitating particles, on the classical theory of gravitation, is an almost perfect example of the ideal of Pure Mechanism" (1925: 45). He pointed out that according to pure mechanism, "the external world has the greatest amount of unity which is conceivable. There is really only one science and the various 'special sciences' are just particular cases of it" (1925: 76). In contrast, on the emergentist view "we have to reconcile ourselves to

much less unity in the external world and a much less intimate connexion between the various sciences. At best the external world and the various sciences that deal with it will form a hierarchy" (1925: 77). He noted that emergentism can "keep the view that there is only one fundamental kind of stuff" (1925: 77). However, if emergentism is true, then "we should have to recognize aggregates of various orders. And there would be two fundamentally different types of laws, which might be called 'intra-ordinal' and 'trans-ordinal' respectively. A trans-ordinal law would be one which connects the properties of adjacent orders. . . . An intra-ordinal law would be one which connects the properties of aggregates of the same order. A trans-ordinal law would be a statement of the irreducible fact that an aggregate composed of aggregates of the next lower order in such and such proportions and arrangements has such and such characteristic and non-deducible properties" (1925: 77–78). Broad maintained that transordinal laws are irreducible, emergent laws because they cannot be deduced from laws governing aggregates at lower levels and any compositional principle governing lower levels.

The British emergentists intended their notion of emergence to imply irreducibility. However, they presupposed a Newtonian conception of mechanistic reduction. Quantum mechanics broadened our conception of mechanistic reduction by providing holistic reductive explanations of chemical bonding that make no appeal to additive or even linear compositional principles. The quantum mechanical explanation of chemical bonding is a paradigm of a reductive explanation. Chemical phenomena are indeed emergent in the sense that the product of chemical reactants is a heteropathic effect of chemical agents; moreover, the chemical properties of atoms are not additive resultants of properties of electrons, and so chemical properties of atoms are emergent. However, the quantum mechanical explanation of chemical bonding teaches us that reductive explanations need not render the reduced property of a whole as an additive resultant of properties of its parts. Reductions need not invoke additive or even linear compositional principles. The quantum mechanical explanation of chemical bonding, and the ensuing successes of molecular biology (such as the discovery of the structure of DNA) led to the almost complete demise of the antireductionist, emergentist view of chemistry and biology (McLaughlin 1992).

Nonetheless, the British emergentists' notion of an emergent property as a property of a whole that is not an additive resultant of, or even linear function of, properties of the parts of the whole continues to be fairly widely used (Kauffman 1993a, 1993b). The term *emergent computation* is used to refer to the computation of nonlinear functions (see the essays in Forrest 1991).

In philosophical circles, there have been some attempts to develop a notion of emergence, loosely based on the British emergentist notion, but that actually implies ontological irreducibility (Klee 1984; Van Cleve 1990; Beckermann, Flohr, and Kim 1992; Kim 1992; McLaughlin 1992, 1997). These attempts invoke the notion of SUPERVENIENCE and make no appeal to nonadditivity or nonlinearity. On one view, bridge laws linking micro and macro properties are emergent laws if they are not semantically implied by initial microconditions and microlaws (McLaughlin 1992). One issue that remains a topic of intense debate is whether, in something like this sense of emergence, bridge laws linking conscious properties with physical properties are irreducible, emergent psychophysical laws, and conscious properties thereby irreducible, emergent properties (Popper and Eccles 1977; Sperry 1980; Van Cleve 1990; Chalmers 1996).

Emotion and the Animal Brain

Emotion, long ignored within the field of neuroscience, has at the end of the twentieth century been experiencing a renaissance. Starting around mid-century, brain researchers began to rely on the LIMBIC SYSTEM concept as an explanation of where emotions come from (MacLean 1949), and subsequently paid scant attention to the adequacy of that account. Riding the wave of the cognitive revolution (Gardner 1987), brain researchers have instead concentrated on the neural basis of perception, MEMORY, ATTENTION, and other cognitive processes. However, starting in the 1980s, studies of a particular model of emotion, classical fear conditioning, began to suggest that the limbic system concept could not provide a meaningful explanation of the emotional brain (LeDoux 1996). The success of these studies in identifying the brain pathways involved in a particular kind of emotion has largely been responsible for the renewed interest in exploring more broadly the brain mechanisms of emotion, including a new wave of studies of EMOTION AND THE HUMAN BRAIN. This article briefly reviews the neural pathways involved in fear conditioning, and then considers how the organization of the fear pathways provides a neuroanatomical framework for understanding emotional processing, including emotional stimulus evaluation (appraisal), emotional response control, and emotional experience (feelings).

The brain circuits involved in fear CONDITIONING have been most thoroughly investigated for situations involving an auditory conditioned stimulus (CS) paired with foot-shock (see LeDoux 1996; Davis 1992; Kapp et al. 1992;

McCabe et al. 1992; Fanselow 1994). In order for conditioning to take place and for learned responses to be evoked by the CS after conditioning, the CS has to be relayed through the auditory system to the amygdala. If the CS is relatively simple (a single tone), it can reach the amygdala either from the auditory thalamus or the auditory cortex. In more complex stimulus conditions that require discrimination or CATEGORIZATION, the auditory cortex becomes involved, though the exact nature of this involvement is poorly understood (see Jarrell et al. 1987; Armony et al. 1997).

CS information coming from either the auditory THALAMUS or the cortex arrives in the lateral nucleus of the amygdala and is then distributed to the central nucleus by way of internal amygdala connections that have been elucidated in some detail (Pitkanen et al. 1997). The central nucleus, in turn, is involved in the control of the expression of conditioned responses through its projections to a variety of areas in the brainstem. These behavioral (e.g., freezing, escape, fighting back), autonomic (e.g. blood pressure, heart rate, sweating), and hormonal (adrenaline and cortisol released from the adrenal gland) responses mediated by the central nucleus are involuntary and occur more or less automatically in the presence of danger (though they are modulated somewhat by the situation).

Other brain areas implicated in fear conditioning are the HIPPOCAMPUS and prefrontal cortex. The hippocampus is important in conditioning to contextual stimuli, such as the situation in which an emotional event occurs. Its role is more of that of a high-level sensory/cognitive structure that integrates the situation into a spatial or conceptual "context" rather than that of an emotional processor per se (Kim and Fanselow 1992; Phillips and LeDoux 1992; LeDoux 1996). The medial area of the prefrontal cortex is important for extinction, the process by which the CS stops eliciting emotional reactions when its association with the shock is weakened (Morgan and LeDoux 1995). Fear/anxiety disorders, where fear persists abnormally, may involve alterations in the function of this region (LeDoux 1996).

The fear pathways can be summarized very succinctly. They involve the transmission of information about external stimuli to the amygdala and the control of emotional responses by way of outputs of the amygdala. The simplicity of this scheme suggests a clear mapping of certain psychological processes (stimulus evaluation and response control) onto brain circuits, and leads to hypotheses about how other aspects of emotion (feeling or experience) come about. However, it is important to point out that the ideas in the discussion that follows mainly pertain to the fear system of the brain, inasmuch as other emotions have not been studied in sufficient detail to allow these kinds of relations to be discussed.

Stimulus evaluation or *appraisal* is a key concept in the psychology of emotion (Lazarus 1991; Scherer 1988; Frijda 1986). Although most psychological work treats appraisal as a high-level cognitive process, often involving conscious access to underlying evaluations, it is clear from studies of animals and people that stimuli are first evaluated at a lower (unconscious) level prior to, and perhaps independent of, higher-level appraisal processes (see LeDoux 1996). In particular, the amygdala, which sits between sensory processes

(including low-level sensory processes originating precortically and higher-level cortical processes) and motor control systems, is likely to be the neural substrate of early (unconscious) appraisal in the fear system. Not only do cells in the amygdala respond to conditioned fear stimuli, but they also learn the predictive value of new stimuli associated with danger (Quirk, Repa, and LeDoux 1995; Rogan, Staubli, and LeDoux 1997).

The amygdala receives inputs from a variety of cortical areas involved in higher cognitive functions. These areas project to the basal and accessory basal nuclei of the amygdala (Pitkanen et al. 1997). Thus, the emotional responses controlled by the amygdala can be triggered by low-level physical features of stimuli (intensity, color, form), higher-level semantic properties (objects), situations involving configurations of stimuli, and thoughts or memories about stimuli, and imaginary stimuli or situations. In this way higher-level appraisal processes can be critically involved in the functioning of this system. It is important to note that these hypotheses about the neural substrate of higher-level processes have emerged from a detailed elucidation of the physiology of lower-level processes. A bottom-up approach can be very useful when it comes to figuring out how psychological processes are represented in the brain.

Involuntary emotional responses are EVOLUTION's immediate solution to the presence of danger. Once these responses occur, however, higher-level appraisal mechanisms are often activated. We begin planning what to do, given the circumstances. We then have two kinds of response possibilities. Habits are well-practiced responses that we have learned to use in routine situations. Emotional habits can enable us to avoid danger and escape from it once we are in it. These kinds of responses may involve the amygdala, cortex, and BASAL GANGLIA (see LeDoux 1996; Everitt and Robbins 1992; McDonald and White 1993). Finally, there are emotional actions, such as choosing to run away rather than to stay put in the presence of danger, given our assessment of the possible outcomes of each course of action. These voluntary actions are controlled by cortical decision processes, most likely in the frontal lobe (Damasio 1994; Goldman-Rakic 1992; Georgopolous et al. 1989). Voluntary processes allow us to override the amygdala and become emotional actors rather than simply reactors (LeDoux 1996). The ability to shift from emotional reaction to action is an important feature of primate and especially human evolution.

The problem of feelings is really the problem of CONSCIOUSNESS (LeDoux 1996). Emotion researchers have been particularly plagued by this problem. Although we are nowhere near solving the problem of consciousness (feelings), there have been some interesting ideas in the area of consciousness that may be useful in understanding feelings. In particular, it seems that consciousness is closely tied up with the process we call WORKING MEMORY (Baddeley 1992), a mental workspace where we think, reason, solve problems, and integrate disparate pieces of information from immediate situations and long-term memory (Kosslyn and Koenig 1992; Johnson-Laird 1988; Kihlstrom 1987). In light of this, we might postulate that feelings result when working memory is occupied with the fact that one's brain and body are in a state of emotional arousal. By integrating immediate stimuli with long-term memories about the occurrence of such stimuli in the past, together with the arousal state of the brain and feedback from the bodily expression of emotion, working memory might just be the stuff that feelings are made of.

Ever since William JAMES raised the question of whether we run from the bear because we are afraid or whether we are afraid because we run, the psychology of emotion has been preoccupied with questions about where fear and other conscious feelings come from. Studies of fear conditioning have gone a long way by addressing James's other question —what causes bodily emotional responses (as opposed to feelings)? Although James was correct in concluding that rapid-fire emotional responses are not caused by feelings of fear, he did not say much about how these come about. However, as we now see, by focusing on the responses we have been able to get a handle on how the system works, and even have gotten some ideas about where the feelings come from.

Emotion and the Human Brain

Popular ideas about the mind evolve over time: emotion came to have its contemporary meaning only in the late nineteenth century (Candland 1977). In current usage, the concept of emotion has two aspects. One pertains to a certain kind of subjective experience, "feeling." The other relates to expression, the public manifestation of feeling. These dual aspects of emotion—the subjective and the expressive—were represented a century ago in the writings of William JAMES (1884), who speculated on the neural and somatic basis of feeling, and Charles DARWIN (1872), who examined the evolution of emotional expression in various species. Most workers in this area have also pointed out that feelings and the actions that go with them are an essential part of an organism's relation to its environment. Thus, together with more elaborated cognition, emotions can be said to be the means by which an animal or person appraises the significance of stimuli so as to prepare the body for an appropriate response.

Emotion is traditionally distinguished from cognition, and for most of this century received little research attention in its own right—excepting possibly studies of the brain mechanisms of aggression. Emotion per se has come to be embraced as a legitimate topic only in the last several decades. Its acceptance was probably due in part to Ekman's influential cross-cultural studies of human facial expression (Ekman, Sorenson, and Friesen 1969), which implied an innate, biological basis for emotional experience. Social factors have undoubtedly also facilitated the entry of emotion into the arena of neuroscience research, for current popular culture upholds emotion as a significant feature of human life (McCarthy 1989).

An additional factor in the acceptance of emotion as a neurobiological entity was MacLean's (1952) persuasive account of a brain system specialized for emotion. Building on earlier anatomical theories, MacLean grouped together certain evolutionarily ancient brain structures, primarily regions of medial cortex and interconnected subcortical regions such as the hypothalamus, and called them the "visceral brain." He suggested that activity in this region was responsible for the subjective aspect of emotional experience. Later, following terminology introduced by the anatomist BROCA, he called these structures the LIMBIC SYSTEM.

In the years following MacLean's account, researchers have debated exactly which structures can be said to be "limbic." Most often included are the AMYGDALA, septum, hippocampal formation, orbitofrontal cortex, and cingulate gyrus. However, it is now appreciated that no criteria—be they anatomic, association with visceral function, or association with the behavioral manifestations of emotional

experience—bind the regions traditionally called "limbic" unequivocally and uniquely together, leaving the status of this proposal in doubt (LeDoux 1991). Indeed, James had asserted a century ago that there is no special brain system mediating emotional experience. Instead, he held, the bodily changes brought about by a stimulus are themselves experienced in turn through interoceptive pathways that project to sensory cortex; the latter somatic sensations "are" emotional experience. The role of afferent activity from the body in producing states of feeling continues to be emphasized: indeed, the idea that somatic sensations form the critical core of ongoing subjective experience has been repeatedly proposed by philosophers and psychologists. Most neuroscientists accept the idea that the body plays a role, but they also believe that there are particular structures in the human brain that are specialized for emotional experience and behavior.

There are several distinct themes in studies of the neural basis of human emotion. One pertains to the role of neural structures in producing states of feeling. In the 1950s, neurosurgeons demonstrated that subjective emotional experiences, especially fear, could be produced by electrical stimulation in the temporal lobes, particularly in the amygdala and hippocampal formation. The amygdala has come to the fore again in modern imaging studies that suggest that individuals with familial depression have increased metabolic activity in the left amygdala. Depression has been associated with both decreased and increased activity in orbitofrontal cortex. Several decades ago, before the rise of activity-dependent imaging techniques, there was an interest in the relation between mood and hemispheric side of brain lesions, with several researchers concluding that strokes involving the left hemisphere, particularly the frontal regions, produce depression, whereas strokes in the right produce euphoria. Although this interpretation of lesion data has been debated subsequently, stable differences in individual temperament have been attributed to differing patterns of activation of anterior frontal and temporal regions in the two hemispheres.

Links between emotion, memory, and learning have also attracted interest. Normal subjects seem to show a right hemisphere superiority for recall of affective material, and subjects with greater activation of the right amygdala appear to have a greater ability to recall emotional movies. Damasio (1994) has emphasized the role of central representations of relevant somatic states for acquiring appropriate responses to positive and negative situations. In support of his thesis, he has demonstrated that certain patients with orbitofrontal lesions, who seem unable to make appropriate decisions in real life situations, are also deficient in their autonomic responses to arousing stimuli.

A second major theme in emotion research relates to the production and understanding of expressive behavior. The right hemisphere appears to predominate for the production and the perception of expressions, both facial and vocal. Indeed, the temporal cortex of the right hemisphere may have a region specialized for decoding facial expression. Furthermore, some patients with bilateral damage to the amygdala are deficient in understanding facial expressions, especially expressions of fear. One such patient was also found to have difficulty interpreting emotional and nonemotional intonations of voice. These findings are consistent with a number of lesion studies carried out from the 1930s to the 1960s in nonhuman primates, involving structures such as the amygdala, orbital frontal cortex, and cortex of the temporal pole. Researchers had concluded, based on the animals' impaired ability to interpret social signals, that these structures are part of a brain system specialized for social responsiveness in primates (Kling and Steklis 1976). Indeed, case reports have repeatedly shown that humans with lesions in structures such as the hypothalamus, amygdala, cingulate gyrus, and orbitofrontal cortex exhibit altered social behavior and expressiveness. It is at present uncertain whether one should conceptualize the defective performance of patients with amygdala lesions in terms of a primary deficiency of emotional state (e.g., fear) or a primary deficiency of social communication (e.g., ability to interpret expression).

A third theme in emotion research is the neurochemistry of mood. The discovery that the antihypertensive drug reserpine induced depression gave rise to models of depression that invoked catecholamine transmission. Subsequently, the discovery of abnormally low levels of serotonin in the cerebrospinal fluid of suicide victims gave rise to hypotheses invoking serotonin. Both theories are supported by the efficacy of medications that enhance catecholaminergic and serotonergic transmission for the treatment of depression, but empirical confirmation of hypotheses regarding the specific sites and mechanisms of action remains lacking. Other workers have proposed a role for dopamine in disorders of mood. At present, the clear efficacy of antidepressant medications is not matched by an equally clear understanding of their mechanisms. Likewise, roles for GABAergic and serotonergic systems in anxiety have been postulated, based on the clinical effects of agents that interact with these neurotransmitters. Imaging studies show some promise of illuminating the relation between neurotransmitters and mood in the future.

There are some persisting uncertainties in emotion research. For one, workers have long debated the relative contributions of somatic states and cognition to emotional experience. A principled distinction between somatic states that are emotional and those that are not is impossible: as a result, emotion cannot be defined in terms of somatic states alone. Furthermore, there is general agreement that somatic changes cannot be specific enough by themselves to yield the various discriminable emotional experiences. But because somatic elements seem indispensable to emotion, researchers such as Schachter and Singer (1962) have argued that cognitive appraisal of the stimulus must be combined with physiological arousal in order for an emotion to be produced. However, the notion of appraisal itself is complex. Another area of uncertainty concerns which emotions deserve to be called "basic" (Ortony and Turner 1990). Finally, one of the pillars of the emotion concept is the idea of subjective experience—feeling. This raises the thorny problem of QUALIA, a philosophical term for the felt nature of experience (cf. MIND-BODY PROBLEM). Nevertheless, despite—or even because of—these uncertainties, emotion will continue to attract interest as a topic in cognitive science.

Emotions

An emotion is a psychological state or process that functions in the management of goals. It is typically elicited by evaluating an event as relevant to a goal; it is positive when the goal is advanced, negative when the goal is impeded. The core of an emotion is readiness to act in a certain way (Frijda 1986); it is an urgency, or prioritization, of some goals and plans rather than others. Emotions can interrupt ongoing action; also they prioritize certain kinds of social interaction, prompting, for instance, COOPERATION or conflict.

The term *emotional* is often used synonymously with the term *affective*. Emotions proper usually have a clear relation to whatever elicited them. They are often associated with brief (lasting a few seconds) expressions of face and voice, and with perturbation of the autonomic nervous system. Such manifestations often go unnoticed by the person who has the emotion. A consciously recognized emotion lasts minutes or hours. A *mood* has similar bases to an emotion but lasts longer; whereas an emotion tends to change the course of action, a mood tends to resist disruption. At the longer end of the time spectrum, an emotional disorder, usually defined as a protracted mood plus specific symptoms, lasts from weeks to years. Personality traits, most with an emotional basis, last for years or a lifetime. (Definitions, distinctions, and the philosophical and psychological

background of emotions discussed in the next paragraphs, are described in more detail by Oatley and Jenkins 1996.)

Emotions have been analyzed by some of the world's leading philosophers, including Aristotle, DESCARTES, and Spinoza. Following Aristotle, in whose functionalist account emotions were species of cognitive evaluations of events, most philosophical work on emotions has been cognitive. The stoics developed subtle analyses of emotions, arguing that most were deleterious, because people had wrong beliefs and inappropriate goals. Stoic influence has continued. Its modern descendent is cognitive therapy for emotional disorders.

Charles DARWIN (1872) argued that emotional expressions are behavioral equivalents of vestigial anatomical organs like the appendix; they derive from earlier phases of EVOLUTION or of individual development, and in adulthood they occur whether or not they are of any use. According to William JAMES (1884), FOLK PSYCHOLOGY wrongly assumes that an event causes an emotion, which in turn causes a reaction. Instead, he argued that an emotion is a perception of the physiological reactions by the body to the event; emotions give color to experience but, as perceptions of physiological changes, they occur after the real business of producing behavior is over. Following James, there has been a long tradition of regarding emotions as bodily states, and although cognitive approaches now dominate the field, body-based research on emotions continues to be influential (see the third and fourth approaches following). FREUD developed theories of emotional disorder, proposing that severe emotional experiences, whether of trauma or conflict, undermine RATIONAL AGENCY subsequently, and interfere with life.

Cultural distrust of emotions was exacerbated by the work of Darwin, James, and Freud. There seemed to be something wrong with emotions; they were either without useful function in adult life or actively dysfunctional. Starting in the 1950s, however, several influential movements began with cognitive emphases, all stressing function, and all making it clear that emotions typically contribute to rationality instead of being primarily irrational. One result of these movements has been to expand concepts of cognition to include emotion. Among the first cognitive approaches to emotions, in the 1950s, was Bowlby's (see e.g., 1971). Bowlby proposed the idea of emotional attachment of infant to a mother or other caregiver. He was influenced by theories of evolution and of PSYCHOANALYSIS. His compelling analogy was with the ethological idea of imprinting. With attachment—love—in infancy, a child's emotional development is based on the child's building a MENTAL MODEL of its relationship with the caregiver (Bowlby called it a "working model") to organize the child's relational goals and plans.

Mental models are also known as *schemas*. Developmentalists have done much to demonstrate the importance of emotional schemas for structuring close relationships (see SOCIAL COGNITION). Such demonstrations include those of children's models of interaction with violent parents, probably functional in the family where they first occur, but often maladaptive in the outside world where they play a large role in later aggressive delinquency (Dodge, Bates, and Pettit 1990). A parallel, second approach was that of Arnold (e.g.,

Arnold and Gasson 1954). She proposed that emotions are relational: they relate selves, including physiological substrates, to events in the world. Events are appraised, consciously or unconsciously, for their suitability to the subject's goals, for whether desired objects are available or not, and according to several other features of the event and its context. Appraisal researchers have shown that which emotion is produced by any event depends on which appraisals are made (e.g., Frijda 1986). Work on appraisal was extended by Lazarus (1991) to research on coping and its effects on health. A third approach was also begun in the 1950s, by Tomkins (see, e.g., 1995). He proposed that, based on feedback from bodily processes, particularly from expressions of the face, emotions act as amplifiers to specific motivational systems. Personality is structured by schemas, each with a theme of some emotional issue. Tomkins inspired a surge of research (e.g., Scherer and Ekman 1984) that did much to place the study of emotions on an accepted empirical base. Notable has been the study of facial expressions and their relation to emotions, both developmentally and cross-culturally. Some aspects of such expressions are agreed to be HUMAN UNIVERSALS, although how they are best analyzed remains controversial. A fourth approach occurred with attempts to reconcile the work of James with cognitive ideas: notable were Schachter and Singer (1962), who proposed that emotion was a physiological perturbation, as had also been proposed by James, although not with the distinctive patterning that James had suggested; instead an undifferentiated arousal was made recognizable by cognitive labeling (a kind of appraisal). This work has been extended by Mandler (1984) who, like Simon (see next paragraph) stressed that emotions occur when an ongoing activity is interrupted, and an expectancy is violated.

Prompted by difficulties of COGNITIVE MODELING in capturing what is essential about the organization of human action, Simon (1967) argued that because resources are always finite, any computational system operating in any complex environment needs some system to manage PLANNING, capable of interrupting ongoing processes. The system for handling interruptions can be identified with the emotional system of human beings. An extended idea of Simon's proposal can be put like this: In the ordinary world there are three large problems for orchestrating cognitively based action.

1. Mental models are always incomplete and sometimes incorrect; resources of time and power are always limited.
2. Human beings typically have multiple goals, not all of which can be reconciled.
3. Human beings are those agents who accomplish together what they cannot do alone; hence individual goals and plans are typically parts of distributed cognitive systems.

Although cooperation helps overcome limitations of resources, it exacerbates problems of multiple goals and requires coordination of mental models among distributed agents. These three problems ensure that fully rational solutions to most problems in life are rare. Humans' biologically based solution is the system of emotions. These provide genetically based heuristics for situations that affect ongoing

action and that have recurred during evolution (e.g., threats, losses, frustrations), they outline scripts for coordination with others during cooperation, social threat, interpersonal conflict, etc.; and they serve as bases for constructing new parts of the cognitive system when older parts are found wrong or inadequate.

Much recent research is concerned with effects of emotions and moods. Emotions bias cognitive processing during judgment and inference, giving preferential availability to some heuristics rather than others. For instance, happiness allows unusual associations and improves creative PROBLEM SOLVING (Isen, Daubman, and Nowicki 1987); anxiety constrains ATTENTION to features of the environment concerned with safety or danger; sadness prompts recall from MEMORY of incidents from the past that elicited comparable sadness. Such biases provide bases for both normal functions, and for disordered emotional processing (Mathews and MacLeod 1994).

As compared with research on learning or perception, research on emotions has been delayed. With newer cognitive emphases, however, emotions are seen to serve important intracognitive and interpersonal functions. A remarkable convergence is occurring: as well as support from evidence of social and developmental psychology, the largely functionalist account given here is supported by evidence from animal neuroscience (EMOTION AND THE ANIMAL BRAIN) and human neuropsychology (EMOTION AND THE HUMAN BRAIN). There is growing consensus: emotions are managers of mental life, prompting heuristics that relate the flow of daily events to goals and social concerns.

Empiricism

See INTRODUCTION: PHILOSOPHY; BEHAVIORISM; RATIONALISM VS. EMPIRICISM

Epiphenomenalism

The traditional doctrine of epiphenomenalism is that mental phenomena are caused by physical phenomena but do not themselves cause anything. Thus, according to this doctrine, mental states and events are causally inert, causally impotent; they figure in the web of causal relations only as effects, never as causes. James Ward (1903) coined the term *epiphenomenalism* for this doctrine. However, William JAMES (1890) was the first to use the term *epiphenomena* to mean phenomena that lack causal efficacy. (It is possible that his use of the term was inspired by the medical use of *epiphenomena* to mean symptoms of an underlying condition.) Huxley (1874) and Hodgson (1870) earlier discussed the doctrine of epiphenomenalism under the heading of "Conscious Automatism." They both held that conscious states are caused by physiological states but have no causal effect on physiological states (see Caston 1997).

According to proponents of epiphenomenalism, mental phenomena seem to be causes only because they figure in regularities. For example, instances of a certain type of mental occurrence M (e.g., trying to raise one's arm) might tend to be followed by instances of a type of physical occurrence P (e.g., one's arm's rising). But it would be fallacious to infer from that regularity that instances of M tend to cause instances of P: it would be to commit the fallacy of *post hoc, ergo propter hoc*. According to the epiphenomenalist, when an M-type occurrence is followed by a P-type occurrence, the occurrences are dual effects of some common physical cause.

Epiphenomenalism is a shocking doctrine. If it is true, then a PAIN could never cause us to wince or flinch, something's looking red to us could never cause us to think it is red, and a nagging headache could never cause us to be in a bad mood. Indeed, if epiphenomenalism is true, then although one thought may follow another, one thought never results in another. If thinking is a causal process, it follows that we never engage in the activity of thinking.

A central premise in the argument for epiphenomenalism is that for every (caused) event, e, there is a causal chain of physical events leading to e such that each link in the chain determines (or, if strict determinism is false, determines the objective probability of) its successor. Such physical causal chains are said to leave "no gap" to be filled by mental occurrences, and it is thus claimed that mental occurrences are epiphenomena (McLaughlin 1994).

One critical response to this no-gap line of argument for epiphenomenalism is that physical events underlie mental events in such a way that mental events are causally efficacious by means of the causal efficacy of their underlying physical events. The task for proponents of this response is to say what it is, exactly, for a physical event to underlie a mental event, and to explain how mental events can count as causes in virtue of the causal efficacy of their underlying physical events. The underlying relationship is typically spelled out in terms of some relationship between mental and physical event types. An explication of the relationship should yield an account of how causal efficacy can transmit from underlying physical events to mental events. (See the discussion of realization that follows.)

Perhaps the leading response to the no-gap line of argument, however, is that every token mental event is identical with some token physical event or other. According to this token physicalism, an event can be both an instance of a mental type (e.g., belief) and an instance of a distinct physical type (e.g., a neurophysiological type). CAUSATION is an extensional relation between states and events: if two states or events are causally related, they are so related however we may type or describe them. Given that the causal relation is extensional, because particular mental states and events are physical states and events with causal effects, mental states and events are causes, and thus epiphenomenalism is false (Davidson 1970, 1993).

The token-identity response to epiphenomenalism does not, however, escape the issue of how mental and physical types (or properties) are related (McLaughlin 1989; 1993). For it prompts a concern about the relevance of mental properties or types to causal relations. C. D. Broad (1925) characterized the view that mental events are epiphenomena as the view "that mental events either (a) do not function at all as causal-factors; or that (b) if they do, they do so in virtue of their physiological characteristics and not in virtue of their mental characteristics" (1925: 473).

Following Broad, we can distinguish two kinds of epiphenomenalism (McLaughlin 1989):

Token Epiphenomenalism Physical events cause mental events, but mental events have no causal effects.
Type Epiphenomenalism Events are causes in virtue of falling under physical types, but no event causes anything in virtue of falling under a mental type.

(*Property epiphenomenalism* is the thesis that no event can cause anything in virtue of having or being an exemplification of a mental property.) Token epiphenomenalism implies type epiphenomenalism; for if an event can cause something in virtue of falling under a mental type, then an event could be both a mental event and a cause, and thus token epiphenomenalism would be false. However, type epiphenomenalism is compatible with the denial of token epiphenomenalism: mental events may be causes, but only in virtue of falling under physical types, and not in virtue of falling under mental types. Whether type epiphenomenalism is true, and whether certain doctrines about the mind (such as Davidson's (1970) doctrine of ANOMALOUS MONISM, which implies token physicalism) imply type epiphenomenalism, have been subjects of intense debate in

recent years (see the essays in Heil and Mele 1993). But one can find the concern about type or property epiphenomenalism even in ancient philosophical texts. Aristotle appears to have criticized the *harmonia* theory of the soul—the theory according to which the soul is like the harmonia of a musical instrument, its tuning or mode—on the grounds that it implies property epiphenomenalism (see Caston 1997).

Type epiphenomenalism is itself a stunning doctrine. If type epiphenomenalism is true, then nothing has any causal powers in virtue of (because of) being an instance of a mental type (or having a mental property). Thus, it could never be the case that it is in virtue of being an urge to scratch that a state results in scratching behavior; and it could never be the case that it is in virtue of a state's being a belief that danger is near that it results in fleeing behavior. If type epiphenomenalism is true, the mental *qua* mental, so to speak, is causally inert: mental types and properties make no difference to causal transactions between states and events (Sosa 1984; Horgan 1989).

How can mental types be related to physical types so that type epiphenomenalism fails? How can mental types be related to physical types so that an event can be a cause in virtue of falling under a mental type? How must mental types relate to physical types so as not to compete for causal relevance?

The notion of multiple realization is often invoked in response to such questions. It is claimed that mental types are multiply realized by physical types and that sometimes a mental type is causally relevant to a certain effect type, whereas the relevant underlying, realizing physical type is merely a matter of implementational detail (Putnam 1975a; Yablo 1992a, 1992b). This happens whenever instances of the mental type would produce an effect of the sort in question however the mental type is in fact physically realized.

This, of course, raises the issue of what realization is. On one notion of realization, the realization relation is that of determinable to determinate (Yablo 1992a, 1992b). But it is highly controversial whether mental types are determinables of physical types. On a related notion of realization, realization is spelled out in terms of the notion of a causal role and the notion of a role-player. Mental state types are types of functional states: they are second-order states, states of being in a state that plays a certain causal role (Loar 1981). The first-order states that realize them are physical states that play the causal roles in question. The second-order state may be multiply realizable in that there are many different first-order states that play the causal role. It is controversial whether appeal to this notion of realization can warrant the rejection of type epiphenomenalism. For it is arguable that second-order state types are themselves epiphenomena. It is arguably not in virtue of falling under such a second-order state type that a state has causal effects, but rather in virtue of falling under some (relevant) first-order state type (Block 1990).

Another notion of realization treats mental concepts (i.e., concepts of mental states) as equivalent to functional concepts, but treats mental states themselves as first-order states that play the relevant causal role (Armstrong 1968; Lewis 1980). On this view, the concept of mental state M of an

organism (or system) is equivalent to the concept of being a state of the organism (or system) that plays a certain causal role *R*. It is claimed that the states that answer to the functional concepts in question are invariably physical states, but which physical states they are may vary from species to species, or even within a species, perhaps even within a given individual at different times.

Concerns about type epiphenomenalism remain, however. We type intentional mental states not only by their intentional mode (e.g., belief, desire, intention), but also by their content (by what is believed, what is desired, or what is intended). According to externalist theories of content, the content of a mental state can fail to supervene on intrinsic physical states of its occupant (Putnam 1975b; Burge 1979). Two intrinsic physical duplicates could have mental states (e.g., beliefs) with different contents. Thus intentional state types seem to involve contextual, environmental factors. The concern is that the contextual, environmental component of content is causally irrelevant to behavior. This is a problem in that the contents of beliefs and desires figure essentially in belief-desire explanations of behavior. The problem is exacerbated by the fact that on some externalist theories, content depends on historical context (Dretske 1988), and that on some it can depend on social context (Burge 1979).

A concern also remains about whether qualitative mental states (states that have a subjective experiential aspect) are epiphenomena. Our concepts of sensory states—e.g., aches, pains, itches, and the like—are arguably not functional concepts in either sense of functional concepts (Hill 1991). This has led some philosophers to embrace token dualism for such states and to maintain both type and token epiphenomenalism for them (Jackson 1982; Chalmers 1996). In rejection of epiphenomenalism for qualitative states, some philosophers argue that sensory concepts are equivalent to functional concepts (White 1991). And some argue that although sensory concepts are not equivalent to functional concepts or physical concepts, nonetheless, sensory properties are identical with neural properties (Hill 1991). Whether PHYSICALISM is true for sensory states raises the mind-body problem in perhaps its toughest form. That a nagging headache can cause one to be in a bad mood and that an itch can cause one to scratch seem to be as intuitive cases of mental causation as one can find. But how, and indeed even whether, a qualitative aspect of a mental state (e.g., the achiness of the headache) can be causally relevant remains an issue of intense debate.

Episodic vs. Semantic Memory

Episodic memory is a recently evolved, late developing, past-oriented memory system, probably unique to humans, that allows remembering of previous experiences as experienced. William JAMES (1890) discussed it as simply "memory." The advent of many different forms of memory since James's time has made adjectival modifications of the term necessary. Semantic memory is the closest relative of episodic memory in the family of memory systems. It allows humans and nonhuman animals to acquire and use knowledge about their world. Although humans habitually express and exchange their knowledge through language, language is not necessary for either remembering past experiences or knowing facts about the world.

Episodic and semantic memory are alike in many ways, and for a long time were thought of and classified together as an undifferentiated "declarative" memory that was distinguished from "procedural" memory. Nevertheless, rapidly accumulating evidence suggests that episodic and semantic memory are fundamentally different in a number of ways, and therefore need to be treated separately. In what follows, the similarities and differences are briefly summarized.

Episodic and semantic systems share a number of features that collectively define "declarative" (or "cognitive") memory in humans.

1. Both are large and complex, and have unmeasurable capacity to hold information, unlike WORKING MEMORY, which has limited capacity.
2. Cognitive operations involved in encoding of information are similar for both episodic and semantic memory. Frequently a single short-lived event is sufficient for a permanent "addition" to the memory store, unlike in many other forms of learning that require repeated experiences of a given kind.
3. Both are open to multimodal influences and can receive information for storage through different sensory modalities, as well as from internally generated sources.
4. The operations of both systems are governed by principles such as encoding specificity and transfer-appropriate processing.
5. Stored information in both systems represents aspects of the world, and it has truth value, unlike many other forms of learned behavior that do not.
6. Both are "cognitive" systems: their informational "contents" can be thought about independently of any overt action, although such action can be and frequently is taken. As cognitive systems, episodic and semantic memory differ from all forms of procedural memory in which overt behavior at input and output is obligatory.
7. Information in both systems is flexibly accessible through a variety of retrieval queries and routes.
8. Information retrieved from either system can be expressed and communicated to others symbolically.
9. Information in both systems is accessible to INTROSPECTION: we can consciously "think" about things and events in the world, as we can "think" about what we did yesterday afternoon, or in the summer camp at age ten.
10. The processes of both forms of memory depend critically on the integrity of the medial temporal lobe and diencephalic structures of the brain.

Consider now the differences.

1. The simplest way of contrasting episodic and semantic memory is in terms of their functions: episodic memory is concerned with *remembering,* whereas semantic memory is concerned with *knowing.* Episodic remembering takes the form of "mental travel through subjective time," accompanied by a special kind of awareness ("autonoetic," or self-knowing, awareness). Semantic knowing takes the form of thinking about what there is, or was, or could be in the world; it is accompanied by another kind of awareness ("noetic," or knowing awareness). Language is frequently involved in both episodic and semantic memory, but it need not be.
2. The relation between remembering and knowing is one of embeddedness: remembering always implies knowing, whereas knowing does not imply remembering.
3. Episodic memory is arguably a more recent arrival on the evolutionary scene than semantic memory. Many animals other than humans, especially mammals and birds, possess well-developed knowledge-of-the-world (semantic memory) systems. But there is no evidence that they have the ability to autonoetically remember past events in the way that humans do.
4. Episodic lags behind semantic memory in human development. Young children acquire a great deal of knowledge about their world before they become capable of adult-like episodic remembering.
5. Episodic memory is the only form of memory that is oriented toward the past: retrieval in episodic memory necessarily involves thinking "back" to an earlier time. All other forms of memory, including semantic memory, are present-oriented: utilization (retrieval) of information usually occurs for the purpose of whatever one is doing now without any thinking "back" to the experiences of the past.
6. Episodic remembering is characterized by a state of awareness (autonoetic) that is different from that in semantic memory (noetic). When one recollects an event autonoetically, one reexperiences aspects of a past experience; when one recalls a fact learned in the past, reexperiencing of the learning episode is not necessary.
7. Episodic remembering has an affectively laden "tone" that is absent in semantic knowing. William James (1890) referred to is as a "feeling of warmth and intimacy."

Given the many similarities and some fundamental differences between episodic and semantic memory, it is difficult to provide a simple description of the relation between the two. According to one proposal, however, the relation is process-specific: The two systems operate serially at the time of encoding: information "enters" episodic memory "through" semantic memory. They operate in parallel in holding the stored information: a given datum may be stored

in one or both systems. And the two systems can act independently at the time of retrieval: recovery of episodic information can occur separately of retrieval of semantic information (Tulving 1995).

The term "episodic memory" is sometimes used in senses that differ from the memory-systems orientation presented here. Some writers use "episodic memory" in its original sense of task orientation: Episodic memory refers to tasks in which information is encoded for storage on a particular occasion. This kind of usage is popular in work with animals. Other writers use "episodic memory" as a particular kind of memory information or "material," namely past "events," in contrast with the "facts" of semantic memory. The systems-based definition of episodic memory as described here is more comprehensive than either the task-specific and material-specific definitions. Finally, some writers still prefer the traditional view that there is only one kind of declarative memory, and they use the terms "episodic" and "semantic" for descriptive purposes only.

The evidential basis for the distinction between episodic and semantic memory has been growing steadily over the past ten or fifteen years. General reviews have been provided by Nyberg and Tulving (1996), Nyberg, McIntosh, and Tulving (1997), and Wheeler, Stuss, and Tulving (1997). Functional dissociations between autonoetic and noetic awareness in memory retrieval have been reviewed by Gardiner and Java (1993). Developmental evidence for the distinction has been presented by Mitchell (1989), Nelson (1993), Nilsson et al. (1997), and Perner and Ruffman (1995). Pertinent psychopharmacological data have been reported by Curran et al. (1993). Dissociations between episodic and semantic memory produced by known or suspected brain damage have been reported, among others, by Hayman, Macdonald, and Tulving (1993); Markowitsch (1995); Shimamura and Squire (1987); and Vargha-Khadem et al. (1997). Electrophysiological correlates of "remembering" versus "knowing" have been described by Düzel et al. (1997), and differences in EEG power spectra in episodic versus semantic retrieval by Klimesch, Schimke, and Schwaiger (1994). Finally, evidence in support of the distinction between episodic and semantic memory has been provided by a number of recent studies of functional neuroimaging, especially POSITRON EMISSION TOMOGRAPHY (Buckner and Tulving 1995). One of the most persistent findings is that episodic retrieval is accompanied by changes in neuronal activity in brain regions such as the right prefrontal cortex, medial parietal cortical regions, and the left CEREBELLUM, whereas comparable semantic retrieval processes are accompanied by changes in the left frontal and temporal regions (Buckner 1996; Cabeza and Nyberg 1997; Fletcher, Frith, and Rugg 1997; Haxby et al. 1996; Nyberg, Cabeza, and Tulving 1996, Nyberg, McIntosh, and Tulving 1997; Shallice et al. 1994; Tulving et al. 1994). Future studies will undoubtedly further clarify the emerging picture of the functional neuroanatomy of episodic and semantic memory.

It is a moot question whether episodic and semantic memory are basically similar or basically different. The question is not unlike one about basic similarities and differences between, say, vertebrates and invertebrates. As frequently happens in science, it all depends on one's interest and purpose.

Epistemology and Cognition

Epistemology and cognition is the confluence of the philosophy of knowledge and the science of cognition. Epistemology is concerned with the prospects for human knowledge, and because these prospects depend on the powers and frailties of our cognitive equipment, epistemology must work hand in hand with cognitive science. Epistemology centers on normative or evaluative questions about cognition: what are the good or right ways to think, reason, and form beliefs? But normative assessments of cognitive systems and activities must rest on their descriptive properties, and characterizing those descriptive properties is a task for cognitive science. Historically rationalism and empiricism exemplified this approach by assigning different values to reason and the senses based on different descriptions of their capacities.

Epistemic evaluation can take many forms. First, it can evaluate entire cognitive systems, selected cognitive subsystems, or particular cognitive performances. Second, there are several possible criteria of epistemic assessment. (1) A system or process might be judged by its *accuracy* or veridicality, including its *reliability*—the proportion of true judgments it generates—and its *power*—the breadth of tasks or situations in which it issues accurate judgments (Goldman 1986). (2) It can be judged by its conformity or nonconformity with normatively approved *formal standards*, such as deductive validity or probabilistic coherence. (3) It might be evaluated by its *adaptiveness*, or conduciveness for achieving desire-satisfaction or goal-attainment (Stich 1990). Normative assessments of these kinds are not only of theoretical interest, but also admit of several types of application. You might judge another person's belief to be untrustworthy if the process productive of that belief is unreliable, or you

might deploy a powerful intellectual strategy to improve your own cognitive attainments.

To illustrate the reliability and power criteria, as well as the two types of application just mentioned, consider MEMORY and its associated processes (Schacter 1996). Studies partly prompted by "recovered" memory claims show that memory is strongly susceptible to postevent distortions, both in adults and especially in children. Suggestive questioning of preschool children can have devastating effects on the reliability of their memories (Ceci 1995). Knowing that someone underwent suggestive questioning should give third parties grounds for distrusting related memories. Another application is the use of encoding strategies to boost memory power. A runner hit on the technique of coding a series of digits in terms of running times. After months of practice with this coding strategy, he could recall over eighty digits in correct order after being exposed to them only once (Chase and Ericsson 1981). Analogous encoding strategies can help anyone increase his memory power. A third memory example illustrates tradeoffs between different epistemic standards. Reliable recollection often depends on "source memory," the recall of how you encountered an object or event. Witnesses have erroneously identified alleged criminals because they had seen them outside the context of the crime, for example, on television. A sense of familiarity was retained, but the source of this familiarity was forgotten (Thomson 1988). People often fail to keep track of the origins of their experience or beliefs. Is this epistemically culpable? The adaptiveness criterion suggests otherwise: forgetting sources is an economical response to the enormous demands on memory (Harman 1986).

The formal-standards criterion of epistemic normativity is applied to both DEDUCTIVE REASONING and PROBABILISTIC REASONING. It is unclear exactly which formal standards are suitable criteria for epistemic rationality. Must a cognitive system possess *all* sound rules of a natural deduction system to qualify as deductively rational? Or would *many* such rules suffice? Must these rules be natively endowed, or would it suffice that the system acquires them under appropriate experience? Whether human deductive capacities qualify as rational depends on which normative criterion is chosen, as well as on the descriptive facts concerning these capacities, about which there is ongoing controversy.

One psychological approach says that people's deductive competence does come in the form of abstract rules akin to natural deduction rules (Rips 1994). On this view, people's native endowments might well qualify as rational, at least under the weaker criterion ("many rules") mentioned above. Other approaches deny that people begin with purely abstract deductive principles, a conclusion supported by content effects discovered in connection with Wason's selection task. Cheng and Holyoak (1985) suggest that generalized rules are induced from experience because of their usefulness. They explain (modest) deductive competence by reference to inductive capacities for acquiring rules, thereby allowing for rationality under one of the foregoing proposals. Cosmides (1989) contends that evolution provided us with specific contentful rules, ones useful in the context of social exchange. Reasoning capacities might qualify as rational under the social exchange approach if the criterion of adaptiveness is applied.

The dominant approach to probabilistic reasoning is the judgments and heuristics (or "heuristics and biases") approach (Tversky and Kahneman 1974; see JUDGMENT HEURISTICS). Its proponents deny that people reason by means of normatively appropriate rules. Instead, people allegedly use shortcuts such as the "representativeness heuristic," which can yield violations of normative rules such as nonutilization of base rates and commission of the conjunction fallacy (Tversky and Kahneman 1983). If someone resembles the prototype of a feminist bank teller more than the prototype of a bank teller, subjects tend to rate the probability of her being both a feminist and a bank teller higher than the probability of her being a bank teller. According to the probability calculus, however, a conjunction cannot have a higher probability than one of its conjuncts.

Recent literature challenges the descriptive claims of the heuristics approach as well as its normative conclusions. Gigerenzer (1991) finds that many so-called cognitive biases or illusions "disappear" when tasks are presented in frequentist terms. People do understand probabilities, but only in connection with relative frequencies, not single cases. Koehler (1996) surveys the literature on the base-rate fallacy and disputes on empirical grounds the conventional wisdom that base rates are routinely ignored. He adds that because base rates are not generally equivalent to prior probabilities, a Bayesian normative standard does not mandate such heavy emphasis on base rates. It is not easy to decide, then, whether people have a general competence at probabilistic reasoning, or the circumstances in which such a competence will be manifested. A related subject is the forms of teaching that can successfully train people in normatively proper reasoning (Nisbett 1993).

Epistemologists are traditionally interested in deciding which beliefs or classes of belief meet the standard for knowledge, where knowledge includes at least true justified belief. The crucial normative notion here is JUSTIFICATION (rather than rationality). Can cognitive science help address this question? One affirmative answer is supported by a reliable process theory of justification (Goldman 1986). If a justified belief is (roughly) a belief produced by reliable cognitive processes, that is, processes that usually output truths, then cognitive science can assist epistemology by determining which mental processes are reliable. Reliabilism is not the only theory of justification, however, that promotes a tight link between epistemology and cognitive science. Any theory can do so that emphasizes the cognitive sources or context of belief.

Assuming that humans do have extensive knowledge, both epistemologists and cognitive scientists ask how such knowledge is possible. During much of the twentieth century, philosophers and psychologists assumed that general-purpose, domain-neutral learning mechanisms, such as deductive and inductive reasoning, were responsible. The most influential approach in current cognitive science, however, is DOMAIN SPECIFICITY (Hirschfeld and Gelman 1994). On this view, the mind is less an all-purpose problem solver than a collection of independent subsystems designed to perform circumscribed tasks. Whether in language, vision,

FOLK PSYCHOLOGY, or other domains, special-purpose modules have been postulated. As the philosopher Goodman (1955) emphasized, wholly unconstrained INDUCTION leads to indeterminacy or antinomy. To resolve this indeterminacy, cognitive scientists have sought to identify constraints on learning or representation in each of multiple domains (Keil 1981; Gelman 1990).

Essentialism

Psychological essentialism is any folk theory of concepts positing that members of a category have a property or attribute (*essence*) that determines their identity. Psychological essentialism is similar to varieties of philosophical essentialism, with roots extending back to ancient Greek philosophers such as Plato and Aristotle. One important difference, however, is that psychological essentialism is a claim about human reasoning, and not a metaphysical claim about the structure of the real world. Psychological essentialism may be divided into three types: sortal, causal, and ideal (see Gelman and Hirschfeld in press).

The *sortal* essence is the set of defining characteristics that all and only members of a category share. This notion of essence is captured in Aristotle's (1924) distinction between essential and accidental properties (see also Keil's 1989 defining versus characteristic properties): the essential properties constitute the essence. For example, on this view the essence of a grandmother would be the property of being the mother of a person's parent (rather than the accidental or characteristic properties of wearing glasses and having gray hair). In effect, this characterization is a restatement of the classical view of concepts: meaning (or identity) is supplied by a set of necessary and sufficient features that determine whether an entity does or does not belong in a category (Smith and Medin 1981). Specific essentialist accounts then provide arguments concerning which sorts of features are essential. The viability of this account has been called into question by more recent models of concepts that stress the

importance of probabilistic features, exemplars, and theories in concepts.

In contrast, the *causal* essence is the substance, power, quality, process, relationship, or entity that causes other category-typical properties to emerge and be sustained, and that confers identity. Locke (1894/1959: Book III, p. 26) describes it as "the very being of anything, whereby it is what it is. And thus the real internal, but generally . . . unknown constitution of things, whereon their discoverable qualities depend, may be called their essence." The causal essence is used to explain the observable properties of category members. Whereas the sortal essence could apply to any entity, the causal essence applies only to entities for which inherent, hidden properties determine observable qualities. For example, the causal essence of water may be something like H_2O, which is responsible for various observable properties that water has. Thus, the cluster of properties "odorless, tasteless, and colorless" is not a causal essence of water, despite being true of all members of the category Water, because the properties have no direct causal force on other phenomenal properties of that kind.

Causal essentialism requires no specialized knowledge, and, in contrast to sortal essentialism, people may possess an "essence placeholder" without knowing what the essence is (Medin 1989; Medin and Ortony 1989). For example, a child might believe that girls have some inner, nonobvious quality that distinguishes them from boys and that is responsible for the many observable differences in appearance and behavior between boys and girls, before ever learning about chromosomes or human physiology.

The *ideal* essence is assumed to have no actual instantiation in the world. For example, on this view the essence of "goodness" is some pure, abstract quality that is imperfectly realized in real-world instances of people performing good deeds. None of these good deeds perfectly embodies "the good," but each reflects some aspect of it. Plato's cave allegory (*The Republic*), in which what we see of the world are mere shadows of what is real and true, exemplifies this view. The ideal essence thus contrasts with both the sortal and the causal essences. There are relatively little empirical data available on ideal essences in human reasoning (but see Barsalou 1985).

Most accounts of psychological essentialism focus on causal essences. Causal essentialism has important implications for category-based inductive inferences, judgments of constancy over time, and stereotyping. By two to three years of age, children expect category members to share nonobvious similarities, even in the face of salient perceptual dissimilarities. For example, on learning that an atypical exemplar is a member of a category (e.g., that a penguin is a bird), children and adults draw novel inferences from typical instances to the atypical member (Gelman and Markman 1986). By four years of age children judge nonvisible internal parts to be especially crucial to the identity and functioning of an item. Children also treat category membership as stable and unchanging over transformations such as costumes, growth, metamorphosis, or changing environmental conditions (Keil 1989; Gelman, Coley, and Gottfried 1994). The finding that young children hold essentialist beliefs thus

suggests that human concepts are not constructed atomistically from perceptual features.

Causal essentialism is closely related to the notion of "kinds" or NATURAL KINDS (Schwartz 1977). Whereas a category is any grouping together of two or more discriminably different things, a kind is a category that is believed to be based in nature, discovered rather than invented, and capturing indefinitely many similarities. "Tigers" is a kind; the set of "striped things" (including tigers, striped shirts, and barbershop poles) is not, because it captures only a single, superficial property (stripedness); it does not capture nonobvious similarities, nor does it serve as a basis of induction (e.g., Mill 1843; Markman 1989). Similarly, the ad hoc category of "things to take on a camping trip" does not form a kind (Barsalou 1991). Whereas kinds are treated as having essences, other categories are not. It is not yet known which categories are construed as "kinds" over development. The majority of evidence for causal essentialism obtains from animal categories. However, similar beliefs seem to characterize how people construe social categories such as race, gender, and personality. These racial, gender, or personality "essences" may be analogical extensions from a folk biological notion, or an outgrowth of a more general "essentialist construal" (see Atran 1990; Carey 1995; Keil 1994; Pinker 1994 for discussion).

Essentialism is pervasive across history, and initial evidence suggests that it may be pervasive across cultures (Atran 1990). Whether biological taxa truly possess essences is a matter of much debate (Sober 1994; Mayr 1982; Kornblith 1993; Dupré 1993), although essentialism is largely believed to be incompatible with current biological knowledge. Some scholars have proposed that essentialist views of the species as fixed and unchanging may present obstacles for accurately learning scientific theories of EVOLUTION (Mayr 1982).

Ethics

See CULTURAL RELATIVISM; ETHICS AND EVOLUTION; MORAL PSYCHOLOGY

Ethics and Evolution

When Charles DARWIN wrote *The Origin of Species,* he withheld discussion of the origins of human morality and cognition. Despite Darwin's restraint, some of the strongest reactions to the theory of natural selection had to do with its connection to ethical matters. The intersection between evolution and ethics continues to be a site of controversy. Some claim that human ethical judgments are to be explained by their adaptive value. Others claim that human ethical systems are the result of cultural evolution, not biological evolution. In the context of cognitive science, the central issue is whether humans have ethics-specific beliefs or cognitive mechanisms that are the result of biological evolution.

There is increasing evidence that the human brain comes prewired for a wide range of specialized capacities (see NATIVISM and DOMAIN SPECIFICITY). With regard to ethics, the central questions are to what extent the human brain is prewired for ethical thinking and, insofar as it is, what the implications of this are.

There is one sense in which humans are prewired for ethics: humans have the capacity for ethical reasoning and reflection while amoebas do not. This human capacity is biologically based and results from EVOLUTION. *Ethical nativism* is the view that there are specific, prewired mechanisms for ethical thought. Adherents of SOCIOBIOLOGY, the view that evolutionary theory can explain all human social behavior, are among those who embrace ethical nativism. E. O. Wilson, in *Sociobiology: The New Synthesis* (1975), goes so far as to say that ethics can be "biologized." Sociobiologists claim that humans have specific ethical beliefs and an associated ethical framework that are innate and are the result of natural selection. They support this view with evidence that humans in all cultures share certain ethical beliefs and certain underlying ethical principles (see HUMAN UNIVERSALS), evidence of ethical or "pre-ethical" behavior among other mammals, especially primates (see de Waal 1996), and with evolutionary accounts of the selective advantage of having innate ethical mental mechanisms. Most notably, they talk about the selective advantage (to the individual or to the species) of ALTRUISM.

Consider a particular moral belief or feeling for which an evolutionary explanation has been offered, namely the belief that it is wrong to have (consensual) sex with one's sibling. Some sociobiologists have argued that this belief (more precisely, the feeling that there is something wrong about having sex with a person one was raised with) is innate and that we have this belief because of its selective advantage. When close blood relatives reproduce, there is a relatively high chance that traits carried on recessive genes (most notably, serious diseases like sickle-cell anemia and hemophilia) will be exhibited in the resulting offspring. Such offspring are thus more likely to fail to reproduce. Engaging in incest is thus an evolutionarily nonadaptive strategy. If a mutation occurred that caused an organism to feel or believe that it is wrong to engage in incest, then, all else being equal, this gene would spread through the population over subsequent generations. Sociobiologists think they can give similar accounts of our other ethical beliefs and the mechanisms that underlie them.

What are the implications for ethics if ethical nativism and some version of the sociobiological story behind it are true? Some philosophers have denied there are any interesting implications. Ethics, they note, is *normative* (it says what we ought to do), whereas biology—in particular, the details of the evolutionary origins of humans and our various capacities—is *descriptive*. One cannot derive normative conclusions from empirical premises. To do so is to commit the naturalistic fallacy. It would be a mistake, for example, to infer from the empirical premise that our teeth evolved for tearing flesh to the normative conclusions that we ought to eat meat. This empirical premise is compatible with ethical arguments that it is morally wrong to eat meat. By the same reasoning, the fact that evolution produced in us the tendency to have some moral feeling or belief does not necessarily entail that we ought to act on that feeling or accept that belief on reflection. In fact, some commentators have suggested, following Thomas Huxley (1894), that "the ethical progress of society depends, not on imitating [biological evolution], . . . but in combating it."

Ethical nativists have various responses to the charge that they commit the naturalistic fallacy. Some allow that the fact that humans have some innate moral belief does not entail that we ought to act on it, while insisting that nativism has something to tell us about ethics. Perhaps biology can tell us that we are not able to do certain things and thus that it cannot be the case that we ought to do this. For example, concerning feminism, some sociobiologists have claimed that many of the differences between men and women are biologically based and unchangeable; a feminist political agenda that strives for equality is therefore destined to failure. This argument has been criticized on both empirical and normative grounds (see Kitcher 1985 and Fausto-Sterling 1992).

Some sociobiologists (Wilson 1975 and Ruse 1986) have argued that the facts of human evolution have implications for moral realism, the metaethical position that there are moral facts like, for example, the moral fact that it is wrong to torture babies for fun. A standard argument for moral realism says that the existence of moral facts explains the fact that we have moral beliefs (on moral realism, see Harman 1977; Mackie 1977; Brink 1989). If, however, ethical nativism is true and an evolutionary account can be given for why people have the moral beliefs they do, then an empirical explanation can be given for why we have the ethical capacities that we do. The standard argument for moral realism is thus undercut.

One promising reply to this line of thought is to note that moral facts might be involved in giving a biological account of why we humans have the moral beliefs that we do. In the case of incest, the moral status of incest might be related to the selective advantageousness of incest. Consider an analogy to mathematics. Although we might give an evolutionary explanation of the spread of mathematical abilities in humans (say, because the ability to perform addition was useful for hunting), mathematical facts, like $2 + 2 = 4$, would still be required to explain *why* mathematical ability is selectively advantageous. Many of our mathematical beliefs are adaptive because they are true. The idea is to give the same sort of account for moral beliefs: they are selectively advantageous because they are true. Selective advantage and moral status can, however, come apart in some instances. One can imagine a context in which it would be selectively advantageous for men to rape women. In such a context, it might be selectively advantageous to have the belief that rape is morally permissible. Rape would, however, remain morally reprehensible and repugnant even if it were selectively advantageous to believe otherwise.

Even if there is a tension between ethical nativism and moral realism, the tension might not be so serious if only a few of our ethical beliefs are in fact innate. Many of our ethical beliefs come from and are justified by a reflective process that involves feedback among our various ethical

beliefs; this suggests that many of them are not innate. The nativist argument against moral realism depends on the strength of its empirical premises.

Ethnopsychology

Ethnopsychology refers to cultural or "folk" models of subjectivity, particularly as applied to the interpretation of social action. It also refers to the comparative, anthropological study of such models as used in particular languages and cultures. Whereas the fields of psychology and philosophy have both given concerted attention to folk theories of the mind (see FOLK PSYCHOLOGY and THEORY OF MIND), the hallmark of anthropological studies has been the empirical study of commonsense psychologies in comparative perspective (Heelas and Lock 1981; White and Kirkpatrick 1985; see also CULTURAL PSYCHOLOGY).

A growing body of ethnographic work has established that (1) people everywhere think and talk in ordinary language about subjective states and personal qualities (D'Andrade 1987), that (2) cultures vary in the conceptual elaboration and sociocultural importance of such concepts, and that (3) determining conceptual universals in this domain is made difficult by problems of translation, interpretation and representation. So, for example, studies of complex emotion concepts such as Ilongot *liget* (roughly, "anger") or Japanese *amae* ("dependent love") have produced extended debates about issues of meaning and representation (see Rosaldo 1980 and Doi 1973, respectively, for extended analyses of these terms).

Beginning in the early 1950s, at about the same time that social psychologists were examining English-language folk psychology (Heider 1958), A. I. Hallowell called for the comparative study of "ethnopsychology," by which he meant "concepts of self, of human nature, of motivation, of personality" (1967: 79). With the advent of COGNITIVE ANTHROPOLOGY and the development of lexical techniques for the semantic analysis of terminological domains such as color, kinship, or botany, anthropologists initially approached ethnopsychology in much the same way as other areas of ethno- or "folk" knowledge, as an essentially cognitive system that could be studied as a set of interrelated categories and propositions. The semantic theories that informed this work derived largely from the study of referential meaning, analyzed in terms of category structures and distinctive features or dimensions (see D'Andrade 1995; Quinn and Holland 1987 for historical overviews).

The two types of psychological vocabulary most frequently studied with lexical methods are personality and emotion. In both cases, comparative research has sought linguistic evidence for cognitive and psychological universals. Studies of personality terms in both English (Schneider 1973) and non-Western languages (e.g., Shweder and Bourne 1982) indicate that two or three dimensions of interpersonal meaning, particularly "solidarity" and "power," structure person concepts across cultures (White 1980). Similarly, studies of emotion vocabularies have found complex patterns of convergence interpreted as evidence for a small number of basic or universal affects (Gerber 1985; Romney, Moore, and Rusch 1997). Claims for universal emotion categories, however, are often complicated by detailed accounts of the relevance of culture-specific models for emotional understanding (Lutz 1988; Heider 1991).

The search for linguistic correlates of basic emotions is motivated by robust findings of biological invariance in facial expressions associated with five or six discrete emotions, often labeled with the English language terms "anger," "disgust," "fear," "happiness," "surprise," and "shame" (Ekman 1992). Inspired by research on COLOR CATEGORIZATION that shows color lexicons everywhere to be structured according to a small set of prototypic categories, numerous authors have speculated that prototype models may be an effective means of representing emotion concepts as internally structured categories (Gerber 1985; Russell 1991) or scenarios (Lakoff and Kövecses 1987).

Lexical studies of an entire corpus of terms extracted from linguistic and social context generally produce highly abstract results. Analyses focusing on the conceptualization of emotion in ordinary language have identified more complex cultural or propositional networks of meaning associated with key emotion terms (e.g., Rosaldo 1980). In particular, analyses of METAPHOR show that metaphorical associations play a central role in the elaboration

of cultural models of emotion. Emotion metaphors often acquire their significance by linking together other metaphors pertaining to the conceptualization of bodies, persons, and minds. So, for example, the English language expression "He is about to explode" obtains its meaning in relation to such metaphorical propositions as *anger is heat* and *the body is a container for emotions* (Lakoff and Kövecses 1987).

Both comparative and developmental studies show that implicit models of emotion frequently take the form of event schemas in which feelings and other psychological states mediate antecedent events and behavioral responses (Harris 1989; Lutz 1988). The most systematic framework developed for the analysis of emotion language is that of linguist Anna Wierzbicka (1992), who has proposed a metalanguage capable of representing the meanings of emotion words in terms of a limited number of semantic primitives. In this approach, scriptlike understandings of emotion are represented as a string of propositions forming prototypic event schemas. Application of this framework has clarified a number of debates about the nature of emotional meaning in specific languages and cultures (White 1992).

The relevance of prototype schemas for emotional understanding follows from the wider salience of narrative as an organizing principle in ethnopsychological thought generally (Bruner 1990; Johnson 1993). Among the many types of narrative used to represent and communicate social experience, "life stories" appear to be an especially salient genre across cultures (Linde 1993; Ochs and Capps 1996; Peacock and Holland 1993). There is, however, some evidence that Euro-American cultures tend to "package" experience in the form of individualized life stories more than many non-Western cultures that do not value or elaborate individual self-narrative.

Research on talk about personal experience in ordinary social contexts indicates that self-reports are often interactively produced by narrators and audiences intent on rendering experience in moral terms and on actively directing the course of social interaction (Miller et al. 1990). This line of sociolinguistic research has identified the importance of sociocultural institutions for analyzing the pragmatic force of psychological talk in context. Ethnographic research in small-scale societies finds that verbal representations of the thoughts and feelings of others are likely to carry considerable moral weight and may be limited to specific, culturally defined occasions.

By raising interpretive questions, the comparative perspective has drawn attention to the constructed nature of commonsense psychologies, noting that concepts of emotion, person, and so forth generally derive their significance from wider systems of cultural meaning and value. The comparative approach of ethnopsychological research focuses attention back on psychological theory itself, noting ways in which English language constructs and paradigms are constrained by implicit cultural concepts of person. The major theme in this line of criticism is that the values and ideology of Euro-American individualism systematically influence a range of psychological concepts, including personality (White 1992), emotion (Markus and Kitayama 1991), and moral reasoning (Shweder 1990).

As is often the case for comparative research, ethnopsychological studies raise questions about the validity of the domain under study, of "psychology" as a basis for cross-cultural interpretation. As working concepts of psychology are adjusted for purposes of comparison, the boundaries between ethnopsychology, NAIVE SOCIOLOGY, and FOLK BIOLOGY, among other areas, are likely to be remapped as psychology's metalanguage comes to terms with the diversity of psychological forms and practices worldwide.

Ethology

Ethology had the most impact from about 1940 to 1970, when it took the discipline of animal behavior by storm, earning Konrad Lorenz and Niko Tinbergen, with Karl von Frisch, a Nobel Prize in 1973. The underlying concepts were biological rather than psychological, derived from a Darwinian approach to naturally occurring animal behavior. Historically, the naturalistic aspect was crucial, with an emphasis lacking in psychology at the time. Although anticipated by American behaviorists, ethology came of age as a mature discipline in Europe. The proceedings of a 1949 conference in Cambridge, England, on physiological mechanisms in animal behavior presented a full exposition of the ideas of Lorenz, Tinbergen, and other participants in the emerging discipline (Lorenz 1950; see 1970, 1971 for collected works). Tinbergen's classical treatise on "The Study of Instinct" followed a year later (Tinbergen 1951). Ethology provided a comprehensive framework for studying the functions, evolution, and development of behavior and its physiological basis. Some insights were conceptual and others methodological. Four historically important aspects were the basic endogeneity of behavior, the concept of sign stimuli, the reinstatement of instincts, and the importance of cross-species comparisons.

Lorenz's medical training in Vienna exposed him to concepts of phylogeny emerging from comparative anatomy, but behavior was viewed as too amorphous to be amenable to the same kind of study. Encouraged by Berlin zoo director Oscar Heinroth, who was intimate with the behavior of scores of animals, Lorenz became convinced that comparative ethological studies could be as objective as anatomical investigations. Young animals of diverse species, raised under similar conditions, consistently develop distinctive behaviors, stable enough to yield insights into taxonomy and phylogeny. Many of the species-specific displays of captive ducks match those in the wild. The emphasis on comparative study, rendered more quantitative by Tinbergen and his students, was an important innovation, embodied in Lorenz's term "fixed action patterns." Although action patterns are not completely "fixed," any more than is morphology, careful scrutiny reveals consistent species and individual differences in modal action patterns. Descriptive studies of behavior took on new momentum, shifting focus somewhat from species comparisons to intraspecific variation, culminating more than a generation later in the quantitative sophistication of mating choice theory, and cladistic and other approaches to problems in phylogeny (Harvey and Pagel 1991).

A second innovation emphasized endogenous sources of motivation. The BEHAVIORISM of Watson (1924), given a more biological flavor by Schneirla and his colleagues, stressed the role of external forces in the control of behavior, perhaps initially as a healthy antidote to the indulgences of introspectionist psychology. Ethologists provided a refreshing reminder that without a genome you have no organism, and no instructions on how to respond to external stimuli or how to learn as a consequence of experience, countering such excesses as "psychology without heredity" (Kuo 1924). The notion of "instinct," eloquently championed by Darwin, had fallen into disrepute. Lorenz redressed this balance by stressing the importance of endogeneity, both in the motivational sense, manifest in the inherent rhythmicity of many behaviors, and in the ontogenetic sense, with certain patterns of behavior developing endogenously, only minimally perturbed or adjusted according to the vagaries of individual experience. The notion of strong internal forces driving behavior was then highly controversial. We now accept that the underlying neural circuitry of many behaviors includes neuronal pacemakers as key components. The theme of endogenous forces came to pervade research at the Institute for Behavioral Physiology established for Lorenz and codirector Eric von Holst by the Max Planck Gesellschaft in Bavaria in 1956, including pioneering studies of swimming rhythms, and later circadian and circannual behavioral cycles. Across the Atlantic, ethologically inspired insect physiologists Kenneth Roeder and Donald Wilson convincingly demonstrated the delicate interplay of exogenous and endogenous forces underlying locomotion and other behaviors (Roeder 1963; reviewed in detail in Gallistel 1980).

The interpretation of responses to external situations not as driven from without but as interactions between changing environments and purposively changing organismal states was not unique to ethology. A generation previously, in an essay on "appetites and aversions as constituents of instincts," the American ethologist Wallace Craig (1918) clarified the issues of uniformity and plasticity with a distinction made previously by Sherrington, and later by

Lorenz, between appetitive (i.e., proceptive) behavior, endogenously motivated and variable, and consummatory behavior, externally triggered and more stereotyped. Craig was a student of Charles Otis Whitman, whose 1898 Woods Hole lectures on animal behavior anticipated other aspects of ethological thinking. But Craig's message fell on deaf ears, appreciated by few psychologists, and apparently known to Lorenz only after his career was well launched. He may also have been unaware of Craig's assertion that aggression is less endogenously driven than most behaviors (Craig 1928). Lorenz's controversial 1966 book "On Aggression," presented the contrary case, that there are strong endogenous wellsprings for agonistic behavior. Few of the many critics of Lorenz's position acknowledged Craig's thoughtful counterargument (see also Heiligenberg and Kramer 1972).

Until the postwar years, American biologists and psychologists alike were curiously unresponsive to efforts within their ranks to instate ethologically styled concepts. A prophetic paper by one of its most respected pioneers, titled "Experimental analysis of instinctive behavior" (LASHLEY 1938; see Beach et al. 1960), anticipated some developments in ethology but had much less impact than his work on cortical memory mechanisms. Lashley's preoccupation with endogenous motivational forces was evident in his arguments with Pavlovian theorists who reduced all behavioral and psychological activity to chains of conditioned reflexes. There had also been limited appreciation of the case made a generation previously by Lashley's teacher, Jennings (1906), for the existence, even in single-celled organisms, of complex, sometimes purposive, endogenously driven behaviors. His suggestion that equivalent observations in higher organisms would suffice to encourage cognitive theorizing may have helped to spur his later colleague Watson (1924) to put an end to subjective, introspective psychologizing. Instead, Watson shifted the emphasis to observable behaviors and Pavlovian reflexes, thus launching behaviorism. But what began as a worthy effort to reintroduce objectivity into comparative psychology hardened into dogma, and the importance of endogenous factors was again forgotten until reinstated by Beach and other students of Lashley, increasingly preoccupied with physiological psychology as an emerging discipline (Beach et al. 1960). The notion of instinct met a similar fate, swept aside by the appeals of pragmatism. In developmental studies, American comparative psychologists grappling with the nature/nurture problem lost sight of the need to balance environmental influences with contributions of the genome, a primary emphasis in ethology.

Environmental factors were not neglected by ethologists. Tinbergen and his students, more experimentally oriented than Lorenz, focused on key components of complex situations to which animals actually respond (collected in Tinbergen 1971, 1973). Many of these "sign stimuli," or "social releasers," often a small fraction of the total that the animal can perceive, were communicative signals (see ANIMAL COMMUNICATION). Physiological mechanisms were inferred for filtering incoming stimuli, apparently operating at birth in many young organisms, such as the nestling birds that Tinbergen studied. Lorenz posited central "innate release mechanisms" with properties varying according to genetically encoded instructions. The determination of ethologists to reinstate concepts of innateness led to the sometimes legitimate criticism that they caricatured young animals as completely preprogrammed automata (Lehrman 1953). It became clear later that even young organisms with well-defined innate responsiveness, such as herring gulls, display great developmental plasticity, quickly acquiring new information about their parents and other aspects of life around them. But they do so by learning processes that are canalized by innate predispositions, insuring a certain range of trajectories for development, whether behavioral or neurological (Hailman 1967; Waddington 1966; Rauschecker and Marler 1987).

The importance of innately guided learning, well illustrated by song learning in birds, was the special province of British ethologist William Homan Thorpe (1956). More than Lorenz or Tinbergen, Thorpe prepared the way for the emergence of COGNITIVE ETHOLOGY (Griffin 1976). He was the first to formalize criteria for different types of learning, some very basic, others with clear cognitive implications. His thoughtful scholarship emphasized the importance of internalized processing in perception and the purposiveness of behavior. The interplay of nature and nurture is most evident in "imprinting," the developmental process for which Lorenz is best known. During imprinting, young of some organisms learn to recognize and bond with their parents, or parent surrogates, and others like them, by processes destined to become favored paradigms for investigating the neural basis of memory formation (Horn 1985). Imprinting occurs most rapidly during sensitive periods, as experience interacts with innate preferences for visual and auditory stimuli that capture attention and initiate the imprinting process. That these early experiences sometimes influence later social and sexual preferences, with varying degrees of reversibility, attracted special attention in psychiatry and the social sciences (Bowlby 1969, 1973; Hinde 1982). There are parallels with song learning in birds and with human speech acquisition, where the choice of what to learn is guided by generalized innate preferences, resulting ultimately in specific learned vocal traditions (Marler 1991; Pinker 1994). The interplay of inheritance and experience that canalizes the development of many behaviors is epitomized by the apparently paradoxical term "instincts to learn" (Gould and Marler 1987). More than any other, the concept of instinctively guided learning captures the essence of what was uniquely distinctive about classical ethology, still providing a valued heuristic framework for contemporary research on behavioral ontogeny (see EVOLUTIONARY PSYCHOLOGY).

Evolution

In its simplest form, the theory of evolution is just the idea that life has changed over time, with younger forms descending from older ones. This idea existed well before the age of Charles DARWIN, but he and his successors developed it to explain both the diversity of life, and the adaptation of living things to their circumstances. Ernest Mayr (1991) argues that this developed conception of evolution

combines five main ideas:

1. The living world is not constant; evolutionary change occurs.
2. Evolutionary change has a branching pattern. The species that we see are descended from one (or a few) remote ancestors.
3. New species form when a population splits into isolated fragments which then diverge.
4. Evolutionary change is gradual. Very few organisms that differ dramatically from their parents are able to survive. Of those few that survive, only a small proportion found populations that preserve these differences.
5. The mechanism of adaptive change is natural selection.

Darwin, Wallace, and others rapidly convinced their scientific contemporaries of the fact of evolution (Darwin 1859/1964; Wallace 1870). They persuaded that community of the existence of the tree of life. Darwin himself was a gradualist, thinking that tiny increments across great periods of time accumulate as evolutionary change, and he thought that the main agent of that change was natural selection. But his views on gradual change and on the importance of selection were not part of the biological consensus until the synthesis of population genetics with evolutionary theory by Fisher, Wright, Haldane, and others in the 1930s (Depew and Weber 1995). The importance of isolation in the generation of new species remained controversial even longer. It became part of the consensus view on evolution only after Mayr's postwar work on speciation and evolution (Mayr 1942, 1976, 1988).

The biological world confronted Darwin, Wallace, and their successors with two central problems. The world of life as we know it is fabulously diverse, even though today's life is only a tiny fraction of its total historical diversity. We tend to underestimate that diversity, because most large animals—animals that we notice—are vertebrates like us. But many organisms are weirdly different from us and from one another, and weird not just in finished adult form, but also in their developmental history. Humans do not undergo major physical reorganizations during their growth from children, whereas (for example) many parasites' life cycles take them through a number of hosts, and in their travels they experience complete physical transformation. Yet though life is diverse, that diversity is clumped in important ways. Arthropods have jointed, segmented bodies with various limbs and feelers attached, the whole covered with an exoskeleton. They are very different from anything else, from vertebrates, worms, and other invertebrates. Before Darwin, the differences between arthropods, vertebrates, worms, and other great branches of life seemed so vast as to rule out evolutionary transitions between them. They are so distinctive that even after the universal acceptance of the evolutionary descent of life, arthropod affinities remain controversial. Thus one task of evolutionary biology is in the explanation of diversity and its clumping, both on the large scale of different kinds of organism, and on the smaller scale of the difference between species of the same general kind.

If diversity is important, so too is ADAPTATION. The structured complexity of organisms, and their adaptation to their environment, is every bit as striking as the diversity of organisms through their environment. Perceptual systems are classic examples of complex, fine-tuned adaptation. Bat ECHOLOCATION requires mechanisms that enable bats to produce highly energetic sound waves. So they also have mechanisms that protect their ears while they are making such loud sounds. They have elaborately structured facial architectures to maximize their chances of detecting return echoes, together with specialized neural machinery to use the information in those echoes to guide their flight to their target. But there are many other examples of complex adaptation. Many parasites, for example, manufacture chemicals that they use to manipulate the morphology and behavior of their host.

Darwin's greatest achievement was to give a naturalistic explanation of adaptation. His key idea, natural selection, can explain both adaptation and diversity. Imagine the population ancestral to the Australasian bittern. Let us suppose that this population, like current bitterns, lived in reeds adjacent to wetlands and sought to escape predation by crouching still when a threatening creature was near. It is quite likely that the color and pattern of the plumage of this ancestral population varied. If so, some birds were favored. Their plumage made them somewhat harder to see when they froze among the reeds. They were more likely to survive to breed. If the plumage patterns of their offspring were like those of their parents, the plumage patterns of the descendant generation would be somewhat different from that of the ancestral generation. Over time, the colors and patterns characteristic of the population would change. Thus we could reach today's superbly well-concealed bitterns. Natural selection selects fitter organisms, and the heritability of their traits ensures a changed descendant population. Evolutionary change depends on variation in a population, fitness differences in the population consequent on that variation and heritability. Adaptive change takes place despite the fact that the mechanisms that generate variation in the population are decoupled from the adaptive needs of the population. But it depends on more than those principles. The adaptive shift to good camouflage took place gradually, over many generations. It depended on cumulative selection. If selection is to explain major adaptation it must be cumulative. Innovation is the result of a long sequence of selective episodes rather than one, for the chances of a single mutation producing a new adaptation are very low.

Thus evolution under natural selection can produce adaptation. At the same time, it can produce diversity, as populations become adapted to different local environments, and thus diverge from one another.

Evolutionary biology has developed a consensus on the broad outline of life's history. There is agreement on important aspects of the mechanism of evolution. Everyone agrees that selection is important, but that chance and other factors play an important role too. No one doubts the importance of isolation in generating diversity. But important disagreements remain. The nature of species and speciation remains problematic. Although everyone agrees that selection, chance, history, and development combine to generate life's history, the nature of that combination remains controversial. Though all agree that selection matters, the mode of its action remains contested. Dawkins and others think of selection as primarily selecting lineages of genes in virtue of their differing capacities to get

themselves replicated (Dawkins 1982). Others—for example, Gould (1989) and Sober (1984)—conceive of selection as acting on many different kinds of entities: genes, organisms, colonies and groups, and even species. Finally, some—David Hull (1988) being one—think of evolution in biology as just a special case of a general mechanism of change involving undirected variation and selective retention. These controversial ideas lead to attempts to give evolutionary accounts of scientific and cultural change.

Evolution of Language

The question of how language evolved has never been a respectable one. In the nineteenth century it motivated so much wild speculation that the Société de Linguistique de Paris banned all discussion on the topic—and many academics today wish this ban were still in place. Over the last thirty or so years, however, findings from psychology, evolutionary biology, and linguistics have radically changed the way that scholars approach this issue, leading to some surprising insights and opening up areas of fruitful empirical investigation.

For one thing, proposals that language is entirely a cultural innovation, akin to agriculture or bowling, can be safely dismissed. Historical linguistics gives no support to the speculation that language was invented once and then spread throughout the world; instead, the capacity to create language is to some extent within every human, and it is invented anew each generation (Pinker 1994). This is most apparent from studies of creolization; children who are exposed to a rudimentary communication system will embellish and expand it, transforming it into a full-fledged language within a single generation—a CREOLE (Bickerton 1981). A similar process might occur in all normal instances of LANGUAGE ACQUISITION: Children are remarkably proficient at obeying subtle syntactic and morphological constraints for which there is little evidence in the sentences they hear (e.g., Crain 1991), suggesting that some capacity for language has emerged through biological evolution.

Could this capacity have emerged as an accidental result of the large brains that humans have evolved, or as a by-product of some enhanced general intelligence? Probably not; there are people of otherwise normal intelligence and brain size who have severe problems learning language (e.g., Gopnik 1990), as well as people with reduced intelligence or small brains who have no problems with language (e.g., Lenneberg 1967). Furthermore, the human language capacity cannot be entirely explained in terms of the evolution of mechanisms for the production and comprehension of speech. Although the human vocal tract shows substantial signs of design for the purpose of articulation—something observed by both DARWIN and the theologian William Paley, though they drew quite different morals from it—humans are equally proficient at learning and using SIGN LANGUAGES (Newport and Meier 1985).

How else could language have evolved? Modern biologists have elaborated Darwin's insight that although natural selection is the most important of all evolutionary mechanisms, it is not the only one. Many traits that animals possess are not adaptations, but emerge either as by-products of adaptations ("spandrels") or through entirely nonselectionist processes, such as random genetic drift (Gould and Lewontin 1979). Natural selection is necessary only in order to explain the evolution of what Darwin (1859) called "organs of extreme perfection and complexity," such as the heart, the hand, and the eye. This is because only a selectionist process can evolve biological traits capable of accomplishing impressive engineering tasks of adaptive benefit to organisms (Dawkins 1986; Williams 1966). Although there is controversy about the proper scope of selectionist theories, this much at least is agreed on, even by those who are most cautious about applying adaptive explanations (e.g., Gould 1977).

Does language show signs of complex adaptive design to the same extent as organs such as the hand and the eye? Many linguists would claim that it does, arguing that language is composed of different parts, including PHONOLOGY,

MORPHOLOGY, and SYNTAX, that interact with one another, as well as with perceptual, motoric, and conceptual systems, so as to make possible an extraordinarily complicated engineering task—the transduction of thoughts into speech or sign. The conclusion that language decomposes into distinct neural and computational components is supported by independent data from studies of acquisition, processing, and pathology (Pinker 1994).

Based on these conclusions, some scholars have argued that language has evolved as a biological adaptation for the function of communication (Newmeyer 1991; Pinker and Bloom 1990). Others have proposed instead that the ability to learn and use language is a by-product of brain mechanisms evolved for other purposes, such as motor control (Lieberman 1984), social cognition (Tomasello 1995) and internal computation and representation (Bickerton, 1995)—and that such mechanisms have been exploited, with limited subsequent modification, for speech and sign.

To put the issue in a different context, nobody doubts that the acquisition and use of human language involves capacities we share with other animals; the interesting debate is over whether the uniquely human ability to learn language can be explained entirely in terms of enhancements of such capacities, or whether much of language has been specifically evolved in the millions of years that separate us from other primates. The study of the communication systems of nonhuman primates is plainly relevant here (e.g., Cheney and Seyfarth 1990) as is the study of their conceptual and social capacities (e.g., Povinelli and Eddy 1996).

The more we learn about the cognitive and neural mechanisms underlying language, the more we will know about how it evolved—which aspects are adaptations for different purposes, which are by-products of adaptations, and which are accidents (Bloom 1998). Perhaps more importantly, we can gain insights in the opposite direction. As Mayr (1983) points out, asking about the function of a given structure or organ "has been the basis for every advance in physiology." And although one can ask about function without considering evolutionary biology, an appreciation of how natural selection works is necessary in order to discipline and guide functional inquiry; this is especially so for the quite nonintuitive functional considerations that arise in the evolution of communication systems (Dawkins and Krebs 1978; Hauser 1996). To the extent that language is part of human physiology, exploring how it evolved will inevitably lead to insights about its current nature.

Evolutionary Computation

Evolutionary computation is a collection of computational search, learning, optimization, and modeling methods loosely inspired by biological EVOLUTION. The methods most often used are called *genetic algorithms* (GAs), *evolution strategies* (ESs), and *evolutionary programming* (EP). These three methods were developed independently in the 1960s: GAs by Holland (1975), ESs by Rechenberg (1973) and Schwefel (1977), and EP by Fogel, Owens, and Walsh (1966). (Genetic programming, a variant of genetic algorithms, was developed in the 1980s by Koza 1992, 1994.) Such methods are part of a general movement for using biological ideas in computer science that started with pioneers such as VON NEUMANN, TURING, and WIENER, and continues today with evolutionary computation, NEURAL NETWORKS,

and methods inspired by the immune system, insect colonies, and other biological systems.

Imitating the mechanisms of evolution has appealed to computer scientists from nearly the beginning of the computer age. Very roughly speaking, evolution can be viewed as searching in parallel among an enormous number of possibilities for "solutions" to the problem of survival in an environment, where the solutions are particular designs for organisms. Viewed from a high level, the "rules" of evolution are remarkably simple: species evolve by means of heritable variation (via mutation, recombination, and other operators), followed by natural selection in which the fittest tend to survive and reproduce, thus propagating their genetic material to future generations. Yet these simple rules are thought to be responsible, in large part, for the extraordinary variety and complexity we see in the biosphere. Seen in this light, the mechanisms of evolution can inspire computational search methods for finding solutions to hard problems in large search spaces or for automatically designing complex systems.

In most evolutionary computation applications, the user has a particular problem to be solved and a way to encode candidate solutions so that the solution space can be searched. For example, in the field of computational protein design, the problem is to design a one-dimensional sequence of amino acids that will fold up into a three-dimensional protein with desired characteristics. Assuming that the sequence is of length l, candidate solutions can be expressed as strings of l amino-acid codes. There are twenty different amino acids, so the number of possible strings is 20^l. The user also provides a "fitness function" or "objective function" that assigns a value to each candidate solution measuring its quality.

Evolutionary computation (EC) methods all begin with a population of randomly generated candidate solutions ("individuals"), and perform fitness-based selection and random variation to create a new population. Typically, some number of the highest-fitness individuals are chosen under selection to create offspring for the next generation. Often, an offspring will be produced via a crossover between two or more parents, in which the offspring receives "genetic material"—different parts of candidate solutions—from different parents. Typically the offspring is also mutated randomly—parts of the candidate solution are changed at random. (Mutation and crossover in evolutionary computation are meant to mimic roughly biological mutation and sexual recombination, two main sources of genetic variation.) Offspring are created in this way until a new generation is complete. This process typically iterates for many generations, often ending up with one or more optimal or high-quality individuals in the population.

GA, EP, and ES methods differ in the details of this process. In general, ESs and EP each define fairly specific versions of this process, whereas the term "genetic algorithm," originally referring to a specific algorithm, has come to refer to many considerably different variations of the basic scheme.

ESs were originally formulated to work on real-valued parameter optimization problems, such as airplane wing-shape optimization. They are still most commonly applied to numerical optimization problems. In the original formulation of EP, candidate solutions to given tasks were represented as finite-state machines, which were evolved by randomly mutating their state-transition diagrams and selecting the fittest. Since that time a somewhat broader formulation has emerged. In contrast with ESs and EP, GAs were originally formulated not to solve specific problems, but rather as a means to study formally the phenomenon of adaptation as it occurs in nature and to develop ways in which the mechanisms of natural adaptation might be imported into computer systems. Only after Holland's original theoretical work were GAs adapted to solving optimization problems. Since the early 1990s there has been much cross-fertilization among the three areas, and the original distinctions among GAs, ESs, and EP have blurred considerably in the current use of these labels.

Setting the parameters for the evolutionary process (population size, selection strength, mutation rate, crossover rate, and so on) is often a matter of guesswork and trial and error, though some theoretical and heuristic guidelines have been discovered. An alternative is to have the parameters "self-adapt"—to change their values automatically over the course of evolution in response to selective pressures. Self-adapting parameters are an intrinsic part of ESs and EP, and are the subject of much research in GAs.

EC methods have been applied widely. Examples of applications include numerical parameter optimization and combinatorial optimization, the automatic design of computer programs, bioengineering, financial prediction, robot learning, evolving production systems for artificial intelligence applications, and designing and training neural networks. In addition to these "problem-solving" applications, EC methods have been used in models of natural systems in which evolutionary processes take place, including economic systems, immune systems, ecologies, biological evolution, evolving systems with adaptive individuals, insect societies, and more complex social systems. (See Mitchell 1996 for an overview of applications in some of these areas.)

Much current research in the EC field is on making the basic EC framework more biologically realistic, both for modeling purposes and in the hope that more realism will improve the search performance of these methods. One approach is incorporating more complex genetic information in individuals in the population, such as sexual differentiation, diploidy, and introns. Another is incorporating additional genetic operators, such as inversion, translocation, and gene doubling and deletion. A third is embedding more complex ecological interactions into the population, such as host-parasite coevolution, symbiosis, sexual selection, and spatial migration. Finally, there has been considerable success in combining EC methods with other types of search methods, such as simple gradient ascent and simulated annealing. Such hybrid algorithms are thought by many to be the best approach to optimization in complex and ill-understood problem spaces (Davis 1991).

EC is relevant for the cognitive sciences both because of its applications in the fields of artificial intelligence and MACHINE LEARNING and because of its use in models of the interaction of evolution and cognitive processes. For

example, researchers in EVOLUTIONARY PSYCHOLOGY and other areas have used EC methods in their models of interactions between evolution and LEARNING (e.g., Ackley and Littman 1992; Belew and Mitchell 1996; Miller and Todd 1990; Parisi, Nolfi and Elman 1994; Todd 1996). Likewise, EC methods have been used in models of the relationship between evolution and development (e.g., Belew 1993; Dellaert and Beer 1994). Social scientists and linguists have used EC methods to study, for example, the evolution of cooperation and communication in multiagent systems (e.g., Ackley and Littman 1994; Axelrod 1987; Batali 1994; Batali and Kitcher 1995; Stanley, Ashlock, and Tesfatsion 1994). Many of these models are considered to fall in the purview of the field of ARTIFICIAL LIFE. These examples by no means exhaust the uses of EC in cognitive science, and the literature is growing as interest increases in the role of evolution in shaping cognition and behavior.

Evolutionary Psychology

Evolutionary psychology is an approach to the cognitive sciences in which evolutionary biology is integrated with the cognitive, neural, and behavioral sciences to guide the systematic mapping of the species-typical computational and neural architectures of animal species, including humans.

Although the field draws on many disciplines, of particular importance was the integration of (1) the cognitive study of functional specializations pioneered in perception and Chomskyan psycholinguistics (MARR 1982); (2) hunter-gatherer and primate studies (Lee and DeVore 1968); and (3) the revolution that placed evolutionary biology on a more rigorous, formal foundation of replicator dynamics (Williams 1966; Dawkins 1982). Beginning in the 1960s, this revolution catalyzed the derivation of a set of theories

about how evolution shapes organic design with respect to kinship, foraging, parental care, mate selection, COOPERATION AND COMPETITION, aggression, communication, life history, and so forth—theories that were refined and tested on an empirical base that now includes thousands of species. This body of theory has allowed evolutionary psychologists to apply the concepts and methods of the cognitive sciences to nontraditional topics, such as reciprocation, foraging memory, parental motivation, coalitional dynamics, incest avoidance, sexual jealousy, and so on. Evolutionary psychology is unusual in that a primary goal is the construction of a comprehensive map of the entire species-typical computational architecture of humans, including motivational and emotional mechanisms, and that its scope includes all human behavior, rather than simply "cold cognition."

George Williams's (1966) volume *Adaptation and Natural Selection* was of particular formative significance to evolutionary psychology. Williams identified the defects in the imprecise, panglossian functionalist thinking that had pervaded evolutionary biology and that continues, implicitly, to permeate other fields. The book outlined the principles of modern adaptationism (see ADAPTATION AND ADAPTATIONISM), showed how tightly constrained any adaptationist (i.e., functionalist) or by-product claim had to be to be consistent with neo-Darwinism, and identified the empirical tests such claims had to pass. Until Williams, many biologists explained the existence of a trait (or attributed functionality to traits) by identifying some beneficial consequence (to the individual, the social group, the ecosystem, the species, etc.). They did so without regard to whether the functionality or benefit was narrowly coupled, as neo-Darwinism requires, to a design that led to systematic genic propagation of replicas of itself within the context of the species' ancestral environment. Evolutionary psychologists apply these precise adaptationist constraints on functionalism to the cognitive, neural, and social sciences, and maintain that cognitive scientists should at least be aware that many cognitive theories routinely posit complex functional organization of kinds that evolutionary processes are unlikely to produce.

Evolutionary psychologists consider their field methodologically analogous to reverse engineering in computer science. In such an enterprise, evolutionary psychologists argue, knowledge of the evolutionary dynamics and ancestral task environments responsible for the construction of each species' architecture can provide valuable, although incomplete, models of the computational problems (sensu Marr 1982) that each species regularly encountered. These, in turn, can be used to pinpoint many candidate design features of the computational devices that could have evolved to solve these problems, which can then be used to guide empirical investigations. For example, if eye direction reliably provided useful information ancestrally about the intentions of conspecifics or predators, then specialized eye direction detectors may have evolved as a component of SOCIAL COGNITION, and it may prove worthwhile testing for their existence and design (Baron-Cohen 1995).

Evolutionary psychologists consider it likely that cognitive architectures contain a large number of evolved compu-

tational devices that are specialized in function (Gallistel 1995), such as FACE RECOGNITION systems, a language acquisition device, navigation specializations, and animate motion recognition. They are skeptical that an architecture consisting predominantly of content-independent cognitive processes, such as general-purpose pattern associators, could solve the diverse array of adaptive problems efficiently enough to reproduce themselves reliably in complex, unforgiving natural environments that include, for example, antagonistically coevolving biotic adversaries, such as parasites, prey, predators, competitors, and incompletely harmonious social partners.

Selection drives design features to become incorporated into architectures in proportion to the actual distribution of adaptive problems encountered by a species over evolutionary time. There is no selection to generalize the scope of problem solving to include never or rarely encountered problems at the cost of efficiency in solving frequently encountered problems. To the extent that problems cluster into types (domains) with statistically recurrent properties and structures (e.g., facial expression statistically cues emotional state), it will often be more efficient to include computational specializations tailored to inferentially exploit the recurrent features of the domain (objects always have locations, are bounded by surfaces, cannot pass through each other without deformation, can be used to move each other, etc.). Because the effects of selection depend on iteration over evolutionary time, evolutionary psychologists expect the detailed design features of domain-specific inference engines to intricately reflect the enduring features of domains. Consequently, evolutionary psychologists are very interested in careful studies of enduring environmental and task regularities, because these predict details of functional design (Shepard 1987). Adaptationist predictions of DOMAIN SPECIFICITY have gained support from many sources, for example, from cognitive neuroscience, demonstrating that many dissociable cognitive deficits show surprising content-specificity, and from developmental research indicating that infants come equipped with evolved domain-specific inference engines (e.g., a NAIVE PHYSICS, a THEORY OF MIND module; Hirschfeld and Gelman 1994).

A distinguishing feature of evolutionary psychology is that evolutionary psychologists have principled theoretical reasons for their hypotheses derived from biology, paleoanthropology, GAME THEORY, and hunter-gatherer studies. Such theoretically derived prior hypotheses allow researchers to devise experiments that make possible the detection and mapping of computational devices that no one would otherwise have thought to test for in the absence of such theories. To the extent that the evolutionary theory used is accurate, evolutionary psychologists argue that this practice allows a far more efficient research strategy than experiments designed and conducted in ignorance of the principles of evolved design or the likely functions of the brain. Using this new research program, many theoretically motivated discoveries have been made about, for instance, internal representations of trajectories; computational specializations for reasoning about danger, social exchanges, and threats; female advantage in the incidental learning of the spatial locations of objects; the frequency format of

probabilistic reasoning representations; the decision rules governing risk aversion and its absence; universal mate selection criteria and standards of beauty; eye direction detection and its relationship to theory of mind; principles of generalization; life history shifts in aggression and parenting decisions; social memory; reasoning about groups and coalitions; the organization of jealousy, and scores of other topics (see Barkow, Cosmides, and Tooby 1992 for review).

Although some critics (Gould 1997) have argued that the field consists of post hoc storytelling, it is difficult to reconcile such claims with the actual practice of evolutionary psychologists, inasmuch as in evolutionary psychology the evolutionary model or "explanation" precedes the empirical discovery and guides researchers to it, rather than being constructed post hoc to explain some known fact. Although critics have also plausibly maintained that reconstructions of the past are inherently speculative, evolutionary psychologists have responded that researchers know with certainty or high confidence thousands of important things about our ancestors, many of which can be deployed in designing cognitive experiments: our ancestors had two sexes; lived in an environment where self-propelled motion reliably predicted that the entity was an animal; inhabited a world where the motions of objects conformed to the principles of kinematic geometry; chose mates; had color vision; were predated upon; had faces; lived in a biotic environment with a hierarchical taxonomic structure; and so on. Moreover, evolutionary psychologists point out that, to the extent that reconstructions are uncertain, they will simply lead to experiments that are no more or less likely to be productive than evolutionarily agnostic empiricism, the alternative research strategy.

Similarly, critics have argued that adaptationist analysis is misconceived, because adaptations are of poor quality, rendering functional predictions irrelevant (Gould 1997). Evolutionary psychologists respond that although selection does not optimize, it demonstrably produces well-engineered adaptations to long-enduring adaptive problems. Indeed, whenever engineers have attempted to duplicate any natural competence (color vision, object recognition, grammar acquisition, texture perception, object manipulation, locomotion over natural terrains, language comprehension, etc.), even when using huge budgets, large research teams, and decades of effort, they are unable to engineer artificial systems that can come close to competing with naturally engineered systems.

The processes of evolutionary change divide into two families: chance and selection. Chance processes (drift, mutation pressure, environmental change, etc.) produce random evolutionary change, and so cannot build organic structure more functionally organized than chance could account for. Natural selection, in contrast, is the only component of the evolutionary process that sorts features into or out of the architecture on the basis of how well they function. Consequently, all cognitive organization that is too improbably well-ordered with respect to function to have arisen by chance must be attributed to the operation of selection, a constrained set of processes that restrict the kinds of functional organization that can appear in organisms. As a result,

features of a species' cognitive or neural architecture can be partitioned into adaptations, which are present because they were selected for (e.g., the enhanced recognition system for snakes coupled with a decision-rule to acquire a motivation to avoid them); by-products, which are present because they are causally coupled to traits that were selected for (e.g., the avoidance of harmless snakes); and noise, which was injected by the stochastic components of evolution (e.g., the fact that a small percentage of humans sneeze when exposed to sunlight). One payoff of integrating adaptationist analysis with cognitive science was the realization that complex functional structures (computational or anatomical), in species with life histories like humans, will be overwhelmingly species-typical (Tooby and Cosmides 1990a). That is, the complex adaptations that compose the human COGNITIVE ARCHITECTURE must be human universals, while variation caused by genetic differences are predominantly noise: minor random perturbations around the species-typical design. This principle allows cross-cultural triangulation of the species-typical design, which is why many evolutionary psychologists include cross-cultural components in their research.

Evolutionary psychologists emphasize the study of adaptations and their by-products not because they think all or most traits are adaptations (or their side effects), but because (1) at present, adaptationist theories of function provide clear and useful prior predictions about cognitive organization; (2) the functional elements are far more likely to be species-typical and hence experimentally extractable; (3) analysis of the random or contingent components of evolution provides very few constrained or falsifiable predictions about cognitive architecture; and (4) theories of phylogenetic constraint are not yet very useful or well developed, although that may change. Evolutionary psychologists do not maintain that all traits are adaptive, that the realized architecture of the human mind is immune to modification, that genes or biology are deterministic, that culture is unimportant, or that existing human social arrangements are fair or inevitable. Indeed, they provide testable theories about the developmental processes that build (and can change) the mechanisms that generate human behavior.

Expert Systems

See EXPERTISE; KNOWLEDGE-BASED SYSTEMS

Expertise

Expertise refers to the mechanisms underlying the superior achievement of an expert, that is, "one who has acquired special skill in or knowledge of a particular subject through professional training and practical experience" (Webster's, 1976: 800). The term *expert* is used to describe highly experienced professionals such as medical doctors, accountants, teachers, and scientists, but has been expanded to include individuals who attained their superior performance by instruction and extended practice: highly skilled performers in the arts, such as music, painting, and writing; sports, such as swimming, running, and golf; and games, such as bridge, chess, and billiards.

When experts exhibit their superior performance in public their behavior looks so effortless and natural that we are tempted to attribute it to special talents. Although a certain amount of knowledge and training seems necessary, the role of acquired skill for the highest levels of achievement has traditionally been minimized. However, when scientists began measuring the experts' supposedly superior powers of speed, memory and intelligence with psychometric tests, no general superiority was found—the demonstrated superiority was domain-specific. For example, the superiority of the CHESS experts' memory was constrained to regular chess positions and did not generalize to other types of materials (Djakow, Petrowski and Rudik 1927). Not even IQ could distinguish the best among chess-players (Doll and Mayr 1987) nor the most successful and creative among artists and scientists (Taylor 1975). Ericsson and Lehmann (1996) found that

1. Measures of general basic capacities do not predict success in a domain.
2. The superior performance of experts is often very domain-specific, and transfer outside their narrow area of expertise is surprisingly limited.
3. Systematic differences between experts and less proficient individuals nearly always reflect attributes acquired by the experts during their lengthy training.

In a pioneering empirical study of the thought processes mediating the highest levels of performance, de Groot (1978) instructed expert and world-class chess players to think aloud while they selected their next move for an unfamiliar chess position. The world-class players did not differ

in the speed of their thoughts or the size of their basic memory capacity, and their ability to recognize promising potential moves was based on their extensive experience and knowledge of patterns in chess. In their influential theory of expertise, Chase and Simon (1973; Simon and Chase 1973) proposed that experts with extended experience acquire a larger number of more complex patterns and use these new patterns to store knowledge about which actions should be taken in similar situations. According to this influential theory, expert performance is viewed as an extreme case of skill acquisition (Proctor and Dutta 1995; Richman et al. 1996; VanLehn 1996) and as the final result of the gradual improvement of performance during extended experience in a domain. Furthermore, the postulated central role of acquired knowledge has encouraged efforts to extract experts' knowledge so that computer scientists can build expert systems that would allow a computer to act as an expert (Hoffman 1992).

Among investigators of expertise, it has generally been assumed that the performance of experts improves as a direct function of increases in their knowledge through training and extended experience. However, recent studies show that there are, at least, some domains where "experts" perform no better then less trained individuals (cf. outcomes of therapy by clinical psychologists; Dawes 1994) and that sometimes experts' decisions are no more accurate than beginners' decisions and simple decision aids (Camerer and Johnson 1991; Bolger and Wright 1992). Most individuals who start as active professionals or as beginners in a domain change their behavior and increase their performance for a limited time until they reach an acceptable level. Beyond this point, however, further improvements appear to be unpredictable, and the number of years of work and leisure experience in a domain is a poor predictor of attained performance (Ericsson and Lehmann 1996). Hence, continued improvements (changes) in achievement are not automatic consequences of more experience, and in those domains where performance consistently increases, aspiring experts seek out particular kinds of experience, that is, deliberate practice (Ericsson, Krampe, and Tesch-Römer 1993)—activities designed, typically by a teacher, for the sole purpose of effectively improving specific aspects of an individual's performance. For example, the critical difference between expert musicians differing in the level of attained solo performance concerned the amounts of time they had spent in solitary practice during their music development, which totaled around ten thousand hours by age twenty for the best experts, around five thousand hours for the least-accomplished expert musicians, and only two thousand hours for serious amateur pianists. More generally, the accumulated amount of deliberate practice is closely related to the attained level of performance of many types of experts, such as musicians (Ericsson, Krampe, and Tesch-Römer 1993; Sloboda et al. 1996), chess players (Charness, Krampe, and Mayr 1996) and athletes (Starkes et al. 1996).

The recent advances in our understanding of the complex representations, knowledge and skills that mediate the superior performance of experts derive primarily from studies where experts are instructed to think aloud while completing representative tasks in their domains, such as chess, music, physics, sports, and medicine (Chi, Glaser, and Farr 1988; Ericsson and Smith 1991; Starkes and Allard 1993). For appropriate challenging problems experts do not just automatically extract patterns and retrieve their response directly from memory. Instead, they select the relevant information and encode it in special representations in WORKING MEMORY that allow PLANNING, evaluation and reasoning about alternative courses of action (Ericsson and Lehmann 1996). Hence, the difference between experts and less skilled subjects is not merely a matter of the amount and complexity of the accumulated knowledge; it also reflects qualitative differences in the organization of knowledge and its representation (Chi, Glaser, and Rees 1982). Experts' knowledge is encoded around key domain-related concepts and solution procedures that allow rapid and reliable retrieval whenever stored information is relevant. Less skilled subjects' knowledge, in contrast, is encoded using everyday concepts that make the retrieval of even their limited relevant knowledge difficult and unreliable. Furthermore, experts have acquired domain-specific memory skills that allow them to rely on long-term memory (Ericsson and Kintsch 1995) to dramatically expand the amount of information that can be kept accessible during planning and during reasoning about alternative courses of action. The superior quality of the experts' mental representations allow them to adapt rapidly to changing circumstances and anticipate future events in advance. The same acquired representations appear to be essential for experts' ability to monitor and evaluate their own performance (Ericsson 1996; Glaser 1996) so that they can keep improving their own performance by designing their own training and assimilating new knowledge.

Explanation

An explanation is a structure or process that provides understanding. Furnishing explanations is one of the most important activities in high-level cognition, and the nature of explanation and its role in thinking has been addressed by philosophers, psychologists, and artificial intelligence researchers.

The main philosophical concern has been to characterize the nature of explanations in science. In 1948, Hempel and Oppenheim proposed the deductive-nomological (D-N) model of explanation, according to which an explanation is an argument that deduces a description of a fact to be explained from general laws and descriptions of observed facts (Hempel 1965). For example, to explain an eclipse of the sun, scientists use laws of planetary motion to deduce that at a particular time the moon will pass between the earth and the sun, producing an eclipse. Many artificial intelligence researchers also assume that explanations consist of deductive proofs (e.g., Mitchell, Keller, and Kedar-Cabelli 1986).

Although the D-N model gives a good approximate account of explanation in some areas of science, particularly mathematical physics, it does not provide an adequate general account of explanation. Some explanations are inductive and statistical rather than deductive, showing only that an event to be explained is likely or falls under some probabilistic law rather than that it follows deductively from laws (see DEDUCTIVE REASONING and INDUCTION). For example, we explain why people get influenza in terms of their exposure to the influenza virus, but many people exposed to the virus do not get sick. In areas of science such as evolutionary biology, scientists cannot predict how different species will evolve, but they can use the theory of evolution by natural selection and the fossil record to explain how a given species has evolved. Often, the main concern of explanation is not so much to deduce what is to be explained from general laws as it is to display causes (Salmon 1984). Understanding an event or class of events then consists of describing the relevant causes and causal mechanisms that produce such events. Salmon (1989) and Kitcher (1989) provide good reviews of philosophical discussions of the nature of scientific explanation. According to Friedman (1974) and Kitcher, explanations yield understanding by unifying facts using common patterns.

Deduction from laws is just one of the ways that facts can be explained by fitting them into a more general, unifying framework. More generally, explanation is a process of applying a schema that fits what is to be explained into a system of information. An explanation schema consists of an explanation target, which is a question to be answered, and an explanatory pattern, which provides a general way of answering the question. For example, when you want to explain why a person is doing an action such as working long hours, you may employ a rough explanation schema like:

Explanation target:
Why does a *person* with a set of *beliefs* and *desires* perform a particular *action*?

Explanatory pattern:
The *person* has the *belief* that the *action* will help fulfil the *desires*. This *belief* causes the *person* to pursue the *action*.

To apply this schema to a particular case, we replace the italicized terms with specific examples, as in explaining

Mary's action of working long hours in terms of her belief that this will help her to fulfill her desire to finish her Ph.D. dissertation. Many writers in philosophy of science and cognitive science have described explanations and theories in terms of schemas, patterns, or similar abstractions (Kitcher 1989, 1993; Kelley 1972; Leake 1992; Schank 1986; Thagard 1992).

One kind of explanation pattern that is common in biology, psychology, and sociology explains the presence of a structure or behavior in a system by reference to how the structure or behavior contributes to the goals of the system. For example, people have hearts because this organ functions to pump blood through the body, and democracies conduct elections in order to allow people to choose their leaders. These functional (teleological) explanations are not incompatible with causal/mechanical ones: in a biological organism, for example, the explanation of an organ in terms of its function goes hand in hand with a causal explanation that the organ developed as the result of natural selection. Craik (1943) originated the important idea that an explanation of events can be accomplished by mental models that parallel the events in the same way that a calculating machine can parallel physical changes.

Analogies can contribute to explanation at a more specific level, without requiring explicit use of laws or schemas. For example, DARWIN's use of his theory of natural selection to explain evolution frequently invoked the familiar effects of artificial selection by breeders of domesticated animals. Pasteur formed the germ theory of disease by analogy with his earlier explanation that fermentation is caused by bacteria. In analogical explanations, something puzzling is compared to a familiar phenomenon whose causes are known (see ANALOGY).

In both scientific and everyday understanding, there is often more than one possible explanation. Perhaps Mary is working long hours merely because she is a workaholic and prefers working to other activities. One explanation of why the dinosaurs became extinct is that they were killed when an asteroid hit the earth, but acceptance of this hypothesis must compare it with alternative explanations. The term *inference to the best explanation* refers to acceptance of a hypothesis on the grounds that it provides a better explanation of the evidence than alternative hypotheses (Harman 1986; Lipton 1991; Thagard 1992). Examples of inference to the best explanation include theory choice in science and inferences we make about the mental states of other people. What social psychologists call *attribution* is inference to the best explanation of a person's behavior (Read and Marcus-Newhall 1993).

Explanations are often useful for improving the performance of human and machine systems. Automated expert systems are sometimes enhanced by giving them the ability to produce computer-generated descriptions of their own operation so that people will be able to understand the inferences underlying their conclusions (Swartout 1983). Chi et al. (1989) found that students learn better when they use "self-explanations" that monitor progress or lack of progress in understanding problems.

Explanation-Based Learning

Explanation-based learning (EBL) systems attempt to improve the performance of a problem solver (PS) by first examining how the PS solved previous problems, then modifying the PS to enable it to solve similar problems *better* (typically, *more efficiently*) in the future.

Many problem-solving tasks—which here include diagnosis, classification, PLANNING, scheduling and parsing (see also KNOWLEDGE-BASED SYSTEMS; NATURAL LANGUAGE

PROCESSING; CONSTRAINT SATISFACTION)—are combinatorially difficult, inasmuch as they require finding a (possibly very long) sequence of rules to reduce a given goal to a set of operational actions, or to a set of facts, and so forth. Unfortunately, this can force a problem solving system (PS) to take a long time to solve a problem. Fortunately, many problems are similar, which means that information obtained from solving one problem may be useful for solving subsequent, related problems. Some PSs therefore include an "explanation-based learning" module that learns from each solution: after the basic problem-solving module has solved a specific problem, the EBL module then modifies the solver (perhaps by changing its underlying rule base, or by adding new control information), to produce a new solver that is able to solve this problem, and related problems, more efficiently.

As a simple example, given the information in the Prolog-style logic program

$$\left\{ \begin{array}{l} \text{lender}(X,Y) \ \text{:- relative}(X,Y), \text{rich}(Y). \\ \text{relative}(X,Y) \ \text{:- aunt}(X,Y) \\ \text{relative}(X,Y) \ \text{:- uncle}(X,Y) \\ \\ \text{rich}(X,Y) \qquad \text{:- ceo}(Y,B), \text{bank}(B). \\ \text{rich}(Y) \qquad \text{:- own}(Y,H), \text{house}(H). \\ \\ \text{uncle}(me,u_1) \quad \text{own}(u_1,h_2). \ \text{house}(h_2) \end{array} \right\}$$

(where the first rule states that a person Y may lend money to X if Y is a relative of X and Y is rich, etc., as well as information about a house-owning uncle u_1), the PS would correctly classify u_1 as a lender—that is, return yes to the query lender(me, u_1).

Most PSs would have had to backtrack here; first asking if u_1 was an aunt, and only when this subquery failed, then asking whether u_1 was an uncle; similarly, to establish rich(u_1), it would first see whether u_1 was the CEO of a bank before backtracking to see if he owns a house. In general, PSs may have to backtrack many times as they search through a combinatorial space of rules until finding a sequence of rules that successfully reduces the given query to a set of known facts.

Although there may be no way to avoid such searches the first time a query is posed (note that many of these tasks are NP-hard; see COMPUTATIONAL COMPLEXITY), an EBL module will try to modify the PS to help it avoid this search the second time it encounters the same query, or one similar to it. As simply "caching" or "memorizing" (Michie 1967) the particular conclusion—here, lender(me, u_1)—would only help the solver if it happens to encounter this exact query a second time, most EBL modules instead incorporate more general information, perhaps by adding in a new rule that directly encodes the fact that any uncle who owns a house is a lender; that is,

lender(X, Y) :– uncle(X, Y), owns(Y, H), house(H).

Many EBL systems would then store this rule—call it r_{new}—in the *front* of the PS's rule set, which means it will be the first rule considered the next time a lender was sought. This would allow the modified solver—call it PS′—to handle houseowning uncles in a single backward-chaining step, without any backtracking.

Such EBL modules first "explain" why u_1 was a lender by examining the derivation structure obtained for this query; hence the name "explanation-based learning." Many such systems then "collapse" the derivation structure of the motivating problem: directly connecting a variablized form of the conclusion to the atomic facts used in its derivation. In general, the antecedents of the new rule are the weakest set of conditions required to establish the conclusion (here lender(X, Y)) in the context of the given instance. The example itself was used to specify what information—in particular, which of the facts about me and u_1—were required.

Although the new r_{new} rule is useful for queries that deal with houseowning uncles, it will not help when dealing with house-owning *aunts* or with *CEO* uncles. In fact, r_{new} will be counterproductive for such queries, as the associated solver PS′ will have to first consider r_{new} before going on to find the appropriate derivation. If only a trivial percentage of the queries deal with houseowning uncles, then the performance of PS′ will be *worse* than the original problem solver, as PS′ will take longer, on average, to reach an answer. This degradation is called the "utility problem" (Minton 1988; Tambe, Newell, and Rosenbloom 1990).

One way to address this problem is first to estimate the distribution of queries that will be posed, then evaluate the efficiency of a PS against that distribution (Greiner and Orponen 1996; Segre, Gordon, and Elkan 1996; Cohen 1990; Zweben et al. 1992). (Note that this estimation process may require the EBL module to examine more than a single example before modifying the solver.) The EBL module can then decide whether to include a new rule, and if so, where it should insert that rule. (Storing the rule in front of the rule set may not be optimal, especially after other EBL-generated rules have already been added.) Because the latter task is unfortunately intractable (Greiner 1991), many EBL systems involve hill-climbing to a local optimum (Greiner 1996; Gratch and DeJong 1996; see GREEDY LOCAL SEARCH).

There are, however, some implemented systems that have successfully addressed these challenges. As examples, the Samuelsson and Rayner EBL module improved the performance of a natural language parsing system by a factor of three (Samuelsson and Rayner 1991); Zweben et al. (1992) improved the performance of their constraint-based scheduling system by about 34 percent on realistic data, and Gratch and Chien (1996), by about 50 percent.

Explanation-based learning differs from typical MACHINE LEARNING tasks in several respects. First, standard learners try to acquire new domain-level information, which the solver can then use to solve problems that it could not solve previously; for example, many INDUCTION learners learn a previously unknown classification function, which can then be used to classify currently unclassified instances. By contrast, a typical EBL module does not extend the set of problems that the underlying solver could solve (Dietterich 1986); instead, its goal is to help the

solver to solve problems more efficiently. Stated another way, explanation-based learning does not extend the deductive closure of the information already known by the solver. Such knowledge-preserving transformations can be critical, as they can turn correct, but inefficient-to-use information (e.g., first-principles knowledge) into useful, efficient, special-purpose expertise.

Of course, the solver must know a great deal initially. There are other learning systems that similarly exploit a body of known information, including work in INDUCTIVE LOGIC PROGRAMMING (attempting to build an accurate deductive knowledge base from examples; Muggleton 1992) and theory revision (modifying a given initial knowledge base, to be more accurate over a set of examples; Ourston and Mooney 1994; Wogulis and Pazzani 1993; Greiner 1999; Craw and Sleeman 1990). However, these other learning systems differ from EBL (and resemble standard learning algorithms) by changing the deductive closure of the initial theory (see DEDUCTIVE REASONING).

Finally, most learners require a great number of training examples to be guaranteed to learn effectively; by contrast, many EBL modules attempt to learn from a single solved problem. As we saw above, this single "solved problem" is in general very structured, and moreover, most recent EBL modules use *many* samples to avoid the utility problem.

This article has focused on EBL modules that add new (entailed) base-level rules to a rule base. Other EBL modules instead try to speed up a performance task by adding new control information, for example, which help the solver to select the appropriate operator when performing a state space search (Minton 1988). In general, EBL modules first detect characteristics that make the search inefficient, and then modify the solver to avoid poor performance in future problems. Also, although our description assumes the background theory to be "perfect," there have been extensions to deal with theories that are incomplete, intractable, or inconsistent (Cohen 1992; Ourston and Mooney 1994; DeJong 1997).

The rules produced by an EBL module resemble the "macro-operators" built by the Abstrips planning system (Fikes, Hart, and Nilsson 1972), as well as the "chunks" built by the Soar system (Laird and Rosenbloom 1986). (Note that Rosenbloom showed that this "chunking" can model the practice effects in humans.)

Explanatory Gap

The MIND-BODY PROBLEM—the problem of understanding the relation between physical and mental phenomena—has both a metaphysical side and an epistemological side. On the metaphysical side, there are arguments that purport to show that mental states could not be (or be realized in) physical states, and therefore some version of dualism must be true. On the epistemological side, there are arguments to the effect that even if in fact mental states are (or are realized in) physical states, there is still a deep problem about how we can explain the distinctive features of mental states in terms of their physical properties. In other words, there seems to be an "explanatory gap" between the physical and the mental (see Levine 1983 and 1993).

The distinctive features that seem to give rise to the explanatory gap are the qualitative characters of conscious experiences (or QUALIA), such as the smell of a rose or the way the blue sky looks on a clear day. With conscious creatures it seems sensible to ask, with regard to their conscious mental states, WHAT-IT'S-LIKE to have them. The answers to these questions refer to properties that seem quite unlike the sorts of properties described by neurophysiologists or computational psychologists. It is very hard to see how the qualitative character of seeing blue can be explained by reference to neural firings, or even to the information flow that encodes the spectral reflectance properties of distal objects. It always seems reasonable to ask, but why should a surface with this specific spectral reflectance look like *that* (as one internally points at one's experience of blue)? For that matter, it seems reasonable to ask why there should be anything it is like at all to see blue, inasmuch as detecting and encoding information about the external world does not automatically entail having a genuine experience. After all, thermometers and desktop computers detect and encode information, but few people are tempted to ascribe experience to them.

Traditionally, dualists have employed conceivability arguments to demonstrate a metaphysical distinction between the mental and the physical. Whether or not these arguments work to establish the metaphysical thesis of dualism (for arguments pro and con see Chalmers 1996; Jackson 1993; Block and Stalnaker forthcoming), they can be employed to support the existence of the explanatory gap. We start with the assumption that adequate explanations reveal a necessary relation between the factors cited in the explanation (the *explanans*) and the phenomenon to be explained (the *explanandum*). For example, suppose we want to know why water boils at 212° F. at sea level. Given the molecular analysis of water, boiling, and temperature, together with the relevant physical and chemical laws, it becomes apparent that under these conditions water just has to boil. The point is, we can see why we should not expect anything else.

Contrast this example with what it is like to see blue. After an exhaustive specification of both the neurological and the computational details, we really do not know why blue should look the way it does, as opposed, say, to the way red or yellow looks. That is, we can still conceive of a situation in which the very same neurological and computational facts obtain, but we have an experience that is like what seeing red or yellow is like. Because we can imagine a device that processed the same information as our visual systems but was not conscious at all, it is also clear that we do not really know why our systems give rise to conscious experience of any sort, much less of this specific sort. Again, the contrast with the boiling point of water is instructive. Once we fill in the appropriate microphysical details, it does not seem conceivable that water should not boil at 212° F. at sea level.

One final example is quite helpful to make the point. Frank Jackson (1982) imagines a neuroscientist, Mary, who knows all there is to know about the physical mechanisms underlying color vision. However, she has been confined all her life to a black and white environment. One day she is allowed to emerge into the world of color and sees a ripe tomato for the first time. Does she learn anything new? Jackson claims that obviously she does; she learns what red looks like. But if all the information she had before really explained what red looked like, it seems as if she should have been able to predict what it would look like. Thus her revelation on emerging from the colorless world supports the existence of the explanatory gap.

There are various responses to the explanatory gap. One view (see McGinn 1991) is that it reflects a limitation on our cognitive capacities. We just do not have, and are constitutionally incapable of forming, the requisite concepts to bridge the gap. Others argue that the gap is real but that it is to be expected given certain peculiarities associated with our first-person access to experience (see Lycan 1996; Rey 1996; Tye 1995). Just as one cannot derive statements involving indexicals from those that do not—e.g., "I am here now" from "Joe Levine is at home on Saturday, June 27, 1997"—so one cannot derive statements containing terms like "the way blue looks" from those that contain only neurological or computational terms. Still others (see Churchland 1985) argue that advocates of the explanatory gap just do not appreciate how much one could explain given a sufficient amount of neurological detail. Finally, some see in the explanatory gap evidence that the very notion of qualitative character at issue is confused and probably inapplicable to any real phenomenon (see Dennett 1991 and Rey 1996). On this view qualia literally do not exist. Although we have experiences, they do not actually possess the features we naively take to be definitive of them.

There are complex and subtle issues involved with each of these responses. For instance, the precise role of identity statements in explanations, and the degree to which identities themselves are susceptible of explanation, must be explored more fully. (For a lengthy discussion of the conceivability argument that deals with these issues, see Levine forthcoming.) Suffice it to say that no consensus yet exists on the best way to respond to the explanatory gap.

Explicit Memory

Extensionality, Thesis of

The thesis of extensionality says that every meaningful declarative sentence is *equivalent* to some *extensional sentence.* Understanding this thesis requires understanding the terms in italics.

Two sentences are *equivalent* if and only if they have the same truth-value in all possible circumstances. The following are equivalent because no matter how far Jody actually ran, the sentences are either both true or both false:

Jody just jogged 3.1 miles.
Jody just jogged 5 kilometers.

When the replacement of a component of a sentence with another component always results in a sentence that has the same truth-value as the original (true if the original is true and false if the original if false) this is a *replacement that preserves truth-value.*

Terms of different kinds have extensions of different kinds. The extension of a name or description is the individual or individuals to which the name or description applies. The extension of a one-place predicate such as "is a synapse" applies to the class of all the individuals, in this case, all the synapses, to which the predicate applies. The extension of an *n*-place predicate is a set of ordered *n*-tuples to which the predicate applies. The extension of a declarative sentence, which one can regard as a zero-place predicate, is its truth value.

Two terms are *coextensive* only when they have the same extension, two sentences that have the same truth value, two names that refer to exactly the same thing (or things), and so on.

A sentence is *extensional* only when each and every replacement of a component of a sentence with a coextensive term preserves truth value.

If "Stan's car" and "the oldest Volvo in North Carolina" are coextensive, then replacing the first with the second in (a) "Stan's car is in the driveway" preserves truth-value. So far as this replacement shows, then, (a) is extensional. A similar replacement in (b) "Hillis thinks that Stan's car is a new Jaguar" does not preserve truth value. Hillis does not think that the oldest Volvo in North Carolina is a new Jaguar. Statements about PROPOSITIONAL ATTITUDES such as thinking, believing, fearing, and hoping are typically not extensional.

If "The Mercury Track Team" and "The Vanguard Video Club" are coextensive because each expression names a group with exactly the same members, then replacing the first with the second in (c) "Nobody in the Mercury Track Team smokes cigars" preserves truth-value. A similar replacement in (d) "The Captain of the Mercury Track Team is Lou Silver" will not preserve truth-value if (d) is true and the Vanguard Video Club does not have a captain. Examples of this sort show at least that clubs are not sets.

"Vicki will discover the greatest prime number" and "Vicki will win the New Jersey Lottery" are coextensive because they are both false. Replacing the first with the second in (e) "It isn't so that Vicki will discover the greatest prime number" preserves truth-value. A similar replacement in (f), "It is absolutely impossible that Vicki will discover the greatest prime number," does not preserve truth value. However unlikely, it is still possible that Vicki will hit the jackpot. The existence of a largest prime number, in contrast, is not merely unlikely; it is impossible. Modal statements about what is possible or necessary, treated by MODAL LOGIC, are often not extensional. The connectives of standard propositional LOGIC such as *not, and, or, if,* and *if and only if* are *truth-functional.* Replacement in a truth-functional sentence

of any component with another with the same truth-value preserves the truth-value of the original.

The thesis of extensionality, a version of REDUCTIONISM, says that every meaningful, declarative sentence is equivalent to some extensional sentence. This does not require that every sentence be extensional but rather that every nonextensional sentence about psychological attitudes, modality, laws, counterfactual conditionals, and so forth, have an extensional equivalent.

An historically important statement of the thesis of extensionality appears in Wittgenstein (1922): "A proposition is a truth-function of elementary propositions (Proposition 5)."

Wittgenstein's later philosophy abandons both elementary propositions and the thesis of extensionality. Russell expresses sympathy for the thesis in several places including "Truth-Functions and Others," Appendix C of Whitehead and Russell (1927).

Rudolf Carnap formulates the thesis of extensionality (hereafter abbreviated TOE) as a relation between extensional and nonextensional languages (see especially Carnap 1937, sect. 67). The truth of TOE promises a greater intelligibility of the world. Extensional languages have "radically simpler structures and hence simpler constitutive rules" than nonextensional languages (Carnap 1958: 42). If "the universal language of science" (Carnap 1937: 245) is extensional, therefore, we can discuss exhaustively every scientific phenomenon in a language that has a radically simple structure.

Carnap defends TOE by finding an extensional sentence about language that he thinks is equivalent to a given nonextensional sentence. The modal, nonextensional sentence "Necessary, if you steal this book, then you steal this book" is equivalent to the extensional sentence "'If you steal this book, then you steal this book' is true in a certain formal metalanguage L" (cf. Carnap 1958: 42). The psychological, nonextensional sentence "John believes that raccoons have knocked over the garbage cans" is equivalent, perhaps, to the extensional sentence "John is disposed to an affirmative response to some sentence in some language which expresses the proposition that raccoons have knocked over the garbage cans" (cf. Carnap 1947: 55).

Although he devotes much time and effort to defend TOE, Carnap does not claim to establish it. He regards it as a likely conjecture. The project, however, now appears to be more difficult than Carnap predicted. A successful translation of a nonextensional sentence must satisfy two requirements: (1) the new sentence must really be equivalent to the original, and (2) the new sentence must really be extensional. In the example above, if someone can have such a belief about raccoons without being disposed to respond to any sentences, (1) is violated. If one cannot understand affirmative response except as a nonextensional notion, then (2) is violated.

In terms of INTENTIONALITY, Chisholm (1955–56) formulates a thesis resembling that of Brentano (1874) about the distinctiveness of the psychological: (A) TOE is true for all nonpsychological sentences, and (B) TOE is false for all psychological sentences. In the 1950s, Chisholm defended (B) by attacking translations of sentences about believing

that Carnap and others proposed. (See Hahn 1998 for a Chisholm bibliography.)

Clause (A), however, cannot be taken for granted. The project of finding extensional equivalents of nonextensional modal sentences also faces difficulties. Quine (1953), like Carnap, attempts syntactic translations that are about language. (See chapter 10, section 3, "The Problems of Intensionality," in Kneale and Kneale 1962.) Montague (1963) derives significant negative results that are beyond the scope of this article.

Eye Movements and Visual Attention

Visual scenes typically contain more objects than can ever be recognized or remembered in a single glance. Some kind of sequential selection of objects for detailed processing is essential if we are to cope with this wealth of information. Built into the earliest levels of vision is a powerful means of accomplishing the selection, namely, the heterogeneous RETINA. Fine grain visual resolution is possible only within

Figure 1. Sequence of saccadic eye movements during reading. The graph on top shows horizontal (top trace) and vertical (bottom trace) eye movements over time. The abrupt changes in eye position are the saccades. The figure shows the sequences of rightward saccades (upward deflections in the trace) made to read a line of text, followed by large leftward resetting saccades made to the beginning of each successive line of text. The locations of the saccadic endpoints are shown in numbered sequence, superimposed on the text, at the bottom of the figure. The figure was made by J. Epelboim from recordings made with R. Steinman's Revolving Magnetic Field Sensor Coil monitor at the University of Maryland (see Epelboim et al. 1995, for a description of the instrument).

the central retinal region known as the fovea, whose diameter is approximately 2 degrees of visual angle (about the size of eight letters on a typical page of text). Eye movements are important because they bring selected images to the fovea, and also keep them there for as long as needed to recognize the object.

Eye movements fall into two broad classes. *Saccadic eye movements* (saccades) are rapid jumps of the eye used to shift gaze to any chosen object. In READING, for example, saccades typically occur about three times each second and are generally made to look from one word to the next (see figure 1). *Smooth eye movements* keep the line of sight on the selected object during the intervals between saccades, compensating for motion on the retina that might be caused either by motion of the object or by motion of the head or body. Intervals between saccades can be as long as several seconds during steady fixation of stationary or moving objects. Saccades can be made in any chosen direction, even in total darkness, whereas directed smooth eye movements cannot be initiated or maintained without some kind of motion signal.

There are two natural links between eye movements and visual attention. One is the role played by ATTENTION in OCULOMOTOR CONTROL. The other is the way in which eye

movements provide overt indicators of the locus of attention during performance of complex cognitive tasks, such as reading or visual search.

Consider first the role of attention in programming smooth eye movements. When we walk forward in an otherwise stationary scene, trying to keep our gaze fixed on our goal ahead, the flow of image motion generated on the retina by our own forward motion creates a large array of motion signals that could potentially drag the line of sight away from its intended goal (a problem described originally by Ernst Mach in 1906). Laboratory simulations of this common situation show that smooth eye movements can maintain a stable line of sight on a small, attended, stationary target superimposed on a large, vivid moving background. Similarly, smooth eye movements can accurately track a target moving across a stationary background. With more complex stimuli (letters, for example), perceptual identification of tracked targets is better than identification of untracked backgrounds (a result that holds after any differences in identification due to different retinal velocities of target and background are taken into account). The greater perceptibility of the target compared to the background implies that the same attentional mechanism serves both perception and eye movements (Khurana and Kowler 1987).

Attention contributes to the control of saccades in an analogous way, namely, attention is allocated to the chosen target shortly before the saccade is made to look at it (Hoffman and Subramaniam 1995; Kowler et al. 1995). Some attention can be transferred to nontargets, with no harmful effect on the latency or accuracy of the eye movements, showing that the attentional demands of eye movements are modest (Kowler et al. 1995; Khurana and Kowler 1987).

On the whole, the arrangement is very efficient. By allowing oculomotor and perceptual systems to share a common attentional filter, the eye will be directed to the object we are most interested in without the need for a separate selective attentional decision. At the same time, the modest attentional requirements of effective oculomotor control mean that it is very likely that we can look wherever we choose with little danger of the eye's being drawn to background objects, regardless of how large, bright, or vivid they may be. Modest attentional requirements also imply that there will be ample cognitive resources left over for identification and recognition; all our efforts need not be devoted to targeting eye movements.

The close link between attention and eye movements is supported by neurophysiology. Cortical centers containing neurons that are active before eye movements also contain neurons (sometimes the same ones) that are active before shifts of attention while the eye is stationary (Colby and Duhamel 1996; Andersen and Gnadt 1989). Some have gone so far as to consider whether shifting attention to an eccentric location while the eye remains stationary is equivalent to planning a saccadic eye movement (Kustov and Robinson 1997; Rizzolatti et al. 1987; Klein 1980).

Attention is involved in the programming of eye movements, and at the same time observations of eye movements provide a record of where someone chooses to attend during performance of complex cognitive tasks. Yarbus's (1967) well-known recordings of eye movements made while inspecting various paintings show systematic preferences to repeatedly look at those elements that would seem to be most relevant to evaluating the content of the picture. Despite the detailed record of preferences that eye movements provide, it has nevertheless proven to be surprisingly difficult to develop valid models of underlying cognitive processing based on eye movements alone (Viviani 1990). More recent work has taken a different tack by using highly constrained and novel tasks. Sequences of fixations have been used to study the modularity of syntactic processing during reading (Tanenhaus et al. 1995), the role of WORKING MEMORY during visual problem-solving tasks (Ballard, Hayhoe, and Pelz 1995; Epelboim and Suppes 1996), the coordination of eye and arm movements (Epelboim et al. 1995), and the size of the effective processing region during reading or search (McConkie and Rayner 1975; Motter and Belky 1998; O'Regan 1990).

This article has emphasized the importance of eye movements for selecting a subset of the available information for detailed processing. The price paid for having this valuable tool is that the visual system must cope with the continual shifts of the retinal image that eye movements will produce. Remarkably, despite the retinal perturbations, the visual scene appears stable and unimpaired. Evidence from studies in which subjects look at or point to targets presented briefly during saccades suggests that stored representations of oculomotor commands ("efferent copies") are used to take the effect of eye movements into account and create a representation of target location with respect to the head or body (Hansen and Skavenski 1977). Other evidence suggests that shifts of the retinal image are effectively ignored. According to these views, visual analysis begins anew each time the line of sight arrives at a target, with attended visual information converted rapidly to a high-level semantic code that can be remembered across sequences of saccades (e.g., O'Regan 1992).

The advantages to visual and cognitive systems of having a fovea are evidently so profound that it has been worth the cost of developing both the capacity for accurate control of eye movements and a tolerance for the retinal perturbations that eye movements produce. Visual attention is crucial for accomplishing both.

Face Recognition

Analysis and retention of facial images is a crucial skill for primates. The survival value of this skill is reflected in our extraordinary MEMORY for faces, in the visual preferences for face stimuli shown by infants, and in our remarkable sensitivity to subtle differences among faces. Striking parallels have emerged between the results of perceptual, developmental, neuropsychological, neurophysiological, and functional neuroimaging studies of face recognition. These indicate that face recognition in primates is a specialized capacity consisting of a discrete set of component processes with neural substrates in ventral portions of occipito-temporal and frontal cortices and in the medial temporal lobes.

Appreciation of the specialness of the face for social organisms can be traced back at least to Darwin's *The Expression of Emotion in Man and Animals* (1872). Moreover, face agnosia—a selective deficit in recognizing faces—has been inferred from the clinical literature since the turn of the century. Intensive research on face perception of normal individuals has a more recent history, linked to a growing interest in INFANT COGNITION and perception. One early milestone was Yin's (1969) demonstration of the *inversion effect,* the tendency for recognition of faces to be differentially impaired (relative to that of other "mono-oriented" stimuli such as houses) by turning the stimulus upside down. This finding has been widely interpreted to mean that face recognition depends on specialized mechanisms for configural processing (i.e., analysis of small differences in details and spatial relations of features within a prototypical organization). Face "specialness" is also supported by data showing that infants preferentially look at or track facelike arrangements of features relative to jumbles of features or control stimuli. Nonetheless, the protracted development of adult levels of performance indicates that face recognition additionally involves either a long period of NEURAL DEVELOPMENT and/or cognitive processing capacity, specific experience with faces, or both. Exactly what improves with maturation or experience remains unclear (Chung and Thomson 1995).

The fascinating syndrome of face agnosia (prosopagnosia) has spurred considerable controversy regarding the "specialness" of faces. The degree of DOMAIN SPECIFICITY present in prosopagnosia is relevant to whether face recognition is best viewed as a unique capacity, or merely as an example of general mechanisms of OBJECT RECOGNITION (Farah 1996). Although prosopagnosics are aware that faces are faces—that is, they know the basic level category—they fail to identify reliably or achieve a sense of familiarity from faces of family members, famous persons, and other individuals they previously knew well. Typically, they also have trouble forming memories of new faces, even if other new objects are learned. However, prosopagnosics may identify individuals by salient details such as clothing and hairstyle, or by nonvisual features such as voice.

Varying patterns of deficits in processing faces occur in brain-damaged individuals, and these differing patterns provide evidence for dissociable component operations in face recognition. Some patients show sparing of ability to judge the age, gender, and even emotional expression of faces whose identity they cannot grasp. Others have difficulty with all aspects of face processing; such patients are unable even to analyze facial features normally, a necessary precondition to identification. Finally, some brain-damaged patients can perceive structural attributes of faces adequately for judgments about emotion and gender, and even judge if a face is familiar, but show a specific inability to recall the associated name.

In both humans and monkeys, faces are analyzed in subregions of the visual-cortical object recognition pathway. In particular, the temporal neocortex in nonhuman primates (notably inferior temporal cortex or "area TE") contains neurons that fire selectively to face stimuli (Gross and Sergent 1992). The question arises as to whether such cells truly

respond to visual information unique to faces, or whether their selectivity is more parsimoniously explained as responsiveness to features shared by faces and other object classes; the bulk of the evidence supports the former description. For example, although face-selective neurons vary in the degree of their preference for face stimuli, many respond to both real faces and pictures of faces, but give nearly no response to any other stimuli tested, including other complex objects and pictures in which features making up the face are rearranged or "scrambled." Moreover, for many such neurons, specificity of response is maintained over transformations in size, stimulus position, angle of lighting of the face, blurring, and so forth. Thus, at least some face-selective neurons are sensitive to the global aspects of a face, such as prototypical configuration of stimulus features. Finally, face-selective neurons are present very early in life (Rodman, Gross, and Ó Scalaidhe 1993), consistent with the idea that they represent inborn "prototypes" for faces.

Subsets of face-selective neurons appear to participate in specific aspects of face coding. For example, some respond selectively to distinctive features, such as eyes per se, distance between the eyes, or extent of the forehead. Others do not respond to isolated features but instead are selective for orientation of a face (e.g., profile or frontal view). Still others have responses specific for particular expressions; a final subset are particularly sensitive to eye gaze direction (looking back or looking to the side), an important social signal in both monkeys and humans. Cells selectively responsive to faces have a localized distribution in several senses. First, although face cells make up only a tiny fraction of neurons (1–5%) within TE and adjacent areas as a whole, their concentration is much higher in irregular localized clumps. Second, different types of face-selective cells are found in different regions, such that cells sensitive to facial expression and gaze direction tend to be found within the superior temporal sulcus, whereas cells more generally selective for faces and, purportedly, for individuals tend to be located in TE on the inferior temporal gyrus.

Electrophysiological correlates of face recognition have also been obtained from humans (Allison et al. 1994). A large evoked potential (called the N200) is generated by faces (but not other stimulus types) at small sites in the ventral occipitotemporal cortex. These sites or "modules" may be comparable to the clumps of face neurons found in monkeys. Longer-latency face-specific potentials were also recorded from the anterior portions of ventral temporal cortex activated by face recognition in POSITRON EMISSION TOMOGRAPHY (PET) studies. Moreover, N200s to inverted faces recorded from the right hemisphere were smaller and longer than for normally oriented faces; the left hemisphere generated comparable N200s under both conditions. These studies thus provide correlates of both the "inversion effect" and of HEMISPHERIC SPECIALIZATION for some aspects of face processing noted in the clinical literature and in tachistoscopic studies of face recognition in normal humans.

Brain imaging studies in normal humans provide converging evidence for the involvement of the ventral occipito-temporal cortices in face recognition and for the existence of dissociable component operations. Sergent et al. (1992), for example, used PET to compare brain activation while sub-jects either made discriminations of the gender of faces (perceptual task) or judged their identity. In the perceptual task, selective activation was found in the right ventral occipitotemporal cortex, to a lesser extent in the same area on the left, and in a more lateral left focus as well. These areas overlap, but are generally anterior to, domains activated by other categories of objects. Judgments of face identity, requiring reactivation of stored information about individuals, also activated the right parahippocampal gyrus, anterior temporal cortex, and temporal pole on both sides. These studies and those of Haxby and colleagues have additionally implicated lateralized portions of frontal cortex in face encoding, perceptual judgments of faces, and subsequent recognition of faces. In particular, a right frontal focus appears to be involved in recognizing facial emotion. Finally, the HIPPOCAMPUS appears to participate, along with parahippocampal cortices, primarily at the time of encoding new faces.

Neuropathological data are generally consistent with results of imaging and evoked potential studies regarding anatomical substrates for face recognition. Initially, prosopagnosia was associated clinically with right posterior cortical damage. In the 1980s, a number of cases came to autopsy. The damage in these lay very ventrally and medially at the occipitotemporal junction, in roughly the same region activated in recent PET studies. However, in all such cases this area (or underlying white matter) was damaged bilaterally, and consequently bilateral damage became thought of as a necessary precondition to prosopagnosia. Recently, cases with proposagnosia and right cortical damage alone, along with the results of imaging and evoked potential studies reviewed above, have reaffirmed the critical role of the right hemisphere in face recognition in humans.

Many explanations have been given for the apparent "specialness" of faces. Face perception and recognition may indeed be unique behavioral capacities and reflect dedicated neural circuits that can be selectively damaged. Such uniqueness of faces might result both from their behavioral significance and from the fact that they differ structurally from most other object classes, necessitating different perceptual strategies (such as encoding on the basis of prototypical configuration), strategies selectively lost in prosopagnosia. An alternative explanation is that faces are processed and stored in a manner similar to that for other objects, but faces are simply harder to tell apart than other kinds of objects; this view is consistent with observations that prosopagnosia is often accompanied by some degree of general object agnosia. A related account holds that face processing requires subtle discriminations between *highly similar exemplars within a category,* and that it is this capacity, not processing of the facial configuration, that is disrupted in prosopagnosia. Interestingly, recent studies show that face processing is still disproportionately impaired when discriminations of face and nonface stimuli are equated for difficulty, so this view has lost some force. A final suggestion is that face processing represents acquisition of EXPERTISE associated with very protracted experience with a category of complex visual stimuli (Carey 1992). Prosopagnosics with deficits in other object recognition domains in which they had previously acquired expertise over long periods (e.g., a show dog expert who lost the ability to differentiate breeds) support this idea.

Growing acceptance of faces as a distinct stimulus type has led, along with growing evidence for component processes, to emergence of theoretical accounts of face recognition tied to central ideas in COMPUTATIONAL NEURO-SCIENCE. For example, drawing on the notion of a computational model advanced by David MARR, Bruce and Young (1986) analyzed face processing as a set of seven types of information code (or representation). In their scheme, which fits well with neuropsychological dissociations, everyday face recognition involves the use of "structural" codes to access identity-specific semantic information, and then finally the attachment of a name to the percept. Other recent theoretical accounts have modeled face recognition using artificial neural network architectures derived from parallel-distributed processing accounts of complex systems. Future advances in understanding face recognition will likely require further incorporation of data on self-organizing (developmental and environmental) and modulatory (emotional and motivational) aspects of face processing into existing models.

Feature Detectors

The existence of feature detectors is based on evidence obtained by recording from single neurons in the visual pathways (Barlow 1953; Lettvin et al. 1959; Hubel and Wiesel 1962; Waterman and Wiersma 1963; see also SINGLE-NEURON RECORDING). It was found that responses from many types of NEURON do not correlate well with the straightforward physical parameters of the stimulus, but instead require some specific *pattern* of excitation, often a spatio-temporal pattern that involves movement. The rabbit retina provides some well-documented examples, though they were not the first to be described. *Direction-*

ally selective ganglion cells respond to movements of the image in one direction, but respond poorly to the reverse motion, however bright or contrasty the stimulus; there are two classes of these ganglion cells, distinguished by the fast or slow speed of movement that each prefers, and within each class there are groups responding to different directions of motion (Barlow, Hill, and Levick 1964). Another class, found mainly in the central zone of the RETINA, are *local edge detectors* that respond only to an edge moving very slowly over precisely the right position in the visual field (Levick 1967). These units are often highly specific in their stimulus requirements, and it can be a difficult task to find out what causes such a unit to fire reliably; yet once the appropriate *trigger feature* has been properly defined it will work every time. Another class, the *fast movement detectors,* respond only to very rapid image movements, and yet another, the *uniformity detectors,* fire continuously at a high rate *except* when patterned stimulation is delivered to the part of the retina they are connected to.

All classes have a restricted retinal region where the appropriate feature has to be positioned, and this is described as the unit's *receptive field,* even though the operations being performed on the input are very different from simple linear summation of excitatory and inhibitory influences, which the term *receptive field* is sometimes thought to imply. Units often show considerable *invariance of response* for changes of the luminance, contrast, and even polarity of the light stimulus, while maintaining selectivity for their particular patterned spatio-temporal feature. There is also evidence for feature detectors in auditory (Evans 1974; Suga 1994; see also DISTINCTIVE FEATURES) and tactile pathways.

Feature detection in the retina makes it clear that complicated logical operations can be achieved in simple neural circuits, and that these processes need to be described in computational, rather than linear, terms. For a time there was some rivalry between *feature creatures,* who espoused this logical, computational view of the operation of visual neurons, and *frequency freaks,* who were devoted to the use of sine wave spatial stimuli and Fourier interpretations. The latter had genuine successes that yielded valid new insights (Braddick, Campbell, and Atkinson 1978), but their approach works best for systems that operate nearly linearly. Object recognition is certainly not a linear process, and the importance of feature detectors lies in the insight they give into how the brain achieves this very difficult task. But first, glance back at the history of feature detection before single-neuron feature-detectors were discovered.

Sherrington found that to elicit the *scratch reflex*—the rhythmical scratching movements made by a dog's hind leg—a tactile stimulus had to be applied to a particular region of the flank, and it was most effective if it was applied to several neighboring cutaneous regions in succession. This must require a tactile feature detector not unlike some of those discovered in visual pathways.

Some years later the ethologists Lorenz (1961) and Tinbergen (1953) popularized the notion of *innate releasers:* these are special sensory stimuli that trigger specific behavioral responses when delivered under the appropriate cir-

cumstances. One example is the red dot on a herring gull's beak, which has been shown to cause the chick to open its bill to receive regurgitated food from its mother. Another example is the stimulus for eliciting the rather stereotyped feeding behavior shown by many vertebrates: a small moving object first alerts the animal, then causes it to orient itself toward the stimulus, next to approach it, and finally to snap at it. It was early suggested that the retinal ganglion cells in the frog that respond to small moving objects might act as such *bug detectors* (Barlow 1953; Lettvin et al. 1959).

Such feature detectors must be related to the specific requirements of particular species in particular ecological niches, but feature detection may have a more general role in perception and classification. A clue to their significance in object recognition may be found in the early attempts by computer scientists to recognize alphanumeric characters (Grimsdale et al. 1959; Selfridge and Neisser 1960; Kamentsky and Liu 1963). It was found that fixed templates, one for each letter, perform very badly because the representation of the same character varies in different fonts. Performance could be much improved by detecting the features (bars, loops, intersections etc.) that make up the characters, for latitude could then be allowed in the positioning of these relative to each other. This is the germ of an idea that seems to provide a good qualitative explanation for the feature detectors found at successive levels in the visual system: operations that restrict response or increase selectivity for one aspect of the stimulus are combined with operations that generalize or relax selectivity for another aspect. In the preceding example the components of letters vary less from font to font than the overall pattern of the letters, so the initial feature detectors can be rather selective. But having found that certain features are present, the system can be less demanding about how they are positioned relative to each other, and this achieves some degree of font-invariant character recognition.

In the primate visual system some retinal ganglion cells are excited by a single foveal cone, so they are very selective for position. Several of these connect, through the lateral geniculate nucleus, to a single neuron in primary visual cortex, but the groups that so connect are arranged along lines: the cortical neuron thus maintains selectivity for position orthogonal to the line, but relaxes selectivity and summates along the line (Hubel and Wiesel 1962). This makes each unit selectively responsive to lines of a particular orientation, and they may be combined together at later stages to generalize in various ways.

The best-described examples of units that generalize for position are provided by the cortical neurons of area MT or V5 that specialize in the analysis of image motion: these collect together information from neurons in cortical area V1 that come from a patch several degrees in diameter in the visual field (Newsome et al. 1990; Raiguel et al. 1995), but all the neurons converging on one MT neuron signal movements of similar direction and velocity. Thus all the information about motion with a particular direction and velocity occurring in a patch of the visual field is pooled onto a single MT neuron, and such neurons have been shown to be as sensitive to weak motion cues as the intact, behaving animal (Newsome, Britten, and Movshon 1989).

Possibly the whole sensory cortex should be viewed as an immense bank of tuned filters, each collecting the information that enables it to detect with high sensitivity the occurrence of a patterned feature having characteristics lying within a specific range (Barlow and Tripathy 1997). The existence of this enormous array of near-optimal detectors, all matched to stimuli of different characteristics, would explain why the mammalian visual system can perform detection and discrimination tasks with a sensitivity and speed that computer vision finds hard to emulate.

Another aspect of the problem is currently arousing interest: Why do we have detectors for some features, but not others? What property of a spatio-temporal pattern makes it desirable as a feature? A suggestion (Barlow 1972; Field 1994) currently receiving some support (Bell and Sejnowski 1995; Ohlshausen and Field 1996) is that the feature detectors we possess are able to create a rather complete representation of the current sensory scene using the principle of *sparse coding*; this means that at any one time only a small selection of all the units is active, yet this small number firing in combination suffices to represent the scene effectively. The types of feature that will achieve this double criterion, sparsity with completeness, can be described as *suspicious coincidences*: they are local patterns in the image that would be expected, from the probabilities of their constituent elements, to occur rarely, but in fact occur more commonly.

Sparse coding goes some way toward preventing accidental conjunctions of attributes, which is the basis for the so-called BINDING PROBLEM. Although sparsely coded features are not mutually exclusive, they nonetheless occur infrequently: hence accidental conjunctions of them will only occur very infrequently, possibly no more often than they do in fact occur.

Like the basis functions that are used for *image compression,* those suitable for sparse coding achieve their result through being adapted to the statistical properties of natural images. This adaptation must be done primarily through evolutionary selection molding their pattern selective mechanisms, though it is known that they are also modified by experience during the *critical period* of development of the visual system (Hubel and Wiesel 1970; Movshon and Van Sluyters 1981), and perhaps also through short term processes of contingent adaptation (Barlow 1990). Feature detectors that exploit statistical properties of natural images in this way could provide a representation that is optimally up-to-date, minimizes the effects of delays in afferent and efferent pathways, and perhaps also achieves some degree of prediction (see also CEREBRAL CORTEX).

Although we are far from being able to give a complete account of the physiological mechanisms that underlie even the simplest examples of object recognition, the existence of feature detecting neurons, and these theories about their functional role, provide grounds for optimism.

Figurative Language

Figurative language allows speakers/writers to communicate meanings that differ in various ways from what they literally say. People speak figuratively for reasons of politeness, to avoid responsibility for the import of what is communicated, to express ideas that are difficult to communicate using literal language, and to express thoughts in a compact and vivid manner. Among the most common forms of figurative language, often referred to as "tropes" or "figures of speech," are *metaphor,* where ideas from dissimilar knowledge domains are either explicitly, in the case of *simile* (e.g., "My love is like a red, red rose"), or implicitly (e.g., "Our marriage is a roller-coaster ride") compared; *metonymy,* where a salient part of a single knowledge domain is used to represent or stand for the entire domain (e.g., "The White House issued a statement"); *idioms,* where a speaker's meaning cannot be derived from an analysis of the words' typical meanings (e.g., "John let the cat out of the bag about Mary's divorce"); *proverbs,* where speakers express widely held moral beliefs or social norms (e.g.,"The early bird captures the worm"); *irony,* where a speaker's meaning is usually, but not always, the opposite of what is said (e.g., "What lovely weather we're having" stated in the midst of a rainstorm); *hyperbole,* where a speaker exaggerates the reality of some situation (e.g., "I have ten thousand papers to grade by the morning"); *understatement,* where a speaker says less than is actually the case (e.g., "John seems a bit tipsy" when John is clearly very drunk); *oxymora,* where two contradictory ideas/concepts are fused together (e.g., "When parting is such sweet sorrow"); and *indirect requests,* where speakers make requests of others in indirect ways by asking questions (e.g., "Can you pass the salt?"), or stating a simple fact (e.g., "It seems cold in here" meaning "Go close the window").

One traditional assumption, still held in some areas of cognitive science, is that figurative language is deviant and requires special cognitive processes to be understood. Whereas literal language can be understood via normal cognitive mechanisms, listeners must recognize the deviant nature of a figurative utterance before determining its nonliteral meaning (Grice 1989; Searle 1979). For instance, understanding a metaphorical comment, such as "Criticism is a branding iron," requires that listeners must first analyze what is stated literally, then recognize that the literal meaning (i.e., that criticism is literally a tool to mark livestock) is contextually inappropriate, and then infer some meaning consistent with the context and the idea that the speaker must be acting cooperatively and rationally (i.e., criticism can psychologically hurt the person who receives it, often with long-lasting consequences). This traditional view suggests, then, that figurative language should always be more difficult to process than roughly equivalent literal speech.

But the results of many psycholinguistic experiments have shown this idea to be false (see Gibbs 1994 for a review). Listeners/readers can often understand the figurative interpretations of metaphors, irony/sarcasm, idioms, proverbs, and indirect speech acts without having to first analyze and reject their literal meanings when these expressions are seen in realistic social contexts. People can read figurative utterances as quickly as, sometimes even more quickly than, they read literal uses of the same expressions in different contexts, or equivalent nonfigurative expressions. These experimental findings demonstrate that the traditional view of figurative language as deviant and ornamental, requiring additional cognitive effort to be understood, has little psychological validity. Although people may not always process the complete literal meanings of different figurative expressions before inferring their nonliteral interpretations, people may analyze aspects of word meaning as part of their understanding of what different phrases and expressions figuratively mean as wholes (Blasko and Connine 1993; Cacciari and Tabossi 1988). At the same time, listeners/readers certainly may slowly ponder the potential meanings of a figurative expression, such as the literary metaphor from Shakespeare, "The world is an unweeded garden." It is this conscious experience that provides much of the basis for the mistaken assumption that figurative language always requires "extra work" to be properly understood.

A great deal of empirical research from all areas of cognitive science has accumulated on how people learn, produce, and understand different kinds of figurative language (see ANALOGY and METAPHOR). Several notable findings have emerged from this work. To give just a few examples, many idioms are analyzable with their individual parts contributing something to what these phrases figuratively mean, contrary to the traditional view (Gibbs 1994). People also learn and make sense of many conventional and idiomatic phrases, not as "frozen" lexical items, but because they tacitly recognize the metaphorical mapping of information between two conceptual domains (e.g., "John spilled the

beans" maps our knowledge of someone tipping over a container of beans to a person revealing some previously hidden secret; Gibbs 1994). Ironic and sarcastic expressions are understood when listeners recognize the pretense underlying a speaker's remark. For instance, a speaker who says "What lovely weather we're having" in the midst of a rainstorm pretends to be an unseeing person, perhaps a weather forecaster, exclaiming about the beautiful weather to an unknown audience (Clark and Gerrig 1984). In many cases, ironic utterances accomplish their communicative intent by reminding listeners of some antecedent event or statement (Sperber and Wilson 1986), or by reminding listeners of a belief or social norm jointly held by a speaker and listener (Kreuz and Glucksberg 1989).

Some cognitive scientists now argue that metaphor, metonymy, irony, and other tropes are not linguistic distortions of literal, mental thought, but constitute basic schemes by which people conceptualize their experience and the external world (Gibbs 1994; Johnson 1987; Lakoff and Johnson 1980; Lakoff 1987; Lakoff and Turner 1989; Sweetser 1990; Turner 1991). Speakers cannot help but employ figurative language in conversation and writing because they conceptualize much of their experience through the figurative schemes of metaphor, metonymy, irony, and so on. Listeners often find figurative discourse easy to understand precisely because much of their thinking is constrained by figurative processes. For instance, people often talk about the concept of time in terms of the widely shared conceptual metaphor *time is money* (e.g., "I saved some time," I wasted my time," "I invested time in the relationship," "We can't spare you any time"). These conventional expressions are not "dead metaphors," but reflect metaphorical conceptualizations of experience that are very much alive and part of ordinary cognition, one reason why these same metaphors are frequently seen in novel expressions and poetic language (Lakoff and Turner 1989). There is much debate over whether people's understanding of various conventional expressions, idioms, proverbs, and metaphors necessarily requires activation of underlying conceptual metaphors that may motivate the existence of these statements in the language (Gibbs 1994; Gibbs et al. 1997; Glucksberg, Brown, and McGlone 1993; McGlone 1996). Nevertheless, there is a growing appreciation from scholars in many fields that metaphors and other tropes not only serve as the foundation for much everyday thinking and reasoning, but also contribute to scholarly theory and practice in a variety of disciplines, as well as providing much of the foundation for our understanding of culture (see Fernandez 1991; Gibbs 1994).

Focus

The term *focus* is used to refer to the highlighting of parts of utterances for communicative purposes, typically by accent. For example, a question like *Who did Mary invite for dinner* is answered by *Mary invited BILL for dinner,* not by *Mary invited Bill for DINner* (capitals mark the syllable with main accent, cf. STRESS, LINGUISTIC and PROSODY AND INTONATION). A contrastive statement like *Mary didn't invite BILL*

for dinner, but JOHN is also fine, whereas *Mary didn't invite Bill for DINner, but JOHN* is odd. Finally, notice that *Mary only invited BILL for dinner* means something different from *Mary only invited Bill for DINner.* Expressions like *only* that depend on the choice of focus are said to *associate with focus* (Jackendoff 1972).

Focus is typically expressed in spoken language by pitch movement, duration, or intensity on a syllable (cf. Ladd 1996). In addition, we often find certain syntactic constructions, like cleft sentences (*It was BILL that she invited for dinner*). There are languages that make use of specific syntactic positions (e.g., the preverbal focus position in Hungarian), dedicated particles (e.g., Quechua), or syntactic movement of nonfocused expressions from their regular position (e.g., Catalan; cf. É Kiss 1995). In American Sign Language (see SIGN LANGUAGES), focus is marked by a non-manual gesture, the brow raise (cf. Wilbur 1991).

Focus marking is often ambiguous, which gives rise to misunderstandings and jokes. When the notorious bank robber Willie Sutton was asked by a reporter, *Why do you rob banks?* he replied: *Because that's where the money is.* The answer makes sense with focus on *banks,* but the intended focus clearly was on *rob banks;* Sutton was asked why he robs banks in contrast to doing other things. The focus is marked by accent on *banks* in both cases. In general, accent on a syntactic *argument* often helps to mark broad focus on predicate + argument (cf. Schmerling 1976; Gussenhoven 1984; Selkirk 1984). Take the difference between (a) *John has PLANS to leave* and (b) *John has plans to LEAVE.* (a) is understood as *John has to leave plans,* with *plans* as object argument, whereas (b) is understood as *John plans to leave,* with VP argument *to leave.* In both cases, *plans to leave* is in focus.

On the semantic side, one influential line of research has been to analyze focus as expressing what is *new* in an utterance (DISCOURSE; cf. Halliday 1967; Sgall, Hajicová, and Panenová 1986; Rochemont 1986). The question *Who did Mary invite for dinner?* can be answered by *Mary invited BILL for dinner,* inasmuch as it presupposes that Mary invited someone for dinner, and the new information is that this person was Bill. Consequently, *Bill* is accented, and the other constituents, which are *given* information, are deaccented. What should count as "given" often requires inferencing, as in the following example: *Many tourists visit (a) Israel / (b) Jerusalem. When BILL arrived in the Holy City, all hotels were booked.* In the (a) case, *Holy City* is accented, while in the (b) case, it is deaccented because it is mentioned before, though not literally.

Another influential research program sees focus as indicating the presence of *alternatives* to the item in focus (cf. Rooth 1992, 1995). For example, a question like *Who did Mary invite for dinner?* asks for answers of the form *Mary invited X for dinner,* where *X* varies over persons. The focus in the answer, *Mary invited BILL for dinner,* identifies a particular answer of this form. In general, focus on an expression marks the fact that alternatives to this expression are under consideration. This idea naturally also applies to the contrastive use of focus and to association with focus. A sentence like *Mary invited BILL for dinner* can be used in contrast to sentences of the type *Mary invited X for dinner,* where *X* applies to some alternative to *Bill.* And a sentence like *Mary only invited BILL for dinner* says that Mary did not invite any alternative to Bill to dinner. Other focus-sensitive operators can be explained similarly. For example, *Mary also invited BILL for dinner* presupposes that there is an alternative *X* to *Bill* such that *Mary invited X for dinner* is true. And *Mary unfortunately invited BILL for dinner* presupposes that there is an alternative *X* to *Bill* such that it would have been more fortunate for Mary to invite *X* for dinner. Sedivy et al. (1994) have used eyetracking techniques to observe the construction of such alternative sets during sentence processing.

The two lines of research sometimes lead to different analyses. Consider the following exchange: A: *My car broke down.* B: *What did you do?* A can answer with (a) *I called a meCHAnic* or with (b) *I FIXed the car.* If focus expresses newness, (a) should have focus on *called a mechanic,* and (b) should have focus just on *fixed,* as *the car* is given. But if focus indicates the presence of alternatives, (b) should have focus on *fixed the car,* as the question asks for an activity. The lack of accent on *the car* in (b) shows that even focus theories based on alternatives must allow for givenness as a factor in accentuation. Notice that there are expressions that are never accentuated, for example, the indefinite pronoun *something,* as in A: *What did you do?* B: *I FIXed something.*

Focus is of interest for the study of the SYNTAX-SEMANTICS INTERFACE, as focus-sensitive operators require a liberal understanding of the principle of COMPOSITIONALITY. Take the view that focus indicates the presence of alternatives. As the VPs *only invited BILL for dinner* and *only invited Bill for DINner* differ in meaning, the placement of focus must lead to differences in the interpretation of the embedded VP *invited Bill for dinner.* One proposal assumes that the item in focus is somehow made "visible," for example by movement on the syntactic level of LOGICAL FORM (cf. MINIMALISM). In this theory, a sentence like *Mary only invited BILL for dinner* means something like "The only *X* such that *invited X for dinner* is true of Mary is Bill" (cf., e.g., von Stechow 1990; Jacobs 1991). A problem is that association with focus seems to disregard syntactic islands (cf. WH-MOVEMENT), as in *Mary only invited [BILL's mother] for dinner.* Another proposal assumes that expressions in focus introduce alternatives, which leads to alternatives for the expressions with embedded focus constituents ("Alternative Semantics," cf. Rooth 1992). Our example is analyzed as "The only predicate of the form *invite X for dinner* that applies to Mary is *invite Bill for dinner.*" In general, alternative semantics is more restrictive, but it may not be sufficient for more complex cases in which multiple foci are involved, as in, A: *Mary only invited BILL for dinner. She also$_1$ only$_2$ invited BILL$_2$ for LUNCH$_1$,* where the second sentence presupposes that there is another person *X* besides *Bill* such that Mary invited only *Bill* to *x.*

There is another use of the term *focus,* unrelated to the one discussed here, in which it refers to discourse referents that are salient at the current point of discourse and are potential antecedents for pronouns (cf. Grosz and Sidner 1986).

Folk Biology

Folk biology is the cognitive study of how people classify and reason about the organic world. Humans everywhere classify animals and plants into species-like groups as obvious to a modern scientist as to a Maya Indian. Such groups are primary loci for thinking about biological causes and relations (Mayr 1969). Historically, they provided a transtheoretical base for scientific biology in that different theories—including evolutionary theory—have sought to account for the apparent constancy of "common species" and the organic processes centering on them. In addition, these preferred groups have "from the most remote period . . . been classed in groups under groups" (Darwin 1859: 431). This taxonomic array provides a natural framework for inference, and an inductive compendium of information, about organic categories and properties. It is not as conventional or arbitrary in structure and content, nor as variable across cultures, as the assembly of entities into cosmologies, materials, or social groups. From the vantage of EVOLUTIONARY PSYCHOLOGY, such natural systems are arguably routine "habits of mind," in part a natural selection for grasping relevant and recurrent "habits of the world."

The relative contributions of mind and world to folk biology are current research topics in COGNITIVE ANTHROPOLOGY and COGNITIVE DEVELOPMENT (Medin and Atran 1998). *Ethnobiology* is the anthropological study of folk biology; a research focus is *folk taxonomy,* which describes the hierarchical structure, organic content, and cultural function of folk biological classifications the world over. *Naive biology* is the psychological study of folk biology in industrialized societies; a research focus is *category-based induction,* which concerns how children and adults learn about, and reason from, biological categories.

Ethnobiology roughly divides into adherents of cultural universals versus CULTURAL RELATIVISM (debated also as "intellectualism" versus "utilitarianism," Brown 1995). Universalists highlight folk taxonomic principles that are only marginally influenced by people's needs and uses to which taxonomies are put (Berlin 1992). Relativists emphasize those structures and contents of folk biological categories that are fashioned by cultural interest, experience, and use (Ellen 1993). Universalists grant that even within a culture there may be different special-purpose classifications (beneficial/noxious, domestic/wild, edible/inedible, etc.). However, there is only one cross-culturally universal kind of general-purpose taxonomy, which supports the widest possible range of inductions about living kinds. This distinction between special- and general-purpose folk biological classifications parallels the distinction in philosophy of science between artificial versus natural classification (Gilmour and Walters 1964).

A culture's general-purpose folk taxonomy is composed of a stable hierarchy of inclusive groups of organisms, or taxa, which are mutually exclusive at each level of the hierarchy. These absolutely distinct levels, or ranks, are: folk kingdom (e.g., animal, plant), life form (e.g., bug, fish, bird, mammal/animal, tree, herb/grass, bush), generic species (gnat, shark, robin, dog, oak, clover, holly), folk specific

(poodle, white oak), and folk varietal (toy poodle; swamp white oak). Ranking is a cognitive mapping that projects living kind categories onto fundamentally different levels of reality. Ranks, not taxa, are universal. Taxa of the same rank tend to display similar linguistic, psychological, and biological characteristics. For example, most generic species are labeled by short, simple words (i.e., unanalyzable lexical stems: "oak," "dog"). In contrast, subordinate specifics are usually labelled binomially (i.e., attributive + lexical stem: "white oak") unless culturally very salient (in which case they may also merit simple words: "poodle," "collie"). Relativists agree there is a preferred taxonomic level roughly corresponding to that of the scientific species (e.g., dog) or genus (e.g., oak). Phenomenally salient species for humans, including most species of large vertebrates and trees, belong to monospecific genera in any given locale, hence the term "generic species" for this preferred taxonomic level (also called "folk generic" or "specieme"). Nevertheless, relativists note that even in seemingly general-purpose taxonomies, categories superordinate or subordinate to generic species can reflect "special-purpose" distinctions of cultural practice and expertise. For example, the Kalam of New Guinea deny that cassowaries fall under the bird life form, not only because flightless cassowaries are physically unlike other birds, but also because they are ritually prized objects of the hunt (Bulmer 1967).

Universalism in folk biology may be further subdivided into tendencies that parallel philosophical and psychological distinctions between RATIONALISM VS. EMPIRICISM (Malt 1995). Empiricists claim that universal structures of folk taxonomy owe primarily to perceived structures of "objective discontinuities" in nature rather than to the mind's conceptual structure. On this view, the mind/brain merely provides domain-general mechanisms for assessing perceptual similarities, which are recursively applied to produce the embedded similarity-structures represented in folk taxonomy (Hunn 1976). Rationalists contend that higher-order cognitive principles are needed to produce regularities in folk biological structures (Atran 1990). For example, one pair of principles is that every object is either an animal or plant or neither, and that no animal or plant can fail to belong uniquely to a generic species. Thus, the rank of folk kingdom—the level of plant and animal—is a category of people's intuitive ontology, and conceiving an object as plant or animal entails notions about generic species that are not applied to objects thought to belong to other ontological categories, such as person, substance, or artifact. Although such principles may be culturally universal, cognitively compelling, and adaptive for everyday life, they no longer neatly accord with the known scientific structure of the organic world.

In the study of naive biology, disagreement arises over whether higher-order principles evince strong or weak NATIVISM; that is, whether they reflect the innate modularity and DOMAIN SPECIFICITY of folk biology (Inagaki and Hatano 1996), or are learned on the basis of cognitive principles inherent to other domains, such as NAIVE PHYSICS or FOLK PSYCHOLOGY (Carey 1995). One candidate for a domain-specific principle involves a particular sort of ESSENTIALISM, which carries an invariable presumption that the various members of each generic species share a unique underlying nature, or biological essence. Such an essence may be considered domain-specific insofar as it is an intrinsic (i.e., nonartifactual) teleological agent, which physically (i.e., nonintentionally) causes the biologically relevant parts and properties of a generic species to function and cohere "for the sake of" the generic species itself. Thus, American preschoolers consistently judge that thorns on a rose bush exist for the sake of there being more roses, whereas physically similar depictions of barbs on barbed wire or the protuberances of a jagged rock do not elicit indications of inherent purpose and design (Keil 1994). People everywhere expect the disparate properties of a generic species to be integrated without having to know the precise causal chains linking universally recognized relationships of morpho-behavioral functioning, inheritance and reproduction, disease and death.

This essentialist concept shares features with the broader philosophical notion NATURAL KIND in regard to category-based induction. Thus, on learning that one cow is susceptible to "mad cow" disease, one might reasonably infer that all cows, but not all mammals or animals, are susceptible to the disease. This is presumably because disease is related to "deep" biological properties, and because *cow* is a generic species with a fairly uniform distribution of such properties. The taxonomic arrangement of generic species systematically extends this inductive power: it is more "natural" to infer a greater probability that all mammals share the disease than that all animals do. Taxonomic stability allows formulation of a general principle of biological induction: a property found in two organisms is most likely found in all organisms belonging to the lowest-ranked taxon containing the two. This powerful inferential principle also underlies systematics, the scientific classification of organic life (Warburton 1967). Still, relativists can point to cultural and historical influences on superordinate and subordinate taxa as suggesting that biologically relevant properties can be weighted differently for induction in different traditions.

Folk Psychology

In recent years, folk psychology has become a topic of debate not just among philosophers, but among developmental psychologists and primatologists as well. Yet there are two different things that "folk psychology" has come to mean, and they are not always distinguished: (1) commonsense psychology that explains human behavior in terms of beliefs, desires, intentions, expectations, preferences, hopes, fears, and so on; (2) an interpretation of such everyday explanations as part of a folk theory, comprising a network of generalizations employing concepts like *belief, desire,* and so on. The second definition—suggested by Sellars (1963) and dubbed "theory-theory" by Morton (1980)— is a philosophical account of the first.

Folk psychology(1) concerns the conceptual framework of explanations of human behavior: If the explanatory framework of folk psychology(1) is correct, then "because Nan wants the baby to sleep," which employs the concept of wanting, may be a good (partial) explanation of Nan's turning the TV off. Folk psychology(2) concerns how folk-psychological(1) explanations are to be interpreted: If folk psychology(2) is correct, then "because Nan wants the baby to sleep" is an hypothesis that Nan had an internal (brain) state of wanting the baby to sleep and that state caused Nan to turn the TV off.

Although the expression *folk psychology* came to prominence as a term for theory-theory, that is, folk psychology(2), it is now used more generally to refer to commonsense psychology, that is, folk psychology(1). This largely unnoticed broadening of the term has made for confusion in the literature. Folk psychology (in one or the other sense, or sometimes equivocally) has been the focus of two debates.

The first is the so-called use issue: What are people doing when they explain behavior in terms of beliefs, desires, and so on? Some philosophers (Goldman 1993; Gordon 1986) argue that folk psychology, in sense (1) is a matter of simulation. Putting it less precisely than either Goldman or Gordon would, to use commonsense psychology is to exercise a skill; to attribute a belief is to project oneself into the situation of the believer. The dominant view, however, is that users of concepts like believing, desiring, intending—folk psychology(1)—are deploying a theory—folk psychology(2). To attribute a belief is to make an hypothesis about the internal state of the putative believer. Some psychologists (e.g., Astington, Harris, and Olson 1988) as well as philosophers simply assume the theory-theory interpretation, and some, though not all, fail to distinguish between folk psychology(1) and folk psychology(2).

The second is the so-called status issue. To what extent is the commonsense belief/desire framework correct? The "status" issue has turned on this question: To what extent will science vindicate (in some relevant sense) commonsense psychology? The question of scientific vindication arises when commonsense psychology is understood as folk psychology(2). On one side are intentional realists like Fodor (1987) and Dretske (1987), who argue that science will vindicate the conceptual framework of commonsense psychology. On the other side are proponents of ELIMINATIVE MATERIALISM like Churchland (1981) and Stich (1983), who argue that as an empirical theory, commonsense psychology is susceptible to replacement by a better theory with radically different conceptual resources (but see Stich 1996 for a revised view). Just as other folk theories (e.g., FOLK BIOLOGY) have been overthrown by scientific theories, we should be prepared for the overthrow of folk psychology by a scientific theory—scientific psychology or neuroscience. Eliminative materialists make the empirical prediction that science very probably will not vindicate the framework of commonsense psychology.

The question of scientific vindication, however, does not by itself decide the "status" issue. To see this, consider an argument for eliminative materialism (EM):

a. Folk psychology will not be vindicated by a physicalistic theory (scientific psychology or neuroscience).
b. Folk psychology is correct if and only if it is vindicated (in some relevant sense) by a physicalistic theory.

So,

c. Folk psychology is incorrect.

Premise (b), which plays an essential role in the argument, has largely been neglected (but see Baker 1995; Horgan and Graham 1991). If premise (b) refers to folk psychology(2), then premise (b) is plausible; but then the conclusion would establish only that commonsense psychology *interpreted as a theory* is incorrect. However, if premise (b) refers to folk psychology(1), then premise (b) is very probably false. If folk psychology is not a putative scientific theory in the first place, then there is no reason to think that a physicalistic theory will reveal it to be incorrect. (Similarly, if cooking, say, is not a scientific theory in the first place, then we need not fear that chemistry will reveal that you cannot really bake a cake.) So, the most that (EM) could show would be that if the theory-theory is the correct philosophical account of folk psychology(1), then folk psychology is a false theory. (EM) would not establish the incorrectness of commonsense psychology on other philosophical accounts (as, say, understood in terms of Aristotle's account of the practical syllogism).

Other positions on the "status" issue include these: commonsense psychology—folk psychology(1)—will be partly confirmed and partly disconfirmed by scientific psychology

(von Eckardt 1994, 1997); commonsense psychology is so robust that we should affirm its physical basis regardless of the course of scientific psychology (Heil 1992); commonsense psychology is causal, and hence, though attributions of attitudes are interpretive and normative, explanations of behavior in terms of attitudes are backed by strict laws (Davidson 1980); commonsense psychology is useless as science, but remains useful in everyday life (Dennett 1987; Wilkes 1991). Still others (Baker 1995; Horgan and Graham 1991) take the legitimacy of commonsense psychology to be borne out in everyday cognitive practice—regardless of the outcome of scientific psychology or neuroscience.

Form/Content

See COMPUTATIONAL THEORY OF MIND; INTENTIONALITY; LOGICAL FORM, ORIGINS OF

Formal Grammars

A grammar is a definition of a set of linguistic structures, where the linguistic structures could be sequences of words (sentences), or "sound-meaning" pairs (that is, pairs $<s,m>$ where s is a representation of phonetic properties and m is a representation of semantic properties), or pairs $<t,p>$ where t is a tree and p is a probability of occurrence in a discourse. A *formal grammar,* then, is a grammar that is completely clear and unambiguous. Obviously, this account of what qualifies as "formal" is neither formal nor rigorous, but in practice there is little dispute.

It might seem that formalization would always be desirable in linguistic theory, but there is little point in spelling out the details of informal hypotheses when their weaknesses can readily be ascertained and addressed without working out the details. In fact, there is considerable varia-

tion in the degree to which empirical proposals about human grammars are formalized, and there are disputes in the literature about how much formalization is appropriate at this stage of linguistic theory (Pullum 1989; Chomsky 1990).

Given this controversy, and given the preliminary and changing nature of linguistic theories, formal studies of grammar have been most significant when they have focused not on the details of any particular grammar, but rather on the fundamental properties of various *kinds* of grammars. Taking this abstract, metagrammatical approach, formal studies have identified a number of basic properties of grammars that raise new questions about human languages.

One basic division among the various ways of defining sets of linguistic structures classifies them as *generative* or *constraint-based.* A GENERATIVE GRAMMAR defines a set of structures by providing some basic elements and applying rules to derive new elements. Again, there are two basic ways of doing this. The first approach, common in "formal language theory" involves beginning with a "category" like "sentence," applying rules that define what parts the sentence has, what parts those parts have, and so on until the sentence has been specified all the way down to the level of words. This style of language definition has proven to be very useful, and many fundamental results have been established (Harrison 1978; Rozenberg and Salomaa 1997).

A second "bottom-up" approach, more common in CATEGORIAL GRAMMAR and some related traditions, involves starting with some lexical items ("generators") and then applying rules to assemble them into more complex structures. This style of language definition comes from LOGIC and algebra, where certain sets are similarly defined by "closing" a set of basic elements with respect to some generating relations. In these formal grammars, the structures of the defined language are analogous to the theorems of formal logic in that they are derived from some specified basic elements by rigorously specified rules. A natural step from this idea is to treat a grammar explicitly as a logic (Lambek 1958; Moortgat 1997).

Unlike the generative methods, which define a language by applying rules to a set of initial elements of some kind, a *constraint grammar* specifies a set by saying what properties the elements of that set must have. In this sort of definition, the structures in the language are not like the (generated, enumerable) theorems of a logic, but more like the sentences that could possibly be true (the "satisfiable" sentences of a logic). This approach to grammar is particularly prominent in linguistic traditions like HEAD-DRIVEN PHRASE STRUCTURE GRAMMAR (Pollard and Sag 1994). However, most linguistic theories use both generative and constraint-based specifications of structure.

Recently, linguists have also shown interest in a special variety of constraint grammar that is sometimes called "over-constrained." These grammars impose constraints that cannot all be met, and the interest then is in the linguistic structures that meet the constraints of the grammar to the greatest degree, the structures that are "most economical" or "most optimal" in some sense. Systems of this kind have been studied in a variety of contexts, but have recently become prominent in OPTIMALITY THEORY. Parts of the transformational grammar tradition called MINIMALISM have a fundamentally similar character, with constraints that can be violated when there is no better option.

The various different kinds of formal grammars have all been studied formally, particularly with regard to the complexities of sets they can define, and with regard to the succinctness of the definitions of those sets.

The study of various kinds of formal grammars has led linguists to consider whether we can determine, in advance of knowing in full detail what the grammars for human languages are like, whether human languages have one or another of the fundamental properties that are well understood in the context of artificial languages. Regardless of how a set of linguistic structures is defined, whether by a generative grammar or constraint grammar or over-constrained grammar, we can consider questions like the following about the complexity of the defined sets of "grammatical" structures. (Of course, such questions apply only to formal grammars for which some significant criterion of "grammaticality" can be formulated, which is a controversial empirical question.)

Is the set of linguistic structures finite? Although there are obvious practical limitations on the lengths of sentences that any human will ever pronounce, these bounds do not seem to be linguistic in nature, but rather derive from limitations in our life span, requirements for sleep, and so on. As far as the grammars of natural languages go, there seems to be no longest sentence, and consequently no maximally complex linguistic structure, and we can conclude that human languages are infinite. This assumption makes all of the following questions more difficult, because it means that the languages that people speak contain structures that no human will ever produce or understand. This basic point is also one of the basic motivations for the competence/performance distinction.

Is the set of linguistic structures "recursive"? That is, is there an algorithm that can effectively decide whether a given structure is in the set or not? This question is more interesting than it looks, because the mere fact that humans use languages does not show they are recursive (Matthews 1979). However, there seems to be no good reason to assume that languages are not recursive.

Is the set of linguistic structures one that is recognized by a finite computing device? As Chomsky (1956) pointed out, as far as the principles of language are concerned, not only are there sentences that are too long for a human to pronounce, but there are sentences that require more memory to recognize than humans have. To recognize an arbitrary sentence of a human language requires infinite memory, just as computing arbitrary multiplication problems does. (In a range of important cases, the complexity of grammatical descriptions of formal languages corresponds to the complexity of the machines needed to recognize those languages, as we see here. The study of formal languages overlaps extensively with the theory of AUTOMATA.)

Is the set of linguistic structures generated by a "context free grammar"? Because "context free grammars" can define languages that cannot be accepted by a finite machine,

this more technical question has received a lot of attention, particularly in studies of the syntax of human languages. The received view is that the sentences of natural languages are not generally definable by context free grammars (Chomsky 1956; Savitch et al. 1987). So the human languages seem to be more complex than context free languages, but still recursive. There have been a number of attempts to pin the matter down more precisely (Joshi 1985; Vijay-Shanker and Weir 1994).

Is the set of linguistic structures "efficiently parsable"? That is, roughly, can the structures be computed efficiently from their spoken or written forms? For human languages, the answer appears to be negative, as argued for example in Barton, Berwick, and Ristad (1987) and in Ristad (1993), but the matter remains controversial. Questions like this one are at the foundations of work in NATURAL LANGUAGE PROCESSING.

Is a set of formal languages "learnable"? Results in formal studies of learning often depend on the particular sets that are learned (in some precise sense of "learned"), and so formal grammars play a fundamental role in LEARNING SYSTEMS; COMPUTATIONAL LEARNING THEORY; SUPERVISED LEARNING; UNSUPERVISED LEARNING; MACHINE LEARNING; STATISTICAL LEARNING THEORY.

Formal Systems, Properties of

Formal systems or theories must satisfy requirements that are sharper than those imposed on the structure of theories by the axiomatic-deductive method, which can be traced back to Euclid's *Elements.* The crucial additional requirement is the regimentation of inferential steps in proofs: not only axioms have to be given in advance, but also the logical rules representing argumentative steps. To avoid a regress in the definition of proof and to achieve intersubjectivity on a minimal basis, the rules are to be "mechanical" and must take into account only the syntactic form of statements. Thus, to exclude any ambiguity, a precise symbolic language is needed and a logical calculus. Both the concept of a "formula" (i.e., statement in the symbolic language) and that of a "rule" (i.e., inference step in the logical calculus) have to be effective; by the Church-Turing Thesis, this means they have to be recursive.

FREGE (1879) presented a symbolic language (with relations and quantifiers) together with an adequate logical calculus, thus providing the means for the completely formal representation of mathematical proofs. The Fregean framework was basic for the later development of mathematical logic; it influenced the work of Whitehead and Russell that

culminated in *Principia Mathematica*. The next crucial step was taken most vigorously by Hilbert; he built on Whitehead and Russell's work and used an appropriate framework for the development of parts of mathematics, but took it also as an object of mathematical investigation. The latter metamathematical perspective proved to be extremely important. Clearly, in a less rigorous way it goes back to the investigations concerning non-Euclidean geometry and Hilbert's own early work (1899) on independence questions in geometry.

Hilbert's emphasis on the mathematical investigation of formal systems really marked the beginning of *mathematical* logic. In the lectures (1918), prepared in collaboration with Paul Bernays, he isolated the language of first order logic as the central language (together with an informal semantics) and developed a suitable logical calculus. Central questions were raised and partially answered; they concerned the completeness, consistency, and decidability of such systems and are still central in mathematical logic and other fields, where formal systems are being explored. Some important results will be presented paradigmatically; for a real impression of the richness and depth of the subject readers have to turn to (classical) textbooks or to up-to-date handbooks (see Further Readings.)

Completeness has been used in a number of different senses, from the *quasi-empirical* completeness of Zermelo Fraenkel set theory (being sufficient for the formal development of mathematics) to the *syntactic completeness* of formal theories (shown to be impossible by Gödel's First Theorem for theories containing a modicum of number theory). For logic the central concept is, however, *Semantic completeness*: a calculus is (semantically) complete, if it allows to prove all statements that are true in all interpretations (models) of the system. In sentential logic these statements are the tautologies; for that logic Hilbert and Bernays (1918) and Post (1921) proved the completeness of appropriate calculi; for first order logic completeness was established by Gödel (1930). Completeness expresses obviously the adequacy of a calculus to capture all logical consequences and entails almost immediately the logic's compactness: if every finite subset of a system has a model, so does the system. Ironically, this immediate consequence of its adequacy is at the root of real inadequacies of first order logic: the existence of nonstandard models for arithmetic and the inexpressibility of important concepts (like "finite," "well-order"). The relativity of "being countable" (leading to the so-called Skolem paradox) is a direct consequence of the proof of the completeness theorem.

Relative *consistency* proofs were obtained in geometry by semantic arguments: given a model of Euclidean geometry one can define a Euclidean model of, say, hyperbolic geometry; thus, if an inconsistency could be found in hyperbolic geometry it could also be found in Euclidean geometry. Hilbert formulated as the central goal of his program to establish by elementary, so-called finitist means the consistency of formal systems. This involved a direct examination of formal proofs; the strongest results before 1931 were obtained by Ackermann, VON NEUMANN, and Herbrand: they established the consistency of number theory with a very restricted induction principle. A basic limitation had indeed been reached, as was made clear by Gödel's Second Theorem; see

GÖDEL'S THEOREMS. Modern proof theory—by using stronger than finitist, but still "constructive" means—has been able to prove the consistency of significant parts of analysis. In pursuing this generalized consistency program, important insights have been gained into structural properties of proofs in special calculi ("normal form" of proofs in sequent and natural deduction calculi; cf. Gentzen 1934–35, 1936; Prawitz 1966). These structural properties are fundamental not only for modern LOGICAL REASONING SYSTEMS, but also for interesting psychological theories of human reasoning (see DEDUCTIVE REASONING and Rips 1994).

Hilbert's *Entscheidungsproblem*, the decision problem for first order logic, was one issue that required a precise characterization of "effective methods"; see CHURCH-TURING THESIS. Though partial positive answers were found during the 1920s, Church and TURING proved in 1936 that the general problem is undecidable. The result and the techniques involved in its proof (not to mention the very mathematical notions) inspired the investigation of the recursion theoretic complexity of sets that led at first to the classification of the arithmetical, hyperarithmetical, and analytical hierarchies, and later to that of computational complexity classes.

Some general questions and results were described for particular systems; as a matter of fact, questions and results that led to three branches of modern logic: model theory, proof theory, and computability theory. However, to reemphasize the point, from an abstract recursion theoretic point of view any system of "syntactic configurations" whose "formulas" and "proofs" are effectively decidable (by a Turing machine) is a formal system. In a footnote to his 1931 paper added in 1963, Gödel made this point most strongly: "In my opinion the term 'formal system' or 'formalism' should never be used for anything but this notion. In a lecture at Princeton . . . I suggested certain transfinite generalizations of formalisms; but these are something radically different from formal systems in the proper sense of the term, whose characteristic property is that reasoning in them, in principle, can be completely replaced by mechanical devices." Thus, formal systems in this sense can in principle be implemented on computers and provide (at least partial) models for a wide variety of mental processes.

Formal Theories

See ACQUISITION, FORMAL THEORIES OF; FORMAL GRAMMARS; FORMAL SYSTEMS, PROPERTIES OF; LEARNING SYSTEMS

Frame-Based Systems

Frame-based systems are knowledge representation systems that use *frames,* a notion originally introduced by Marvin Minsky, as their primary means to represent domain knowledge. A frame is a structure for representing a CONCEPT or situation such as "living room" or "being in a living room." Attached to a frame are several kinds of information, for instance, definitional and descriptive information and how to use the frame. Based on the original proposal, several knowledge representation systems have been built and the theory of frames has evolved. Important descendants of frame-based representation formalisms are *description logics* that capture the declarative part of frames using a logic-based semantics. Most of these logics are decidable fragments of *first order logic* and are very closely related to other formalisms such as modal logics and *feature logics.*

In the seminal paper "A framework for representing knowledge," Minsky (1975) proposed a KNOWLEDGE REP-RESENTATION scheme that was completely different from formalisms used in those days, namely, rule-based and logic-based formalisms. Minsky proposed organizing knowledge into chunks called *frames.* These frames are supposed to capture the essence of concepts or stereotypical situations, for example being in a living room or going out for dinner, by clustering all relevant information for these situations together. This includes information about how to use the frame, information about expectations (which may turn out to be wrong), information about what to do if expectations are not confirmed, and so on. This means, in particular, that a great deal of procedurally expressed knowledge should be part of the frames. Collections of such frames are to be organized in *frame systems* in which the frames are interconnected. The processes working on such frame systems are supposed to match a frame to a specific situation, to use default values to fill unspecified aspects, and so on. If this brief summary sounds vague, it correctly reproduces the paper's general tone. Despite the fact that this paper was a first approach to the idea of what frames could be, Minsky explicitly argued in favor of staying flexible and nonformal.

Details that had been left out in Minsky's 1975 paper were later filled in by knowledge representation systems that were inspired by Minsky's ideas—the most prominent being FRL and KRL (Bobrow and Winograd 1977). KRL was one of the most ambitious projects in this direction. It addressed almost every representational problem discussed in the literature. The net result is a very complex language with a very rich repertoire of representational primitives and almost unlimited flexibility.

Features that are common to FRL, KRL, and later frame-based systems (Fikes and Kehler 1985) are: (1) frames are organized in (tangled) *hierarchies*; (2) frames are composed out of *slots* (attributes) for which *fillers* (scalar values, references to other frames or procedures) have to be specified or computed; and (3) properties (fillers, restriction on fillers, etc.) are inherited from superframes to subframes in the hierarchy according to some *inheritance strategy.* These organizational principles turned out to be very useful, and, indeed, the now popular object-oriented languages have adopted these organizational principles.

From a formal point of view, it was unsatisfying that the *semantics* of frames and of inheritance was specified only operationally. So, subsequent research in the area of knowledge representation addressed these problems. In the area of *defeasible inheritance,* principles based on nonmonotonic logics together with preferences derived from the topology of the inheritance network were applied in order to derive a formal semantics (Touretzky 1986; Selman and Levesque 1993). The task of assigning *declarative semantics* to frames was addressed by applying methods based on first order LOGIC.

Hayes (1980) argued that "most of frames is just a new syntax for parts of first order logic." Although this means that frames do not offer anything new in expressiveness, there are two important points in which frame-based systems may have an advantage over systems using first-order logic. Firstly, they offer a concise way to express knowledge in an *object-oriented* way (Fikes and Kehler 1985). Secondly, by using only a fragment of first order logic,

frame-based systems may offer more efficient means for reasoning.

These two points are addressed by the so-called *description logics* (also called terminological logics, concept languages, and attributive description languages; Nebel and Smolka 1991), which formalize the declarative part of frame-based systems and grew out of the development of the frame-based system KL-ONE (Brachman and Schmolze 1985). In description logics, it is possible to build up a concept hierarchy out of *atomic concepts* (interpreted as unary predicates and denoted by capitalized words) and attributes, usually called *roles* (interpreted as binary predicates and denoted by lowercase words). The intended meaning of atomic concepts can be specified by providing *concept descriptions* made up of other concepts and *role restrictions,* as in the following informal example:

Woman = Person and Female
Parent = Person with some child
Grandmother = Woman with some child who is a Parent

One of the most important reasoning tasks in this context is the determination of *subsumption* between two concepts, that is, determining whether all instances of one concept are necessarily instances of the other concept taking into account the definitions. For example, "Grandmother" is subsumed by "Parent" because everything that is a "Grandmother" is—by definition—also a "Parent." Similar to the subsumption task is the *instance-checking* task, where one wants to know if a given object is an *instance* of the specified concept.

Starting with a paper by Brachman and Levesque (1984), the COMPUTATIONAL COMPLEXITY of subsumption determination for different variants of description logics has extensively been analyzed and a family of algorithms for solving the subsumption problem has been developed (Schmidt-Schauss and Smolka 1991).

Although in most cases subsumption is decidable, that is, easier than inference in full first order logic, there are cases when subsumption becomes undecidable (Schmidt-Schauss 1989). Aiming for polynomial-time decidability, however, leads to very restricted description logics, as shown by Donini et al. (1991). Further, if definitions of concepts as in the example above are part of the language, even the weakest possible description logic has an NP-hard subsumption problem (Nebel 1990). Although these results seem to suggest that description logics are not usable because the computational complexity of reasoning is too high, experience with implemented systems shows that moderately expressive description logics are computationally feasible (Heinsohn et al. 1994). In fact, current frame-based systems are efficient enough to support large configuration systems that are in everyday use at AT&T (Brachman 1992).

In the course of analyzing the logical and computational properties of frame-based systems, it turned out that description logics are very similar to other formalisms used in computer science and COMPUTATIONAL LINGUISTICS (Nebel and Smolka 1991). First of all, the declarative part of *object-oriented database languages* bears a strong resemblance to description logics, and it is possible to apply techniques and methods developed for description logics in this area (Buch-

heit et al. 1994). Second, there is a very strong connection to modal logics and to dynamic logics (Schild 1991). In fact, the "standard" description logic ALC (Schmidt-Schauss and Smolka 1991) is simply a notational variant of the MODAL LOGIC K with multiple agents. Third, *feature logics,* which are the constraint logic part of so-called unification grammars such as HPSG, are very similar to description logics. The only difference is that attributes in feature logics are single-valued, whereas they are multivalued in description logics. Although this seems to be a minor difference, it can make the difference between decidable and undecidable reasoning problems (Nebel and Smolka 1991).

Frame Problem

From its humble origins labeling a technical annoyance for a particular AI formalism, the term *frame problem* has grown to cover issues confronting broader research programs in AI. In philosophy, the term has come to encompass allegedly fundamental, but merely superficially related, objections to computational models of mind in AI and beyond.

The original frame problem appears within the SITUATION CALCULUS for representing a changing world. In such systems there are "axioms" about changes conditional on prior occurrences—that pressing a switch changes the illumination of a lamp, that selling the lamp changes who owns it, and so on. Unfortunately, because inferences are to be made solely by deduction, axioms are needed for purported *non*changes—that pressing the switch does not change the owner, that selling the lamp does not change its illumination, and so on. Without such "frame axioms," a system is unable strictly to deduce that any states *persist*. The resulting problem is to do without huge numbers of frame axioms potentially relating *each* representable occurrence to *each* representable nonchange.

A common response is to handle nonchanges *implicitly* by allowing the system to assume *by default* that a state persists, unless there is an axiom specifying that it is changed by an occurrence, given surrounding conditions. Because such assumptions are not *deducible* from the axioms of change (even given surrounding conditions), and because the licensed conclusions are not *cumulative* as evidence is added, the frame problem helps motivate the development of special NONMONOTONIC LOGICS intended to minimize the assumptions that must be *retracted* given further evidence. This is related to discussions of defeasibility and *ceteris paribus* reasoning in epistemology and philosophy of science (e.g., Harman 1986).

A related challenge is to determine *which* assumptions to retract when necessary, as in the "Yale Shooting Problem" (Hanks and McDermott 1986). Let a system assume by default (1) that live creatures remain alive, and (2) that loaded guns remain loaded. Confront it with this information: Fred is alive, then a gun is loaded, then, after a delay, the gun is fired at Fred. If assumption (2) is in force through the delay, Fred probably violates (1). But equally, if assumption (1) is in force after the shooting, the gun probably violates (2). Why is (2) the more natural assumption to

enforce? Some favor (2) because the delay occurs *before* the shooting (e.g., Shoham 1988). Others favor (2) because there is no represented *reason* to believe it violated, although the shooting provides some reason for believing (1) violated (e.g., Morgenstern 1996; cf. philosophical discussions of inference to the best EXPLANATION, e.g., Thagard 1988). Work continues in this vein, seeking to formalize the relevant temporal and rational notions, and to insure that the strategies apply more broadly than the situation calculus.

Another approach to the frame problem seeks to remain within the strictures of classical (monotonic) logic (Reiter 1991). In most circumstances, it avoids the use of huge *numbers* of axioms about nonchanges, but at the cost of using hugely and implausibly *bold* axioms about nonchanges. For example, it is assumed that all the possible causes of a certain kind of effect are known, or that all the actual events or actions operating on a given situation are known.

Some philosophers of mind maintain that the original frame problem portends deeper problems for traditional AI, or at least for cognitive science more broadly. (Unless otherwise mentioned, the relevant papers of the authors cited may be found in Pylyshyn 1987.) Daniel Dennett wonders how to ignore information *obviously irrelevant to one's goals,* as one ignores many obvious nonchanges. John Haugeland wonders how to keep track of *salient side effects* without constantly checking for them. This includes the "ramification" and "qualification" problems of AI; see Morgenstern (1996) for a survey. Jerry Fodor wonders how to avoid the use of *"kooky" concepts* that render intuitive nonchanges as changes —for instance, "fridgeon" which applies to physical particles if and only if Fodor's fridge is on, so that Fodor can "change" the entire universe simply by unplugging his fridge. AI researchers, including Drew McDermott and Pat Hayes, protest that these further issues are unconnected to the original frame problem.

Nevertheless, the philosophers' challenges must be met somehow if human cognition is to be understood in computational terms (see CAUSAL REASONING). Exotic suggestions involve mental IMAGERY as opposed to a LANGUAGE OF THOUGHT (Haugeland, cf. Janlert in AI), nonrepresentational practical skills (Dreyfus and Dreyfus), and emotion-induced temporary modularity (de Sousa 1987, chap. 7). The authors of the Yale Shooting Problem argue, as well, against the hegemony of logical deduction — whether classical or nonmonotonic— in AI simulations of commonsense reasoning. More conservative proposed solutions appeal to HEURISTIC SEARCH techniques and ideas about MEMORY long familiar in AI and cognitive psychology (Lormand, in Ford and Pylyshyn 1996; Morgenstern 1996 provides an especially keen survey of AI proposals).

Frege, Gottlob

Gottlob Frege (1848–1925) was a professional mathematician who, together with Bertrand Russell, is considered to be one of the two grandfathers of modern analytic philosophy. However, the importance of his work extends far beyond the field of philosophy. Frege first introduced the concepts of modern quantificational LOGIC (1879). Indeed, with apologies to C. S. Pierce, it is no exaggeration to call modern quantificational logic Frege's discovery. Frege was also the first to present a formal system in the modern sense in which it was possible to carry out complex mathematical investigations (cf. FORMAL SYSTEMS, PROPERTIES OF).

In addition to contemporary, second-order quantificational logic, a host of logical and semantical techniques occur explicitly for the first time in his work. In Part III of his 1879 work, he introduced the notion of the ancestral of a relation, which yields a logical characterization of one important notion of mathematical sequence; for example, the ancestral can be used to define the notion of natural number. Indeed, the ancestral provides a general technique for transforming an inductive definition of a concept into an explicit one (Dedekind was the codiscoverer of this notion). Frege's later work was also of logico-semantical significance. The "smooth-breathing" operator of his *Grund-gesetze der Arithmetik*, a variable binding device for the formation of complex names for extensions of functional expressions, is the inspiration for lambda abstraction. The brilliant semantic discussion in Part I, though hindered by the lack of an analysis of the consequence relation, nonetheless anticipated many future developments in logic and semantics. For instance, Frege's hierarchy of functions (see Dummett 1973: chap. 3) could be taken as the catalyst for CATEGORIAL GRAMMAR. Even the influential technique of treating two-place functional expressions as denoting functions from objects to one-place functions described in Schoenfinkel (1924) is anticipated by Frege in his discussion of the extensions of two-place functional expressions (1893: §36).

Other ideas of Frege have also had a tremendous impact on research in the cognitive sciences. Perhaps the most important of these is the distinction between sense and reference, which occurs in his 1892 paper, "On Sense and Reference," the defining article of the analytic tradition in philosophy (see SENSE AND REFERENCE for an extended discussion). In that paper, he also gave the first modern informal semantic analysis of PROPOSITIONAL ATTITUDES and introduced the notion of presupposition into the literature (though he introduced the negation test for presupposition, it is clear that he was unaware of the Projection Problem; see PRESUPPOSITION). His 1918 essay "Thoughts" contains a sophisticated discussion of indexicality (cf. INDEXICALS AND DEMONSTRATIVES). Though some of the students of BRENTANO also made distinctions like the one between sense and reference, and even had interesting discussions of indexicals and demonstratives (e.g., Husserl 1903: Book VI), none of them achieved the conceptual clarity of Frege on these topics. Furthermore, Frege's conception of thoughts as structured in a way similar to sentences is a precursor to one aspect of Fodor's (1975) LANGUAGE OF THOUGHT, though Frege's conception of the ontology of thoughts as abstract, mind independent entities, much like numbers and sets, is incompatible with a Fodorian construal of them, and indeed with much of what is said on the matter in the philosophy of mind today.

Though Frege's ideas and discoveries have clearly had a profound effect on subsequent research in philosophy, computer science, and linguistics, his life's project, logicism, is usually considered to be a failure (for an influential defense of part of Frege's version of logicism, see Wright 1983). Logicism is the doctrine that arithmetic is reducible to logic. Frege announced this project in his *Foundations of Arithmetic,* which contained the most sophisticated discussion of the concept of number in the history of philosophy, together with an informal description of how the logicist program could be carried out. In his Magnum Opus, *Grundgesetze der Arithmetik (Basic Laws of Arithmetic)* (1893, 1903), Frege tried to carry out the logicist program in full detail, attempting to derive the basic laws of arithmetic, and indeed analysis, within a formal system whose axioms he believed expressed laws of logic. Unfortunately, the theory was inconsistent. This discovery, by Bertrand Russell, devastated Frege, and essentially ended his career as a mathematician. Recent research has shown, however, that there is a great deal of interest that is salvageable from his mathematical work (Wright 1983; and the essays in Demopoulos 1995).

Frege is not merely of historical interest for the student of cognitive science. Rather than being interested in how we in fact reason, he is interested in how we ought to reason, and rather than being interested in the biological component of mentality, he is interested in the abstract structure of thought. Studying his works provides a useful curative for those who need to be reminded about the public and normative aspects of the notions that concern cognitive science.

Freud, Sigmund

A prolific and gifted writer, whose broad learning extended from neurophysiology and EVOLUTION to the literature of six languages, Sigmund Freud (1826–1939) was one of the most influential scientists of the late nineteenth and early twentieth centuries. He was also one of the most controversial scientists of any time, so much so that both his critics and admirers have occasionally succumbed to the temptation to deny that he was a scientist at all.

Freud's positive and negative reputations flow from the same source—the extraordinary scope of his theories. Although the notions of unconscious ideas and processes did not originate with Freud, having philosophical antecedents in Gottfried Leibniz's (1646–1716) theory of *petites perceptions* and psychiatric antecedents in the work of, *inter alia,* Pierre Janet (1859–1947), Freud made them the centerpiece of his complex theory of the mind. Unlike other psychiatrists, Freud took unconscious ideas and processes to be critical in explaining the behavior of all people in all circumstances and not merely the outré actions of psychotics. Unlike Leibniz and his followers, Freud presented unconscious ideas not merely as a theoretical necessity, but as the key to human action. Through his spirited defense of the necessity and importance of unconscious ideas and processes, he gave these concepts theoretical respectability, almost in spite of their associations with him.

The explanatory scope of unconscious ideas and processes was enormous for Freud, because he saw psychoanalysis (see PSYCHOANALYSIS, CONTEMPORARY VIEWS OF and PSYCHOANALYSIS, HISTORY OF) as bridging the gap between the biological and the "human" sciences. Freud's early training in neurophysiology led him to try to ground psychological theorizing in the known structures of the brain. His incomplete manuscript, "Project for a Scientific Psychology" attempted to relate specific psychological functions, such as learning and memory, to recently discovered properties of the neurons. In this respect, his methodological principles exactly paralleled the current view in cognitive science that psychological theorizing must be consistent with and informed by the most recent knowledge in neuroscience. Freud was also an avid supporter of DARWIN and was explicit in stating that his theory of sexual and self-preservative instincts was firmly rooted in (evolutionary) biology. Prototypical of his synthetic approach to knowledge, he made a bold conjecture about an important relation between the findings of neurophysiology and evolutionary biology. If, as nearly all psychologists agreed, the mind functioned as a reflex, then it required constant stimulation, and if, as Darwin argued, the sexual instinct is one of the two most important forces governing animal life, then these findings could be brought together under a more comprehensive theory that sexual instincts (libido) drove the nervous system. Although Freud, his disciples, and his critics often present libido theory as an extrapolation from the sexual difficulties of his patients, its real strength and appeal came from its plausible biological premises.

Thanks to Darwin's influence, sexuality also played an important role in the social sciences of the late nineteenth century. A methodological imperative of evolutionary anthropology and sociology was to connect sophisticated human achievements to "primitive" conditions shared with animals, and sexual behavior was the most obvious point of connection. Given these trends in social science, Freud was able to make "upward" connections between psychoanalysis and the social sciences, as well as "downward" connections to neurophysiology and biology. In his efforts to find links among all the "mental" sciences, Freud's methodological approach again bears a striking resemblance to the interdisciplinary emphasis of current cognitive science. This approach was also the basis of the tremendous appeal of psychoanalysis: he believed that he had a theory that could provide biologically grounded explanations, in terms of sexual and self-preservative instincts and the various mental processes that operated on them, for everything from psychotic symptoms, dreams, and jokes to cultural practices such as art and religion.

Freud's theories of CONSCIOUSNESS and the EMOTIONS were also the product of an interdisciplinary synthesis between psychiatry and philosophy. Individuals whose behavior was driven by natural, but unconscious, emotional forces needed treatment in order to gain control of their lives by bringing the forces that govern them to consciousness. This was possible, Freud believed, because affective states were also cognitive and so could be made conscious through their ideational components. Although the *Project* offered some speculations about the qualitative character of consciousness, Freud's later approach was functionalist. Conscious ideas differed from the unconscious, because they could be expressed verbally,

because they were subject to rational constraints such as consistency, and because they could interact with sensory evidence.

Although Freud regarded the consilience of psychoanalysis with the biological and social sciences as the strongest argument in its favor, important changes in both the biological and social sciences undermined the plausibility of his basic assumptions about how mental processes worked. Rather than alter the scientific foundations of psychoanalysis, he continued to try to increase its scope and influence, leading to charges of disingenuousness and even pseudoscience. Despite Freud's tarnished reputation, many of his central substantive and methodological assumptions about studying the mind have reemerged with the rise of cognitive science, in particular, the assumption (from his teacher BRENTANO) that mental states are intentional (see INTENTIONALITY) and must be understood in terms of their contents, but that they are likewise physical and must be related to neuroscience, the assumption (which he described as an extension of KANT) that most mental processes are unconscious, the view that cognition and emotion are not separate faculties, but deeply intertwined aspects of mentality, and the basic methodological assumption that the biological and "human" sciences must learn from each other, because the ultimate goal is to develop a comprehensive theory of the social, psychological, and physical aspects of mentality. Further, although its emphasis on input-output computation has given cognitive science a synchronic time scale for much of its history, recent work on ARTIFICIAL LIFE and EVOLUTIONARY COMPUTATION reintroduces the sort of diachronic or genetic approach that Freud thought was essential in understanding the complexities of a mentality that was produced via individual development and the evolution of the species.

Functional Decomposition

Functional decomposition is the analysis of the activity of a system as the product of a set of subordinate functions performed by independent subsystems, each with its own characteristic domain of application. It assumes that there are a variety of functionally independent units, with intrinsically determined functions, that are minimally interactive. Functional decomposition plays important roles in engineering, physiology, biology, and in artificial intelligence. Functional morphologists, for example, distinguish the causal or functional roles of structures within organisms, the extent to which one structure may be altered without changing overall function, and the effects of these structures for evolutionary change. Within cognitive science, the assumption is that there are a variety of mechanisms underlying our mental life, which are domain specific and functionally independent. The classical distinction in DESCARTES between understanding, imagination and will is a functional decomposition, which postulates at least three independent faculties responsible for specific mental functions; likewise, the distinction drawn by KANT between sensation, judgment, understanding, and reason offers a partitioning of our mental faculties based on their cognitive functions, and is equally one that postulates a variety of independent faculties responsible for specific mental operations. In more recent psychological work, the distinction between sensory stores, short-term MEMORY, and long-term memory elaborated by Richard Atkinson and Richard Shiffrin (1968) is a functional decomposition of memory, based on their domains of application (for a classic source, see Neisser 1967).

Functional decomposition typically assumes a hierarchical organization, though a hierarchical organization is consistent with different modes of organization. Thus, the mind is conceived as having a modular organization (cf. MODULARITY OF MIND), with a variety of faculties, each with independent, intrinsically determined functions. Each of those modules in turn may have a modular organization, with a variety of independent, intrinsically determined functions. Sensory systems are relatively independent of one another, and independent of memory, language, and cognition. Language in turn may be taken to consist of a variety of relatively independent subsystems (cf. MODULARITY AND LANGUAGE), including modules responsible for PHONOLOGY, PHONETICS, SEMANTICS, and SYNTAX. The extent to which a hierarchical organization, or functional independence, is realistic can be decided only empirically, by seeing the extent to which we can approximate or explain system behavior by assuming it.

Functional decomposition is easily illustrated by appealing to the understanding of language. In the early nineteenth century, Franz Joseph Gall (1758–1828) defended the view that the mind consists of a variety of "organs" or "centers," each subserving specific intellectual or moral (that is, practical) functions, with dedicated locations in the cerebral hemispheres. These intellectual and moral functions were sharply distinguished at a higher level from the "vital" functions and affections that Gall located in the "lower" portions of the brain, and the specific functions in turn were distinguished from one another. There were differences between Gall and his fellow phrenologists concerning the number and characterization of the specific faculties, but within the intellectual faculties, phrenologists typically distinguished broadly between the external senses, various "perceptive" faculties (including faculties for perceiving weight, color,

tune, and language, among others), and the "reflective" faculties constitutive of reason. The primary faculties were the species of intellection, and they were assumed to belong to specific organs in the brain. Gall held an extreme view, assuming that the basic functions were strictly limited in application, invariable in their operation, and wholly independent of the activities of other faculties. That is, he assumed that the mind was simply an aggregate of its independent functions and that there was no overlap or interaction between these organs. Because he recognized no interaction between the faculties, complex abilities became simply the aggregates of simple abilities. Gall assumed, in other words, that the mind was both hierarchical and aggregative, or simply decomposable.

Paul Pierre BROCA (1824–1880) was also a defender of "organology," retaining both the discrete localizations of the phrenologists and the view that the size of organs was responsible for differing mental abilities. Following Jean Baptiste Bouillard (1796–1881), Broca emphasized the importance of dysfunction in determining functional organization. By August 1861, Broca had described in some detail the anatomical changes accompanying a disorder of speech that he called "aphemia," and that we would describe as an APHASIA. The patient, known as "Tan," lost the ability to speak by the time he was thirty, and over the years his case degenerated. Broca relied on interviews with the hospital staff to discover that Tan's initial "loss of articulate language" was due to a focal lesion in the frontal lobe. Broca's conclusion was that there were a variety of "organs" corresponding to discrete mental functions. Karl Wernicke (1848–1905) subsequently elaborated the basic model, reframing it in terms of an associationistic psychology rather than a faculty psychology and distinguishing sensory and motor aphasias. Wernicke concluded that there was a series of discrete loci mediating the comprehension and production of speech. On the basis of clinical observations, Wernicke concluded there were three distinctive "centers" associated with language use: a center for the acoustic representations of speech, a center for motor representations of speech, and a center for concepts typically mediating between the two. Disruptions of the various associations between these centers resulted in the various aphasias. The resulting functional decomposition for language use thus had at least three components, and a linear organization: the output of one "organ" serves as the input for the next, though the function performed or realized by each module is intrinsically determined. This basic model has since been elaborated by a number of clinical neurologists, including Norman GESCHWIND. The organization is no longer aggregative, but sequential, with relatively independent functional units. This is near decomposability.

A commitment to functional decomposition has continued in a variety of forms in more recent work in cognitive science, including the new "organology" of Noam Chomsky (1980), the "modularity" defended by Jerry Fodor (1983), and the FUNCTIONALISM of William Lycan (1987). Steven Pinker (1994), for example, argues that language is an ability that is relatively independent of cognitive abilities in general. The clear implication of such independence is that

it should be possible to disrupt linguistic abilities without impairing cognition, and vice versa. The studies of aphasia exhibit such patterns. A commitment to some form of functional decomposition or modularity might seem inevitable when dealing with a phenomenon as complex as mental life. Herbert Simon (1969) has emphasized the importance of simple decomposability and near decomposability, as well as of hierarchical organization in complex systems. In explaining the behavior of a complex system, it is often possible to establish independent functional characterizations for components, ignoring both the contributions of other components at the same level as well as the influences operative at higher or lower levels. This is, however, not always true, and the cases are often more complex than they might initially appear.

Numerous examples of functional decomposition are available from recent work in cognitive science. It is common, as noted, to analyze memory into distinctive subsystems. Commonly, it is assumed that there are at least two stages, presumably with discrete physiological mechanisms: the first process is short-lived, lasting from minutes to hours, and the second is of indefinite duration. Conventionally, this distinction between short-term and long-term memory is assayed by recall tests. This is by no means the only decomposition of memory, and is anything but unproblematic; more specifically, the experimental evidence leaves it unclear whether the distinction between short- and long-term memory is a distinction between modules, or modes of processing, and whether short-term memory is a unitary entity. Experimentation in memory typically involves some measure of retention based on recall or recognition of some predetermined material, and more recently using dual tasks in parallel. This research has led to a variety of ways of understanding the organization of memory, including distinctions between working memory, semantic memory, and declarative memory. There is currently no clear consensus concerning the most appropriate theory, and no model that naturally accommodates the entire range of the phenomena. In a similar way, linguistic competence is generally understood as the product of a set of distinct subsystems. Wernicke's distinction between comprehension and production has been replaced with distinct processes involved in language use, typically distinguishing between semantic and syntactic functions. Again, this decomposition is not unproblematic, and there is some evidence suggesting that such decompositions do not yield functionally independent subsystems.

Functional Grammar

See LEXICAL FUNCTIONAL GRAMMAR

Functional Role Semantics

According to functional role semantics (FRS), the meaning of a MENTAL REPRESENTATION is its role in the cognitive life of the agent, for example in perception, thought and DECISION MAKING. It is an extension of the well-known "use" theory of meaning, according to which the meaning of a word is its use in communication and more generally, in social interaction. FRS supplements external use by including the role of a symbol inside a computer or a brain. The uses appealed to are not just actual, but also counterfactual: not only what effects a thought does have, but also what effects it would have had if stimuli or other states had differed. The view has arisen separately in philosophy (where it is sometimes called "inferential," or "functional" role semantics) and in cognitive science (where it is sometimes called "procedural semantics"). The view originated with Wittgenstein and Sellars, but the source in contemporary philosophy is a series of papers by Harman (see his 1987) and Field (1977). Other proponents in philosophy have included Block, Horwich, Loar, McGinn, and Peacocke; in cognitive science, they include Woods, Miller, and Johnson-Laird.

FRS is motivated in part by the fact that many terms seem definable only in conjunction with one another, and not in terms outside of the circle they form. For example, in learning the theoretical terms of Newtonian mechanics—force, mass, kinetic energy, momentum, and so on—we do not learn definitions outside the circle. There are no such definitions. We learn the terms by learning how to use them in our thought processes, especially in solving problems. Indeed, FRS explains the fact that modern scientists cannot understand the phlogiston theory without learning elements of an old language that expresses the old concepts. The functional role of, for example, "principle" as used by phlogiston theorists is very different from the functional role of any term or complex of terms of modern physics, and hence we must acquire some approximation of the eighteenth century functional roles if we want to understand their ideas.

FRS seems to give a plausible account of the meanings of the logical connectives. For example, we could specify the meaning of "and" by noting that certain inferences—for example, the inferences from sentences p and q to p *and* q, and the inference from p *and* q to p—have a special status (they are "primitively compelling" in Peacocke's 1992 terminology). But it may be said that the logical connectives are a poor model for language and for concepts more generally. One of the most important features of our CONCEPTS is that they refer—that is, that they pick out objects in the world.

In part for this reason, many theorists prefer a two-factor version of FRS. On this view, meaning consists of an internal, "narrow" aspect of meaning—which is handled by functional roles that are within the body—and an external referential/truth-theoretic aspect of meaning. According to the external factor, "Superman flies" and "Clark Kent flies" are semantically the same because Superman = Clark Kent; the internal factor is what distinguishes them. But the internal factor counts "Water is more greenish than bluish" as semantically the same in my mouth as in the mouth of my twin on TWIN EARTH. In this case, it is the external factor that distinguishes them.

Two-factor theories gain some independent plausibility from the need of them to account for indexical thought and assertions, assertions whose truth depends on facts about

when and where they were made and by whom. For example, suppose that you and I say "I am ill." One aspect of the meaning of "I" is common to us, another aspect is different. What is the same is that our terms are both used according to the rule that they refer to the speaker; what is different is that the speakers are different. White (1982) generalized this distinction to apply to the internal and external factors for all referring expressions, not just INDEXICALS.

In a two-factor account, the functional roles stop at the skin in sense and effector organs; they are "short-arm" roles. But FRS can also be held in a one-factor version in which the functional roles reach out into the world—these roles are "long-arm." Harman (1987) has advocated a one-factor account that includes in the long-arm roles much of the machinery that a two-factor theorist includes in the referential factor, but without any commitment to a separable narrow aspect of meaning. Harman's approach and the two-factor theory show that the general approach of FRS is actually compatible with metaphysical accounts of reference such as the causal theory or teleological theories, for they can be taken to be partial specifications of roles.

Actual functional roles involve errors, even dispositions to err. For example, in applying the word *dog* to candidate dogs, one will make errors, for example in mistaking coyotes for dogs (see Fodor 1987). This problem arises in one form or another for all naturalistic theories of truth and reference, but in the case of FRS it applies to erroneous inferences as well as to erroneous applications of words to things. Among all the conceptual connections of a symbol with other symbols, or (in the case of long-arm roles) with the world, which ones are correct and which ones are errors? One line of reply is to attempt to specify some sort of naturalistic idealization that specifies roles that abstract away from error, in the way that laws of free fall abstract away from friction.

FRS is often viewed as essentially holistic, but the FRS theorist does have the option of regarding some proper subset of the functional roles in which an expression participates as the ones that constitute its meaning. One natural and common view of what distinguishes the meaning-constitutive roles is that they are "analytic." Proponents of FRS are thus viewed as having to choose between accepting holism and accepting that this distinction between the analytic and synthetic is scientifically respectable, a claim that has been challenged by Quine. Indeed, Fodor and Lepore (1992) argue that, lacking an analytic/synthetic distinction, FRS is committed to semantic holism, regarding the meaning of any expression as depending on its inferential relations to every other expression in the language. This, they argue, amounts to the denial of a psychologically viable account of meaning.

Proponents of FRS can reply that the view is not committed to regarding what is meaning constitutive as analytic. In terms of our earlier two-factor account, they can, for example, regard the meaning-constitutive roles as those that are primitively compelling, or perhaps as ones that are explanatorily basic: they are the roles that explain other roles (see Horwich 1994). Another approach to accommodating holism with a psychologically viable account of meaning is to substitute close enough similarity of meaning for strict

identity of meaning. That may be all we need for making sense of psychological generalizations, interpersonal comparisons, and the processes of reasoning and changing one's mind.

Functionalism

Compare neurons and neutrons to planets and pendula. They all cluster into kinds or categories conforming to nomic generalizations and comporting with scientific investigation. However, whereas all neurons and neutrons must be composed of distinctive types of matter structured in ruthlessly precise ways, individual planets and pendula can be made of wildly disparate sorts of differently structured stuff. Neurons and neutrons are examples of physical kinds; planets and pendula exemplify functional kinds. Physical

kinds are identified by their material composition, which in turn determines their conformity to the laws of nature. Functional kinds are not identified by their material composition but rather by their activities or tendencies. All planets, no matter the differences in their composition, orbit or tend to. All pendula, no matter the differences in their composition, oscillate or tend to.

What, then, of minds or mental states, kinds that process information and control intelligent activity or behavior? Do they define physical or functional kinds? Naturally occurring minds, at least those most familiar to us, are brains. The human mind is most certainly the human brain; the mammal mind, the mammal brain (Kak 1996). Hence, under the assumption that brains are physical kinds, we might conjecture that all minds must be brains and, therefore, physical kinds. If so, we should study the brain if curious about the mind.

However, perhaps we are misled by our familiar, local and possibly parochial sample of minds. If all the pendula at hand happened to be aluminum, we might, failing to imagine copper ones, mistakenly suppose that pendula must—of *necessity*—be aluminum. Maybe, then, we should ask whether it is *possible* that minds occur in structures other than brains. Might there be silicon Martians capable of reading *Finnegan's Wake* and solving differential equations? Such fabled creatures would have minds although, being silicon instead of carbon, they could not have brains. Moving away from fiction and closer toward fact, what should we make of artificially intelligent devices? They can be liberated from human biochemistry while exhibiting talents that appear to demand the kind of cognition that fuels much of what is psychologically distinctive in human activity.

Possibly, then, some minds are not brains. These minds might be made of virtually any sort of material as long as it should be so organized as to process information, control behavior and generally support the sort of performances indicative of minds. Minds would then be functional, not physical, kinds. Respectively like planets and pendula, minds might arise naturally or artificially. Their coalescing into a single unified kind would be determined by their proclivity to process information and to control behavior independently of the stuff in which individual minds might happen to reside. Terrestrial evolution may here have settled on brains as the local natural solution to the problem of evolving minds. Still, because differing local pressures and opportunities may induce evolution to offer up alternative solutions to the same problem (say, mammals versus marsupials), evolution could develop minds from radically divergent kinds of matter. Should craft follow suit, art might fabricate intelligence in any computational medium. Functionalism, then, is the thesis that minds are functional kinds (Putnam 1960; Armstrong 1968; Lewis 1972; Cummins 1983).

The significance of functionalism for the study of the mind is profound, for it liberates cognitive science from concern with how the mind is embodied or composed. Given functionalism, it may be true that every individual mind is itself a physical structure. Nevertheless, by the lights of functionalism, physical structure is utterly irrelevant to the deep nature of the mind. Consequently, functionalism is foundational to those cognitive sciences that would abstract from details of physical implementation in order to discern principles common to all possible cognizers, thinkers who need not share any physical features immediately relevant to thought. Such a research strategy befriends Artificial Intelligence inasmuch as it attends to algorithms, programs, and computation rather than cortex, ganglia, and neurotransmitters. True, the study of *human or mammalian* cognition might focus on the physical properties of the brain. But if functionalism is true, the most general features of cognition must be independent of neurology.

According to functionalism, a mind is a physical system or device—with a host of possible internal states—normally situated in an environment itself consisting of an array of possible external states. External states can induce changes in such a device's internal states, and fluctuations in these internal states can cause subsequent internal changes determining the device's overt behavior. Standard formulations of functionalism accommodate the mind's management of information by treating the internal, that is, cognitive, states of the device as its representations, symbols, or signs of its world (Dennett 1978; Fodor 1980; Dretske 1981). Hence, disciplined change in internal state amounts to change in representation or manipulation of information.

Some (Pylyshyn 1985), but not all (Lycan 1981), formulations of functionalism model the mind in terms of a TURING machine (Turing 1950), perhaps in the form of a classical digital computer. A Turing machine possesses a segmented tape with segments corresponding to a cognitive device's internal states or representations. The machine is designed to read from and write to segments of the tape according to rules that themselves are sensitive to how the tape may be antecedently marked. If the device is an information processor, the marks on the tape can be viewed as semantically disciplined symbols that resonate to the environment and induce the machine appropriately to respond (Haugeland 1981). For functionalism, then, the mind, like a computer, may process information and control behavior simply by implementing a Turing machine.

In allowing that minds are functional kinds, one supposes that mental state types (for example, believing, desiring, willing, hoping, feeling, and sensing) are themselves functionally characterized. Thus belief, as a type of mental state, would be a kind of mental state with characteristic causes and effects (Fodor 1975; Block and Fodor 1972). The idea can be extended to identify or individuate specific beliefs (Harman 1973; Field 1977). The belief, say, that snow is white might be identified by its unique causal position in the mental economy (see FUNCTIONAL ROLE SEMANTICS). On this model, specific mental states are aligned with the unobservable or theoretical states of science generally and identified by their peculiar potential causal relations.

Although functionalism has been, and remains, the dominant position in the philosophy of mind since at least 1970, it remains an unhappy hostage to several important objections. First, the argument above in favor of functionalism begins with a premise about how it is *possible* for the mind to be realized or implemented outside of the brain. This premise is dramatized by supposing, for example, that it is possible that carbon-free Martians have minds but lack

brains. However, what justifies the crucial assumption of the real possibility of brainless, silicon Martian minds?

It is no answer to reply that anything imaginable is possible. For in that case, one can evidently imagine that it is *necessary* that minds are brains. If the imaginable is possible, it would follow that it is *possible* that it is *necessary* that minds are brains. However, on at least one version of modal logic it is axiomatic that whatever is *possibly necessary* is simply *necessary*. Hence, if it is *possible* that it is *necessary* that minds are brains, it is simply *necessary* that minds are brains. This, however, is in flat contradiction to the premise that launches functionalism, namely the premise that it is *possible* that minds are not brains! Evidently, what is desperately wanting here is a reasonable way of justifying premises about what is genuinely possible or what can be known to be possible. Until the functionalist can certify the possibility of a mind without a brain, the argument from such a possibility to the plausibility of functionalism appears disturbingly inconclusive (Maloney 1987).

Beyond this objection to the functionalist program is the worry that functionalism, if unwittingly in the service of a false psychology, could fly in the face of good scientific practice. To see this, suppose that minds are *defined* in terms of current (perhaps popular or folk) psychology and that this psychology turns out, unsurprisingly, to be false. In this case, minds—as defined by a false theory—would not be real, and that would be the deep and true reason why minds are not identical with real physical types such as brains. Nevertheless, a misguided functionalism, because it construes the mind as "whatever satisfies the principles of (false current) psychology," would wrongly bless the discontinuity of mind and brain and insist on the reality of mind disenfranchised from any physical kind. Put differently, our failure to identify phlogiston with any physical kind properly leads us to repudiate phlogiston rather than to elevate it to a functional kind. So too, the objection goes, perhaps our failure to identify the mind with a physical type should lead us to repudiate the mind rather than elevate it to a functional kind (Churchland 1981).

Others object to functionalism charging that it ignores the (presumed) centrality of CONSCIOUSNESS in cognition (Shoemaker 1975; Block 1978; Lewis 1980). They argue that functionally identical persons could differ in how they feel, that is, in their conscious, qualitative, or affective states. For example, you and I might be functionally isomorphic in the presence of a stimulus while we differ in our consciousness of it. You and I might both see the same apple and treat it much the same. Yet, this functional congruence might mask dramatic differences in our color QUALIA, differences that might have no behavioral or functional manifestation. If these conscious, qualitative differences differentiate our mental states, functionalism would seem unable to recognize them.

Finally, mental states are semantically significant representational states. As you play chess, you are thinking *about* the game. You realize that your knight is threatened but that its loss shall ensure the success of the trap you have set. But consider a computer programmed perfectly to emulate you at chess. It is your functional equivalent. Hence, according to functionalism it has the same mental states as do you. But does it think the same as you; does it realize, genuinely realize in exactly the manner that you do, that its knight is threatened but that the knight's loss ensures ultimate success? Or is the computer a semantically impoverished device designed merely to mimic you and your internal mental states without ever representing its world in anything like the manner in which you represent and recognize your world through your mental states (Searle 1980; Dennett and Searle 1982)? If you and the computer differ in how you represent the world, if you represent the world but the computer does not, then functionalism may have obscured a fundamentally important aspect of our cognition.

Fuzzy Logic

What is fuzzy logic? This question does not have a simple answer because fuzzy logic, or FL for short, has many distinct facets—facets that overlap and have unsharp boundaries (Zadeh 1996*a*; Dubois, Prade, and Yager 1993).

To a first approximation, fuzzy logic is a body of concepts, constructs, and techniques that relate to modes of reasoning that are approximate rather than exact. Much of— perhaps most—human reasoning is approximate in nature. In this perspective, the role model for fuzzy logic is the human mind. By contrast, classical LOGIC is normative in spirit in the sense that it is aimed at serving as a role model for human reasoning rather than having the human mind as its role model. Fundamentally, fuzzy logic is a generalization of classical logic and rests on the same mathematical foundations. However, as a generalization that reflects the pervasive imprecision of human reasoning, fuzzy logic is much better suited than classical logic to serve as the logic of human cognition.

Among the many facets of fuzzy logic there are four that stand out in importance. They are the following:

1. the logical facet, FL/L;
2. the set-theoretic facet, FL/S;
3. the relational facet, FL/R;
4. the epistemic facet, FL/E (see figure 1).

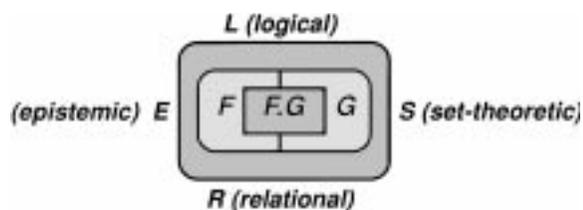
The logical facet of FL, FL/L, is a logical system or, more accurately, a collection of logical systems that include as a special case both two-valued and multiple-valued systems. As in any logical system, at the core of the logical facet of FL lies a system of rules of inference. In FL/L, however, the rules of inference play the role of rules that govern propagation of various types of fuzzy constraints. Concomitantly, a proposition, *p*, is viewed as a fuzzy constraint on an explicitly or implicitly defined variable. For example, the proposition "Mary is young" may be viewed as a fuzzy constraint on the variable Age (Mary), with "young" playing the role of a constraining fuzzy relation. Similarly, the proposition "Most students are young" may be viewed as a fuzzy


Figure 1. Conceptual structure of fuzzy logic.

constraint on the proportion of young students among students, with the fuzzy quantifier "most" playing the role of a fuzzy constraint on the proportion. The logical facet of FL plays a pivotal role in the applications of FL to knowledge representation and to inference from information that is imprecise, incomplete, uncertain, or partially true.

The set-theoretic facet of FL, FL/S, is concerned with fuzzy sets, that is, classes or sets whose boundaries are not sharply defined. The initial development of FL was focused on this facet. Most of the applications of FL in mathematics have been and continue to be related to the set-theoretic facet. Among the examples of such applications are: fuzzy topology, fuzzy groups, fuzzy differential equations, and fuzzy arithmetic. Actually, any concept, method or theory can be generalized by fuzzification, that is, by replacing the concept of a set with that of a fuzzy set. Fuzzification serves an important purpose: it provides a way of constructing theories that are more general and more reflective of the imprecision of the real world than theories in which the sets are assumed to be crisp.

The relational facet of FL, FL/R, is concerned in the main with representation and manipulation of imprecisely defined functions and relations. It is this facet of FL that plays a pivotal role in its applications to systems analysis and control. The three basic concepts that lie at the core of this facet of FL are those of a linguistic variable, fuzzy if-then rule, and fuzzy graph. The relational facet of FL provides a foundation for the fuzzy-logic-based methodology of computing with words (CW).

Basically, a linguistic variable is a variable whose values are words drawn from a natural or synthetic language, with words playing the role of labels of fuzzy sets. For example, Height is a linguistic variable if its values are assumed to be: tall, very tall, quite tall, short, not very short, and so on. The concept of a linguistic variable plays a fundamentally important role in fuzzy logic and in particular, in computing with words. The use of words instead of—or in addition to—numbers serves two major purposes: (1) exploitation of the tolerance for imprecision; and (2) reflection of the finite ability of the human mind to resolve detail and store precise information.

The epistemic facet of FL, FL/E, is linked to its logical facet and is focused on the applications of FL to knowledge representation, information systems, fuzzy databases, and the theories of possibility and probability. A particularly important application area for the epistemic facet of FL relates to the conception and design of information/intelligent systems.

At the core of FL lie two basic concepts: (1) fuzziness/ fuzzification; and (2) granularity/granulation. As was alluded to already, fuzziness is a condition that relates to classes whose boundaries are not sharply defined, whereas fuzzification refers to replacing a crisp set, that is, a set with sharply defined boundaries, with a set whose boundaries are fuzzy. For example, the number 5 is fuzzified when it is transformed into approximately 5.

In a similar spirit, granularity relates to clumpiness of structure, whereas granulation refers to partitioning an object into a collection of granules, with a granule being a clump of objects (points) drawn together by indistinguishability,

similarity, proximity, or functionality. For example, the granules of an article might be the introduction, section 1, section 2, and so forth. Similarly, the granules of a human body might be the head, neck, chest, stomach, legs, and so on. Granulation may be crisp or fuzzy, dense or sparse, physical or mental.

A concept that plays a pivotal role in fuzzy logic is that of *fuzzy information granulation,* or fuzzy IG, for short. In crisp IG, the granules are crisp, whereas in fuzzy IG the granules are fuzzy. For example, when the variable Age is granulated into the time intervals $\{0,1\}, \{1,2\}, \{2,3\}, \ldots$, the granules $\{0,1\}, \{1,2\}, \{2,3\}, \ldots$ are crisp; when Age is treated as a linguistic variable, the fuzzy sets labeled young, middle-aged, old, are fuzzy granules that play the role of linguistic values of Age. The importance of fuzzy logic—especially in the realm of applications—derives in large measure from the fact that FL is the only methodology that provides a machinery for fuzzy information granulation. In the figure, the core concept of fuzzy granulation is represented as the conjunction F. G.

The point of departure in fuzzy logic is the concept of a fuzzy set. A fuzzy set A in a universe U is characterized by its grade of membership μ_A, which associates with every point u in U its grade of membership $\mu_A(u)$, with $\mu_A(u)$ taking values in the unit interval [0,1]. More generally, μ_A may take values in a partially ordered set. For crisp sets, the concept of a membership function reduces to the familiar concept of a characteristic function, with $\mu_A(u)$ being 1 or 0 depending, respectively, on whether u belongs or does not belong to A.

Two interpretations of A play basic roles in fuzzy logic: *possibilistic* and *veristic.* More specifically, assume that X is a variable taking values in U, and A is a fuzzy set in U. In the possibilistic interpretation, in the proposition X is A, A plays the role of the possibility distribution of X, and $\mu_A(u)$ is the possibility that X can take the value u. In the veristic interpretation, $\mu_A(u)$ is the truth value (verity) of the proposition $X = u$. As an illustration, in the proposition *Mary is young* if $\mu_{young}(25) = 0.8$, then the possibility that Mary is twenty-five given that *Mary is young* is 0.8. Reciprocally, given that *Mary is 25,* the truth value (verity) of the proposition *Mary is young* is 0.8.

In addition to the concept of a fuzzy set, the basic concepts in fuzzy logic are those of a linguistic variable, fuzzy if-then rule, and fuzzy graph. In combination, these concepts provide a foundation for the theory of fuzzy information granulation (Zadeh 1997), the calculus of fuzzy if-then rules (Zadeh 1996a), and, ultimately, the methodology of computing with words (Zadeh 1996b). Most of the practical applications of fuzzy logic, especially in the realm of control and information/intelligent systems, involve the use of the machinery of computing with words.

Fuzzy if-then rules can assume a variety of forms. The simplest rule can be expressed as: if X is A then Y is B, where X and Y are variables taking values in universes of discourse U and V, respectively; and A and B are fuzzy sets in U and V. Generally, A and B play the role of linguistic values of X and Y; for example, if Pressure is high then Volume is low. In practice, the membership functions of A and B are usually triangular or trapezoidal.

A fuzzy graph is a union of fuzzy points (granules) each of which represents a fuzzy if-then rule. A fuzzy graph of a function f may be interpreted as a granular approximation to f. In most of the practical applications of fuzzy logic, fuzzy graphs are employed in this role as granular approximations to functions and relations.

In computing with words, the initial data set (IDS) and the terminal data set (TDS) are assumed to consist of collections of propositions expressed in a natural language. An input interface transforms IDS into a system of fuzzy constraints that are propagated from premises to conclusions through the use of the inference rules in fuzzy logic. The output interface transforms the conclusions into TDS.

The machinery for computing with words instead of or in addition to numbers may be viewed as one of the principal contributions of fuzzy logic. In a way, computing with words may be regarded as a step toward a better understanding of the remarkable human ability to perform complex tasks without any measurements and any numerical computations.

Game-Playing Systems

Games have long been popular in Artificial Intelligence as idealized domains suitable for research into various aspects of search, KNOWLEDGE REPRESENTATION, and the interaction between the two. CHESS, in particular, has been dubbed the "Drosophila of Artificial Intelligence" (McCarthy 1990), suggesting that the role of games in Artificial Intelligence is akin to that of the fruit fly in genetic research. In each case, certain practical advantages compensate for the lack of intrinsic importance of the given problem. In genetic

research. In each case, certain practical advantages compensate for the lack of intrinsic importance of the given problem. In genetic research, fruit flies make it easy to maintain large populations with a short breeding cycle at low cost. In Artificial Intelligence research, games generally have rules that are well defined and can be stated in a few sentences, thus allowing for a relatively straightforward computer implementation. Yet the combinatorial complexity of interesting games can create immensely difficult problems. It has taken many decades of research combined with sufficiently powerful computers in order to approximate the level of leading human experts in many popular games. And in some games, human players still reign supreme.

Games can be classified according to a number of criteria, among them number of players, perfect versus hidden information, presence of a stochastic element, zero-sum versus non-zero-sum, average branching factor, and the size of the state space. Different combinations of characteristics emphasize different research issues. Much of the early research in game-playing systems concentrated on two-person zero-sum games of perfect information with low or moderate branching factors, in particular chess and checkers. Claude Shannon's 1950 paper on programming a computer to play chess mapped out much territory for later researchers. Alan TURING wrote a chess program (Turing et al. 1953), which he hand-simulated in the early 1950s. The earliest fully functioning chess program was described in Bernstein et al. (1958). The first chess program demonstrably superior to casual human chess players appeared in the mid-sixties (Greenblatt et al. 1967), and progress continued as faster machines became available and algorithms were refined (Slate and Atkin 1977; Condon and Thompson 1982; Hyatt, Gower, and Nelson 1990; Berliner and Ebeling 1990; Hsu et al. 1990). But it took until 1997 for a computer, the IBM Deep Blue chess machine, to defeat the human world chess champion, Gary Kasparov, in a regulation match.

Much of the success in game-playing systems has come from approaches based on depth-first minimax search with alpha-beta pruning in two-person zero-sum games of perfect information. This is essentially a brute-force search technique, searching forward as many moves as possible in an allotted time, assessing positions according to an evaluation function, and choosing the best move based on the minimax principle. The evaluation function captures essential domain knowledge. In fact, there is often a trade-off between the quality of the evaluation function and the depth of search required to achieve a given level of play. Minimax search is made more efficient through the use of alpha-beta pruning (Knuth and Moore 1975), which allows searching roughly twice as deep as would be possible in a pure minimax search. Notable examples of this approach include Deep Blue; Chinook (Schaeffer et al. 1992), which has defeated the world's best checkers players; and Logistello (Buro 1995), which has easily beaten the top human Othello players. The methods used in these programs and others of this type have been constantly improved and refined, and include such techniques as iterative deepening, transposition tables, null-move pruning, endgame databases, and singular extensions, as well as increasingly sophisticated evaluation functions.

In spite of the success of high-performance alpha-beta-based game-playing systems, there has been limited transference of ideas generated in this work to other areas of Artificial Intelligence (although see, for example, Newborn's work on theorem proving; Newborn 1992). There are, however, many alternatives to minimax alpha-beta that have been examined. Conspiracy numbers search (McAllester 1988) counts the number of positions whose evaluations must change in order for a different move choice to be made. This idea has led to methods that are capable of solving some interesting nontrivial games (Allis 1994). Decision-theoretic approaches to game playing, particularly under constraints of limited resources (BOUNDED RATIONALITY), are promising and have broad applicability outside the game-playing area. For example, Russell and Wefald (1991) reasoned specifically about when to terminate a search, based on the expected utility of further search and the cost of the time required for the additional work. Statistical methods for search and evaluation (Baum and Smith 1997) also have shown promise, adding uncertainty to a standard evaluation function and then using the inexact statistical information to approximate the exploration of the most important positions.

MACHINE LEARNING has a long history of using games as domains for experimentation. Samuel's checkers program (Samuel 1959), originally developed in the 1950s, employed both a rote-learning scheme and a method for tuning the coefficients of his evaluation function. Many current chess and Othello programs use forms of rote learning to avoid losing the same game twice. The Logistello program has also used an automatically tuned evaluation function with excellent results. However, the most noteworthy example of learning in game-playing systems is TD-Gammon (Tesauro 1995), a neural network program for playing backgammon. For games with stochastic elements, for instance the dice in backgammon, forward searching approaches are less efficient, which places a premium on the quality of the evaluation function. TD-Gammon used a reinforcement learning algorithm to train its neural network solely by playing against itself and learning from the results. This network, with or without some limited search, produces world-class play in backgammon (Tesauro and Galperin 1997). Reinforcement learning also has applications in other decision making and scheduling problems.

Some games are very difficult for computers at the present time. Go programs are actively being developed (Chen et al. 1990), but are far from the level of the best human players. The alpha-beta search paradigm, which is so successful in chess, checkers, and the like, is not directly applicable to Go because of the large branching factor. More subtle approaches involving decomposition of a game state into subproblems appear to be necessary. Hidden information games, such as bridge, are also not appropriate for direct application of the alpha-beta ALGORITHM, and have begun to receive more attention (Ginsberg 1996). Some other games are too difficult for even initial attempts. For example, in the game of Nomic (Suber 1990) a player's turn involves an amendment or addition to an existing set of rules. Initially players vote on proposed changes, but the game can evolve into something completely different. There

is no clear way at present to design a game-playing system to play a game such as Nomic due to the tremendous amount of world knowledge required.

Game-playing systems have helped illustrate the role of search and knowledge working together in systems for solving complex problems, but games have also been useful as domains for experimentation with various types of machine learning and HEURISTIC SEARCH. The absence of significant learning capabilities in most game-playing systems, as well as the difficulty in creating high-performance programs for games such as Go, suggest that games are still fertile domains for Artificial Intelligence research.

Game Theory

Game theory is a mathematical framework designed for analyzing the interaction between several agents whose decisions affect each other. In a game-theoretic analysis, an interactive situation is described as a *game*: an abstract description of the players (agents), the courses of actions available to them, and their preferences over the possible outcomes. The game-theoretic framework assumes that the players employ RATIONAL DECISION MAKING, that is, they act so as to achieve outcomes that they prefer (VON NEUMANN and Morgenstern 1944). Typically, preferences are modeled using numeric utilities, and players are assumed to be expected utility maximizers.

Unlike decision making for a single agent, in the multiagent case this assumption is not enough to define an "optimal decision," because the agent cannot unilaterally control the outcome. One of the roles of game theory is to define notions of "optimal solution" for different classes of games. These solutions assume that players reason strategically, basing their decisions on their expectations regarding the behavior of other players. Typically, players are assumed to have *common knowledge* that they are all rational (see MODAL LOGIC).

A large part of game theory deals with noncooperative situations, where each player acts independently. In such a game, a *strategy* s_i for player i specifies the action player i should take in any state of the game. A *solution* to the game is a strategy combination $s_1, \ldots, s_n$ satisfying certain optimality conditions.

Most abstractly, a situation is represented as a *strategic form* game, where the possible strategies for the players are simply enumerated. Each strategy combination $s_1, \ldots, s_n$ leads to some outcome, whose value to player i is a payoff $u_i(s_1, \ldots, s_n)$. A two-player strategic form game is often represented by a matrix where the rows are player 1 strategies, the columns are player 2 strategies, and the matrix entries are the associated payoff pairs.

	heads	tails
heads	1, -1	-1, 1
tails	-1, 1	1, -1

(a)

	silent	confess
silent	-1,-1	0,-10
confess	-10,0	-8,-8

(b)

Figure 1. (a) Flipping Pennies. (b) Prisoner's Dilemma: Two conspirators, in prison, are each given the opportunity to confess in return for a reduced prison sentence; the payoffs correspond to numbers of years in prison.

The simplest game is a two-player *zero-sum* game, where the players' interests are completely opposed (see figure 1). Because any gain for one player corresponds to a loss for the other, each player should make a worst-case assumption about the behavior of the other. Thus, it appears that player 1 should choose the *maximin* strategy s_1^* that achieves $\max_{s_1^i} \min_{s_1^j} u_1(s_1^i, s_1^j)$; player 2 has an analogous rational strategy s_2^*. Common knowledge of rationality implies that the "rational" strategy of one player will be known to the other. However, s_1^* may not be optimal against s_2^*, making it irrational for player 1 to play as anticipated. This circularity can be avoided if we allow the players to use randomness. In game (a), player 2 can play the *mixed* strategy μ_2^* where he chooses heads and tails each with probability *1/2*. If each player plays the maximin mixed strategy μ_i^*, we avoid the problem: μ_1^* and μ_2^* are in equilibrium, that is, each is optimal against the other (von Neumann and Morgenstern 1944).

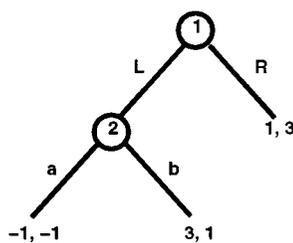
The equilibrium concept can be extended to general *n*-player games. A strategy combination $\mu_1^* \ldots \mu_n^*$ is said to be in *Nash equilibrium* (Nash 1950) if no player *i* can benefit by deviating from it (playing a strategy $\mu_i \neq \mu_i^*$). In game (b), the (unique) equilibrium is the nonrandomized strategy combination (confess, confess). An equilibrium in mixed strategies is always guaranteed to exist.

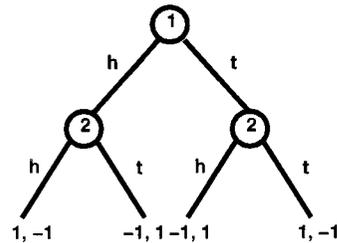
The Nash equilibrium is arguably the most fundamental concept in noncooperative games. However, several problems reduce its intuitive appeal. Many games have several very different equilibria. In such games, it is not clear which equilibrium should be the "recommended solution," nor how the players can pick a single equilibrium without communication. One important mechanism that addresses these concerns is based on the assumption that the game is played repeatedly, allowing players to adapt their strategies gradually over time (Luce and Raiffa 1957; Battigalli, Gilli, and Milinari 1992). This process is a variant of multiagent REINFORCEMENT LEARNING. Some variants are related to BAYESIAN LEARNING (Milgrom and Roberts 1989). Others are related to the evolution of biological populations, and have led to a branch of game theory called *evolutionary games* (Maynard Smith 1982).

Furthermore, many equilibria are unintuitive. In game (b), the Nash equilibrium has a utility of *–8,–8*, which is worse for both players than the "desired" outcome *–1,–1*. There have been many attempts to find alternative models where the desired outcome is the solution. Some success has been achieved in the case of infinitely repeated play where the players have BOUNDED RATIONALITY (e.g., when their strategies are restricted to be finite-state AUTOMATA; Abreu and Rubenstein 1992).

A more refined representation of a game takes into consideration the evolution of the game. A game in *extensive form* (Kuhn 1953) is a tree whose edges represent possible actions and whose leaves represent outcomes. Most simply, the players have *perfect information*—any action taken is revealed to all players.

The notion of equilibrium often leads to unintuitive results when applied to extensive-form games. For example, in game (a), the strategy combination (*R, a*) is one equilibrium: given that player 2 will play *a*, player 1 prefers *R*, and given that player 1 plays *R*, player 2's choice is irrelevant. This equilibrium is sustained only by a noncredible "threat" by player 2 to play the suboptimal move *a*. The extensive-form equilibrium concept has been refined to deal with this issue, by adding the requirement that, at each point in the game, the player's chosen action be optimal (Selten 1965). In our example, the optimal move for player 2 is *b*, and therefore player 1's optimal action is *L*. This process, whereby optimal moves are selected at the bottom of the tree, and these determine optimal moves higher up, is called *backward induction*. In the context of zero-sum games, the algorithm is called the *minimax algorithm,* and is the fundamental technique used in GAME-PLAYING SYSTEMS.

The extensive form also includes imperfect information games (Kuhn 1953): the tree is augmented with *information sets,* representing sets of nodes among which the player cannot distinguish. For example, a simultaneous-move game such as Flipping Pennies can be represented as in figure (2). Clearly, imperfect information games require the use of randomization in order to guarantee the existence of a Nash


(a)


(b)

Figure 2. (a) Unintuitive equilibrium. (b) Flipping Pennies.

equilibrium. Refinements of the Nash equilibrium concept addressing the temporal sequencing of decisions have also been proposed for imperfect information games (Kreps and Wilson 1982; Selten 1975; Fudenberg and Tirole 1991), largely based on the intuition that the player's actions must be optimal relative to his or her *beliefs* about the current state.

Game theory also deals with *cooperative* games, where players can form coalitions and make binding agreements about their choice of actions (von Neumann and Morgenstern 1944; Luce and Raiffa 1957; Shapley and Shubik 1953). In this case, the outcome of the game is determined by the coalition that forms and the joint action it takes. The game-theoretic models for such situations typically focus on how the payoff resulting from the optimal group action is divided between group members. Various solution concepts have been proposed for coalition games, essentially requiring that the payoff division be such that no subgroup is better off by leaving the coalition and forming another (see Aumann 1989 for a survey).

Game theory is a unified theory for rational decision making in multiagent settings. It encompasses bargaining, negotiation, auctions, voting, deterrence, competition, and more. It lies at the heart of much of economic theory, but it has also been used in political science, government policy, law, military analysis, and biology (Aumann and Hart 1992, 1994, 1997). One of the most exciting prospects for the future is the wide-scale application of game theory in the domain of autonomous computer agents (Rosenschein and Zlotkin 1994; Koller and Pfeffer 1997).

Generative Grammar

The motivating idea of generative grammar is that we can gain insight into human language through the construction of explicit grammars. A language is taken to be a collection of structured symbolic expressions, and a generative grammar is simply an explicit theoretical account of one such collection.

Simple finite sets of rules can describe infinite languages with interesting structure. For example, the following instruction describes all palindromes over the alphabet {*A*, *B*}:

Start with *S* and recursively replace *S* by *ASA*, *BSB*, or nothing.

We prove that *ABBA* is a palindrome by constructing the sequence *S—ASA—ABSBA—ABBA*, which represents a *derivation* of the string. The instruction, or rule, constitutes a generative grammar for the language comprising such palindromes; for every palindrome over the alphabet {A,B} the grammar provides a derivation. *S* can be regarded as a grammatical category analogous to a sentence, and *A* and *B* are analogous to words in a language.

The following condition on nodes in trees turns out to be equivalent to the above grammar:

Nodes labeled *S* have left and right daughters either both labeled *A* or both labeled *B;* optionally these are separated by a node labeled *S;* nodes labeled *A* or *B* have no daughters.

If a set of trees *T* satisfies this condition, then its frontier (the sequence of daughterless nodes) is a palindrome of *A*'s and *B*'s; and any such palindrome is the frontier of some such tree. This is a declarative definition of a set of trees, not a procedure for deriving strings. But it provides an alternative way of defining the same language of strings, a different type of generative grammar.

Studying English in generative terms involves trying to determine whether some finite set of rules could generate the entire set of strings of words that a native speaker of (say) English would find acceptable. It presumably is possible, because speakers, despite their finite mental capacities, seem to have a full grasp of what is in their language.

A fundamental early insight was that limitations on the format of rules or constraints set limits on definable languages, and some limits are too tight to allow for description of languages like English. String-rewriting rules having the form "rewrite *X* as *wY*," where *w* is a string of words and *X* and *Y* are grammatical categories, are too weak. (This limitation would make grammars exactly equivalent to finite automata, so strictly speaking English cannot be recognized by any finite computer.) However, if limits are too slack, the opposite problem emerges: the theory may be Turing-equivalent, meaning that it provides a grammar for any recursively enumerable set of strings. That means it does not make a formal distinction between natural languages and any other recursively enumerable sets. Building on work by Zellig Harris, Chomsky (1957) argued that a grammar for English needed to go beyond the sort of rules seen so far, and must employ transformational rules that convert one structural representation into another. For example, using transformations, passive sentences might be described in terms of a rearrangement of structural constituents of corresponding active sentences:

Take a subjectless active sentence structure with root label *S* and move the postverbal noun phrase leftward to become the subject (left branch) of that *S*.

Several researchers (beginning with Putnam 1961) have noted that transformational grammars introduce the undesirable property of Turing-equivalence. Others, including Chomsky, have argued that this is not a vitiating result.

Generative grammatical study and the investigation of human mental capacities have been related via widely discussed claims, including the following:

1. People tacitly know (and learn in infancy) which sentences are grammatical and meaningful in their language.
2. They possess (and acquire) such knowledge even about novel sentences.
3. Therefore they must be relying not on memorization but on mentally represented rules.
4. Generative grammars can be interpreted as models of mentally represented rule sets.
5. The ability to have (and acquire) such rules must be a significant (probably species-defining) feature of human minds.

Critics have challenged all these claims. (It has been a key contribution of generative grammar to cognitive science to have stimulated enormous amounts of interesting critical discussion on issues of this sort.) Psycholinguistic studies of speakers' reactions to novel strings have been held to undercut (1). One response to (2) is that speakers might simply generalize or analogize from familiar cases. Regarding (3), some philosophers object that one cannot draw conclusions about brain inscriptions (which are concrete objects) from properties of sentences (arguably abstract objects). In response to (4), it has been noted that the most compact and nonredundant set of rules for a language will not necessarily be identical with the sets people actually use, and that the Turing-equivalence results mean that (4) does not imply any distinction between being able to learn a natural language and being able to learn any arbitrary finitely representable subject matter. And primatologists have tried to demonstrate language learning in apes to challenge (5).

Two major rifts appeared in the history of generative grammar, one in the years following 1968 and the other about ten years later. The first rift developed when a group of syntacticians who became known as the generative semanticists suggested that syntactic investigations revealed that transformations must act directly on semantic structures that looked nothing like superficial ones (in particular, they did not respect basic constituent order or even integrity of words), and might represent *They persuaded Mike to fell the tree* thus (a predicate-initial representation of clauses is adopted here, though this is not essential):

[_S*PAST* [_S*CAUSE they* [_S*AGREE Mike* [_S*CAUSE Mike* [_S*FALL the tree*]]]]].

The late 1960s and early 1970s saw much dispute about the generative semantics program (Harris 1993), which ultimately dissolved, though many of its insights have been revived in recent work. Some adherents became interested in the semantic program of logician Richard Montague (1973), bringing the apparatus of model-theoretic semantics into the core of theoretical linguistics; others participated in the development of RELATIONAL GRAMMAR (Perlmutter and Postal 1983).

The second split in generative grammar, which developed in the late 1970s and persists to the present, is between those who continue to employ transformational analyses (especially movement transformations) and hence derivations, and those who by 1980 had completely abandoned them to formulate grammars in constraint-based terms. The transformationalists currently predominate. The constraint-based minority is a heterogenous group exemplified by the proponents of, inter alia, relational grammar (especially the formalized version in Johnson and Postal 1980), HEAD-DRIVEN PHRASE STRUCTURE GRAMMAR (Pollard and Sag 1994), LEXICAL FUNCTIONAL GRAMMAR (Bresnan and Kaplan 1982), and earlier frameworks including tree adjoining grammar (Joshi, Levy, and Takahashi 1975) and generalized phrase structure grammar (Gazdar et al. 1985).

In general, transformationalist grammarians have been less interested, and constraint-based grammarians more interested, in such topics as COMPUTATIONAL LINGUISTICS and the mathematical analysis of properties of languages (sets of expressions) and classes of formalized grammars.

Transformationalists formulate grammars procedurally, defining processes for deriving a sentence in a series of steps. The constraint-based minority states them declaratively, as sets of constraints satisfied by the correct structures. The derivational account of passives alluded to above involves a movement transformation: a representation like

[[$_{NP}$___] *PAST made* [$_{NP}$ *mistakes*] ([$_{PP}$ *by* people]])

is changed by transformation into something more like

[[$_{NP}$ *mistakes*] *were made* [$_{NP}$___]] ([$_{PP}$ *by* people]])

The same facts might be described declaratively by means of constraints ensuring that for every transitive verb *V* there is a corresponding intransitive verb *V** used in such a way that *for B to be V*ed by A means the same as for A to V B*. This is vague and informal, but may serve to indicate how passive sentences can be described without giving instructions for deriving them from active structures, yet without missing the systematic synonymy of actives and their related passives.

There is little explicit debate between transformationalists and constraint-based theorists, though there have been a few interchanges on such topics as (1) whether a concern with formal exactitude in constructing grammars (much stressed in the constraint-based literature) is premature at the present stage of knowledge; (2) whether claims about grammars can sensibly be claimed to have neurophysiological relevance (as transformationalists have claimed); and (3) whether progress in computational implementation of nontransformational grammars is relevant to providing a theoretical argument in their favor.

At least two topics can be identified that have been of interest to both factions within generative grammar. First, broadening the range of languages from which data are drawn is regarded as most important. The influence of relational grammar during the 1980s helped expand considerably the number of languages studied by generative grammarians, and so did the growth of the community of generative grammarians in European countries after 1975. Second, the theoretical study of how natural languages might be learned by infants—particularly how SYNTAX is learned—has been growing in prominence and deserves some further discussion here.

Transformationalists argue that what makes languages learnable is that grammars differ only in a finite number of parameter settings triggered by crucial pieces of evidence. For example, identifying a clause with verb following object might trigger the "head-final" value for the head-position parameter, as in Japanese (where verbs come at the ends of clauses), rather than the "head-initial" value that characterizes English. (In some recent transformationalist work having the head-final parameter actually corresponds to having a required leftward movement of postverbal constituents into preverbal positions, but the point is that it is conjectured that only finitely many distinct alternatives are made available by universal grammar.) Theories of learning based on this idea face significant computational problems, because even quite simple parameter systems can define local blind alleys from which a learning algorithm cannot escape regardless of further input data (see Gibson and Wexler 1995).

The general goal is seen as that of overcoming the problem of the POVERTY OF THE STIMULUS: the putative lack of an adequate evidential basis to support induction of a grammar via general knowledge acquisition procedures (see LEARNING SYSTEMS and ACQUISITION, FORMAL THEORIES OF).

Nontransformationalists are somewhat more receptive than transformationalists to the view that the infant's experience might not be all that poverty-stricken: once one takes account of the vast amount of statistical information contained in the corpus of observed utterances (see STATISTICAL TECHNIQUES IN NATURAL LANGUAGE PROCESSING), it can be seen that the child's input might be rich enough to account for language acquisition through processes of gradual generalization and statistical approximation. This idea, familiar from pre-1957 structuralism, is reemerging in a form that is cognizant of the past four decades of generative grammatical research without being wholly antagonistic in spirit to such trends as CONNECTIONIST APPROACHES TO LANGUAGE. The research on OPTIMALITY THEORY that has emerged under the influence of connectionism meshes well both with constraint-based approaches to grammar and with work on how exposure to data can facilitate identification of constraint systems.

There is no reason to see such developments as being at odds with the original motivating idea of generative grammar, inasmuch as rigorous and exact description of human languages and what they have in common—that is, a thorough understanding of what is acquired—is surely a prerequisite to any kind of language acquisition research, whatever its conclusions.

Geschwind, Norman

Norman Geschwind (1926–1984) was an eminent American neurologist whose major contribution was to help revive the CORTICAL LOCALIZATION-based anatomophysiological analysis of human behavior and behavioral disorders typical of the approach of the last decades of the nineteenth century. In this way, in the early 1960s and almost single-handedly, he brought the study of behavior back into the framework of neurology and away from purely behavioral explanations characteristic of most of the first half of the twentieth century. Thus, he helped to pave the way to what is now the domain of cognitive neuroscience. His research interests included the study of brain connections as a way of explaining the neural basis and disorders of language, knowledge, and action (Geschwind 1965a, 1965b), the study of HEMISPHERIC SPECIALIZATION and its biological underpinnings (Geschwind and Levitsky 1968; Geschwind and Galaburda 1984), and the study of developmental learning disorders such as DYSLEXIA (Geschwind and Galaburda 1987).

Geschwind was born in New York City on January 8, 1926 (for a more extensive biographical sketch, see Gala-

burda 1985 and Damasio and Galaburda 1985). His parents had emigrated from Poland at the turn of the century. Geschwind graduated from Boys' High School in Brooklyn, New York, in 1942, and attended Harvard College on a Pulitzer Scholarship from 1942 until 1944, when his studies were interrupted by service in the United States Army in the last years of World War II. After the war, Geschwind finished his undergraduate studies and then attended Harvard Medical School. After graduation in 1951 he carried out an internship at Boston's Beth Israel Hospital (to which he would return at the end of his life as chair of neurology). Afterward Geschwind traveled to England to study muscle physiology with neurologist Ian Simpson at the National Hospital in Queen Square. He returned from London to continue his neurological training under Derek Denny-Brown at the Boston City Hospital. In 1958, Geschwind joined Fred Quadfasel at the Boston's Veterans Administration Hospital, where his education and work on the neurology of behavior began. When Quadfasel retired in 1963, Geschwind replaced him as chief of service and remained at that post until 1969. That year Geschwind returned to Harvard as the James Jackson Putnam Professor of Neurology and chief of the neurological unit of Boston City Hospital. He continued to be involved in the APHASIA Research Center, which he had founded while at the Veterans Hospital.

Initially Geschwind was influenced in his thinking about behavior by the holistic views of Hughlings Jackson, Kurt Goldstein, Henry Head, and Carl LASHLEY (Geschwind 1964). In the early 1960s, however, he was seduced by the style of explanation of neurologists BROCA, Wernicke, Bastian, Dejerine, and Charcot, and others, which relied heavily on anatomical relationships among areas of the brain by way of neural connections. From that time on Geschwind became the clearest and most forceful and incisive champion of this localizationist approach to the understanding of behavior and behavioral disorders. Geschwind's analysis of the case of a patient with a brain tumor who could write correct language with his right hand but not with his left showed the power of this approach and launched Geschwind's career as a behavioral neurologist (Geschwind and Kaplan 1962). The explanation was damage to the large bundle of neural connections linking the two hemispheres of the brain, the corpus callosum, whose importance was also being recognized by the neurobiologist Roger SPERRY through his work with monkeys. Additional reports and impressive review of the world's literature led to Geschwind's famous two-part paper in the journal *Brain*, 'Disconnexion syndromes in animals and man' (1965a and b). The clarity of exposition and conviction about the power of the anatomical method produced a strong following and established Geschwind as the leading figure in American behavioral neurology, which he remained until his death.

Irked by a statement by the anatomist Gerhard von Bonin that there were no anatomical asymmetries in the human brain to account for the striking hemispheric specialization the brain exhibits, Geschwind undertook his own literature review and laboratory studies and published an important paper, together with Walter Levitsky, which disclosed striking asymmetries in a region of the temporal lobe, in an area important to language, called the planum temporale

(Geschwind and Levitsky 1968). Several others confirmed these findings, and the paper stimulated a great deal of additional research on brain asymmetries, some of which are still actively studied using anatomical brain imaging techniques such as computed assisted tomography (CAT scans) and MAGNETIC RESONANCE IMAGING (MRI scans) in living subjects, as well as functional MRI and POSITRON EMISSION TOMOGRAPHY (PET).

During the last few years of his life Geschwind became interested in developmental learning disabilities. In Geschwind's mind, strict localization theory began to give way to localization with NEURAL PLASTICITY resulting from early extrinsic influences on brain development occurring in utero or soon after birth. These effects were capable of changing standard patterns of brain asymmetry and could lead to developmental learning disorders. His keen clinical acumen led to his noticing that mothers of dyslexic children often reported left-handedness, atopic illnesses such as asthma, and autoimmune diseases such as hypothyroidism. In an epidemiological study carried out with Peter Behan in London, they showed an association between stuttering, dyslexia, colitis, thyroid disease, and myasthenia gravis in left-handers (Geschwind and Behan 1983). This work engendered massive additional research and debate and may constitute Geschwind's most creative contribution to new knowledge. Since his death a slightly larger number of reports have found support for this last of Geschwind's insight than the number finding no support.

Norman Geschwind wrote more than 160 journal articles and books, and his name became a household word among not only neurologists but also psychologists, philosophers of mind, educators, and neurobiologists. He was recognized by many prizes, honorary degrees, and visiting professorships, which led him to travel widely. He spoke several languages and possessed a strong memory, a sharp logical mind, and a broad culture, which turned him into a powerful adversary in debate and discussion. He left a legacy of knowledge and ideas, as well as a long list of students and followers, many of whom became leaders in behavioral neurology in the United States and abroad.

Gestalt Perception

Gestalt perception is the name given to various perceptual phenomena and theoretical principles associated with the school of GESTALT PSYCHOLOGY (Koffka 1935). Its most important contributions concerned *perceptual organization*: the nature of relations among parts and wholes and how they are determined. Previously, perceptual theory was dominated by the *structuralist* proposal that complex perceptions were constructed from *atoms* of elementary color sensations and unified by *associations* due to spatial and temporal contiguity. Gestalt theorists rejected both assumptions, arguing that perception was *holistic* and *organized* due to interactions between stimulus structure and underlying brain processes.

Wertheimer (1923) posed the problem of perceptual organization in terms of how people manage to perceive organized scenes consisting of surfaces, parts, and whole objects coherently arranged in space rather than the chaotic, dynamic juxtaposition of millions of different colors registered by retinal receptors. He attempted to answer this question by identifying stimulus factors that caused simple arrays of elements to be perceived as organized in distinct groups. The factors he identified are usually called the *laws* (or *principles*) *of grouping*, several of which are illustrated in figures A–F: *proximity* (A), *similarity of color* (B), *similarity of size* (C), *common fate* (D), *good continuation* (E), and *closure* (F). More recently other principles have been identified (Palmer and Rock 1994), including *common region* (G) and *element connectedness* (H). In each case, elements that have a stronger relation in terms of the specified property (i.e., those that are closer, more similarly colored, etc.) tend to be grouped together. These "laws" are actually *ceteris paribus rules*: all else being equal, the elements most closely related by the specified factor will be grouped together. They cannot predict the result when two or more factors vary in opposition because the rules fail to specify how multiple factors are integrated. No general theory has yet been formulated that overcomes this problem.

A second important phenomenon of Gestalt perception is *figure-ground organization* (Rubin 1921). In figure I, for instance, one can perceive either a white object on a black background or a black object on a white background. The crucial feature of figure-ground organization is that the boundary is perceived as belonging to the figural region. As a result, it seems "thing-like," has definite shape, and appears closer, whereas the ground appears farther and to extend behind the figure. Gestalt psychologists identified several factors that govern figure-ground organization,

Figure 1.

the *rod-and-frame effect* (P), observers perceive an upright rod as tilted when it is presented inside a large tilted rectangle in an otherwise darkened environment (Asch and Witkin 1948), much as one perceives a vertical chandelier as hanging askew inside a tilted room in a fun house. Larger, surrounding objects or surfaces thus tend to be taken as the frame of reference for the smaller objects they enclose.

Several other organizational phenomena are strongly identified with the Gestalt approach to perception. *Amodal completion* refers to the perception of partly visible figures as completed behind an occluding object. Figure Q, for example, is invariably perceived as a complete circle behind a square even though only three-fourths of it is actually showing. *Illusory contours* refer to the perception of a figure defined by edges that are not physically present in the image. As figure R illustrates, an illusory figure is perceived when aligned contours in the inducing elements cause them to be seen as partly occluded by a figure that has the same color as the background (Kanisza 1979). *Color scission* (figure S) refers to the splitting of perceived color into one component due to an opaque figure and another component due to a translucent figure through which the farther figure is seen (Metelli 1974).

Although these examples do not exhaust the perceptual contributions of Gestalt psychologists and their followers, they are representative of the phenomena they studied in the visual domain. They also investigated the perceptual organization of sounds, a topic that has been extended significantly by modern researchers (Bregman 1990). Recent studies of PERCEPTUAL DEVELOPMENT demonstrate that, contrary to the nativistic beliefs of Gestalt theorists, most principles of organization are not present at birth, but develop at different times during the first year of life (Kellman and Spelke 1983).

Theoretically, Gestalt psychologists maintained that these phenomena of perceptual organization support *holism*, the doctrine that the whole is different from the sum of its parts. They attempted to explain such holistic effects in terms of their *principle of Prägnanz* (or *minimum principle*), the claim that the percept will be as "good" as the stimulus conditions allow. This means that the preferred organization should be the simplest, most regular possibility compatible with the constraints imposed by the retinal image. Unfortunately, they did not provide an adequate definition of goodness, simplicity, or regularity, so their central claim was untestable in any rigorous way. Later theorists have attempted to ground these concepts in objective analyses, suggesting that simple perceptions correspond to low information content, economy of symbolic representation, and/or minimal transformational distance. Non-Gestalt theorists typically appeal instead to HELMHOLTZ's *likelihood principle* that the perceptual system is biased toward the most likely (rather than the simplest) interpretation. The difficulty in discriminating between these two alternatives arises in part from the fact that the most likely interpretation is usually the simplest in some plausible sense. (See Pomerantz and Kubovy 1986 for a review of this issue.)

Most phenomena of Gestalt perception have resisted explanation at computational, algorithmic, and physiological levels. Köhler (1940) suggested that the best organization

including *surroundedness* (J), *size* (K), *contrast* (L), *convexity* (M), and *symmetry* (N). These principles are also *ceteris paribus* rules: all else being equal, the surrounded, smaller, higher contrast, more convex, or symmetrical region tends to be seen as the figure. They therefore suffer from the same problem as the laws of grouping: they cannot predict the result when two or more factors conflict.

A third important phenomenon of Gestalt perception is that certain properties of objects are perceived relative to a *frame of reference.* MOTION and orientation provide two compelling examples. In *induced motion* (O), a slowly moving larger object surrounds a smaller stationary object in an otherwise dark environment. Surprisingly, observers perceive the frame as still and the dot as moving in the opposite direction (Duncker 1929)—for example, when the moon appears to move through a cloud that appears stationary. In

was achieved by *electromagnetic fields* in the CEREBRAL CORTEX that settled into states of *minimum energy*, much as soap bubbles stabilize into perfect spheres, which are minimal in both energy and complexity. Although subsequent physiological findings have discredited the brain-field conjecture, the more abstract idea of a *physical Gestalt* is compatible with modern investigations of RECURRENT NETWORKS (e.g., Grossberg and Mingolla 1985) that converge on a solution by reaching a minimum in an energy-like function. This suggests new theoretical approaches to the many important organizational phenomena Gestalt psychologists discovered more than a half century ago.

Gestalt Psychology

The scope of Gestalt psychology goes beyond its origins in research on perception. The founder of the Gestalt school,
Max Wertheimer, invested much of his energies in other topics, such as epistemology (Wertheimer 1934), ethics (1935), problem solving (1920), and creativity (1959/1978; see also Duncker 1945/1972; Luchins 1942). Koffka, one of Wertheimer's foremost collaborators, devoted more than half of his *Principles of Gestalt Psychology* (1935) to attitudes, emotion, the will, memory (see also Wulf 1921; Restorff 1933), learning, and the relations between society and personality (see also Lewin 1935; Dembo 1931/1976). Köhler, the third member of the leadership of the Gestalt school, did research on the insightful problem-solving of apes (1921/1976) and wrote about ethics (claiming that value is an emergent property of situations) and *requiredness* (1938), which anticipates Gibson's notion of AFFORDANCES.

After the dismantling of German psychology—beginning with the coming to power of Hitler in 1933—American psychology, dominated by doctrinaire BEHAVIORISM, was disdainful of cognitive ideas and saw Gestalt psychology as outmoded and suspiciously vitalistic. These suspicions were reinforced by the views of some Gestalt psychologists about the way the brain creates Gestalts, views that seemed to have been spectacularly refuted (for a summary, see Pomerantz and Kubovy 1981). It was perhaps for this reason that during this period, the influence of Gestalt psychologists—many of whom were refugees from Nazi Germany—on American psychology was felt mostly in social psychology (e.g., Lewin 1951; Heider 1958/1982; Krech and Crutchfield 1948) and psychology of art (e.g., Arnheim 1974, 1969), which were not under the control of behaviorists and were not concerned with brain theory (Zajonc 1980).

During the eclipse of Gestalt psychology as cognitive psychology, some of the questions posed by the Gestalt psychologists were kept alive by Attneave (1959), Garner (1974), Goldmeier (1973), and Rock (1973). A more general revival of these questions took place in the early 1980s with the publication of three edited books: Kubovy and Pomerantz (1981), Beck (1982), and Dodwell and Caelli (1984).

Gestalt psychology can be characterized by four main features: (1) its method: phenomenology; (2) its attitude towards REDUCTIONISM: brain-experience isomorphism; (3) its focus of investigation: part-whole relationships; (4) its theoretical principle: Prägnanz (Pomerantz and Kubovy 1981; Epstein and Hatfield 1994). Let us consider these features one by one.

Phenomenology. The application of phenomenology to perception involves a descriptive text laced with pictures (exemplified by GESTALT PERCEPTION, and Ihde 1977). According to Bozzi (1989: chap. 7), a conventional psychological experiment (in any field of psychology) differs from a phenomenological experiment in the way summarized in Table 1. This comparison shows how close phenomenological research is to protocol analysis, the use of verbal reports as data, often used in research on problem-solving (Simon and Kaplan 1989: 21–29). In recent years some psychologists have confirmed and elaborated results obtained with the phenomenological method by using more conventional experimental methodology (Kubovy, Holcombe, and Wagermans forthcoming). Phenomenology as practiced by the Gestalt psychologists should not be confused with introspec-

Table 1. Comparison of conventional and phenomenological experiments (after Bozzi 1989: chap. 7)

	Conventional	**Phenomenological**
environment	isolated (such as a laboratory)	any (preferably not a laboratory)
participants	kept naive about the topic or purpose of the research (to minimize *demand characteristics*)	are told everything
task	well-defined	jointly defined by participant and researcher
participants' response	• often the first that comes to mind	• may transcend their first impression, and thus provide information about their solution space
	• may not be modified	• may be reconsidered
	• are either correct or incorrect	• all answers are valid
	• unambiguous, or are filtered into a set of mutually exclusive and collectively exhaustive a priori categories	• responses are classified only after all the data have been examined

tionism as practiced by early psychologists such as Titchener (cf. INTROSPECTION). In fact, in its methodological assumptions, introspectionism is closer to contemporary experimental psychology than to phenomenology. Any account of the introspectionists' methods (Lyons 1986) will confirm that they are well described by Bozzi's six features of conventional psychological experiments (Table 1).

Brain Theory. Despite the refutation of the specifics of the Gestalt psychologists' brain theory, their search for specific correspondences between experiences and brain events and their idea of brain fields anticipated important current foci of research (e.g., NEURAL NETWORKS and massively parallel processing). Köhler (1947: 132–133) predicted that future psychological research would study "dynamic self-distribution. . . which Gestalt Psychology believes to be essential in neurological and psychological theory," whose "final result always constitutes an orderly distribution," that is, a "balance of forces" (p. 130; this is a statement of the principle of Prägnanz, discussed below). It is impossible to read this prophecy without thinking of Hopfield networks and Boltzman machines, that can be thought of as minimizing a system energy function (Anderson 1995; Kelso 1995).

It should be noted that for all their emphasis on brain theory, the Gestalt psychologists did not think of themselves as nativists (Köhler 1947: 113, 117, 215). They were nevertheless vigorously opposed to the behaviorists' empirism (a psychological metatheory that gives primacy to learning theories; to be carefully distinguished from the epistemological theory of empiricism).

Part-whole relationships. The problem of part-whole relationships, which is currently under vigorous investigation in perception, was first discussed by Christian von Ehrenfels, in a seminal essay "On 'Gestalt Qualities'" (1988) written twenty-two years before Wertheimer's (1912a) first discussion of the subject. He is the one who first asked, "Is a melody (i) a mere *Zusammenfassung* of elements, or (ii) something novel in relation to this *Zusammenfassung,* something that. . . is distinguishable from the *Zusammenfassung* of the elements?" (p. 82). Although *Zusammenfassung* has usually been translated as "sum," this translation may have led to confusion because the notion of *Zusammenfassung* is more vague than the word "sum" suggests. The word means "combination," "summing-up," "summary," "synopsis," that is to say, "sum" as in the expression "in sum," rather than as an arithmetic operation (Grelling and Oppenheim 1939/1988: 198, propose the translation "totality").

Consider the tune *Row Your Boat.* The melody is different from the following *Zusammenfassung:* "10 *C*s, 3 *D*s, 7 *E*s, 2 *F*s, and 5 *G*s," because the duration of the notes is important. The melody is also different from a more detailed *Zusammenfassung* (if the time signature is $\frac{6}{8}$): "1 × < *C*,6>, 2 × <*C*,3S>, 1 × <*C*,2> , 6 × <*C*,1>, 3 × <*D*,1>, . . ." where 2 × <*C*,3>, means two tokens of *C* whose duration is equivalent to three eighth notes, because the order of the notes is important. But even the score—which specifies the notes, their duration, and their order—does not capture the melody. The tune could be transposed from the key of C to the key of F#, and played at a faster tempo so that it would share no pitches and no absolute durations with the original version. It would still be the same tune. What is preserved are the ratios of frequencies (musical intervals) and the ratios of durations (rhythm). Melody is a property of the whole that depends on *relationships* among the elements, not on the elements themselves. According to von Ehrenfels, the Gestalt is a quality one perceives *in addition to* perceiving the individual elements. It was Wertheimer who reformulated this idea of the Gestalt as a whole embracing perceived elements as parts.

Prägnanz. The notion of Prägnanz (introduced by Wertheimer 1912b) is of great importance to the understanding of cognition. Textbooks define Prägnanz as the tendency of a process to realize the most regular, ordered, stable, balanced state possible in a given situation. This notion is illustrated by the behavior of soap films, which are laminae of minimal potential energy. Unconstrained, a soap film becomes a spherical bubble, but when constrained by a wire, the film takes on a graceful and seemingly complex shape (Hildebrandt and Tromba 1985: chap. 5). But the standard definition of Prägnanz ignores an important difference between physical and cognitive systems. Physical systems are exquisitely sensitive to the exact form of the constraints: small changes in the constraints can make a big difference to the shape of the soap film. In contrast, cognitive systems are relatively insensitive to the details of the input, because they decompose it into a *schema* that has Prägnanz, to which a *correction* is added to characterize the input (Woodworth 1938: chap. 4). Cognitive systems have several ways to extract Prägnanz from inputs (Rausch 1966—summarized by Smith 1988—proposed seven of them). Here are five of them (the first three are exemplified in figure 1): (1) *Lawfulness:* extract the part of an event or an object that conforms to a law or a rule. (2) *Originality:* extract the part of

Figure 1. Three ways to apply Prägnanz to the perception of shape. For each of these ways, the smaller the "correction" to the "schema," the greater the Prägnanz of the shape. *Originality:* A shape can be seen as a transformed prototype: a parallelogram can be seen as a skewed rectangle. *Integrity:* A shape can be seen as an intact shape ("rectangle") modified by a feature or a flaw: "rectangle with a bump," "rectangle with one side missing." *Lawfulness:* A hard-to-name irregular shape can be said to be roughly rectangular in form.

Figure 2. A puzzle that is hard to solve because of Prägnanz.

an event or an object that is a prototype (in the sense currently used in theories of the structure of CONCEPTS) with respect to other events or objects. (3) *Integrity:* extract the part of an event or an object that is whole, complete or intact, rather than partial, incomplete or flawed. (4) *Simplicity:* extract that part of an event or an object that is simple or "good." (5) *Diversity:* extract that part of an event or an object that is "pregnant," that is, rich, fruitful, significant, weighty.

Much of the work of Gestalt psychologists on obstacles to PROBLEM SOLVING has implicated Prägnanz. For example, if the six pieces shown in figure 2 are scattered in front of you, and you are asked to make a square out of them, you are likely to start by forming a disk—a good form that delays the solution (Kanizsa 1979: chap. 14).

Gibson, James Jerome

In his last book, *The Ecological Approach to Visual Perception,* James Gibson (1904–1979) concluded with a plea that the terms and concepts of his theory "...never shackle thought as the old terms and concepts have!" He was referring to the framework of traditional perception, as was reflected, for example, in the classical problem of space perception Bishop Berkeley posed more than three hundred years ago (Berkeley 1963). How is it possible to perceive three-dimensional space when the input to our senses is a two-dimensional retinal surface in the case of vision, or a skin surface in the case of touch? Logically, it seemed this inadequate stimulation had to be supplemented somehow to account for our ordinary perception of a three-dimensional world. There have been two general proposals for the nature of this supplementation. An empiricist proposal, advocated by Berkeley himself, based the supplementation in the prior experience of the individual. The alternative nativist proposal based the supplementation in the innate functioning of the mental apparatus which intrinsically imposes a three-dimensional structure on two-dimensional stimulation. These two alternatives in only slightly modified forms persist to this day.

Gibson challenged Berkeley's initial assumption, asserting that there is indeed sufficient information available to observers for perceiving a three-dimensional world. It does not have to be supplemented from our past experience or from our innate mental operations. Gibson's refutation of the traditional formulation depended on confirming the hypothesis that information is sufficient to account for what we perceive. He argued that the traditional physical analysis of energy available to our senses (rays of light and sound waves) is the wrong level of analysis for perceiving organisms with mobile eyes in mobile heads who look and walk around. Rather, light in ambient arrays (as opposed to radiant light) is structured by, and fully specifies, its sources in the objects and events of the world we perceive. He showed that if the entire structure of the optic array at any point in space were examined, rather than punctate stimuli impinging on the retina, the information available is exceedingly rich. Moreover it specifies important features of the environment. Thus textured optic arrays specify surfaces, gradients of texture specify slanted or receding surfaces, changing patterns in the structure are specific to particular types of object and observer movement, and so on.

Two implications of Gibson's reformulation need to be emphasized. First, patterns of stimulation change when an

observing organism is active. The very act of moving makes information available. Gibson showed that the transformations in the optic array sampled by a moving observer simultaneously specify the path of locomotion (perspective structure) and the stable environment (invariant structure). The traditional formulation of perception involves a passive observer with stimulation imposed by the natural physical world or by a psychological experimenter; either observer or object movement is a complication. Gibson emphasized the active nature of perceiving, and the idea that movement is essential. Second, in Gibson's formulation perception is of properties that are relevant to an organism's being in contact with its environment: things like surfaces and changes in surface layout, places that enclose, paths that are open for mobility, objects approaching or receding, and so on. In the traditional Berkeley perspective perception is of abstract three-dimensional space. For Gibson abstract three-dimensional space is a conceptual achievement. Perception is concerned with guiding behavior in a populated and cluttered environment.

Gibson's emphasis on the functional aspects of perception had roots in his work on pilot selection and training in the Army Air Force during World War II (Gibson 1947). This functional emphasis was developed most thoroughly in his last book, where he presented his ecological approach (Gibson 1979). The first section of the book included an analysis of the physical world at a level ecologically relevant to the activity of a perceiving organism. This provided a taxonomy of the features that are perceived and an analysis of how the physical world structures light so as to provide the information for the meaningful properties to be perceived.

Gibson's ecological perspective emphasizes both the environment/organism mutuality of perception and its intrinsic meaningfulness. This emphasis has the radical implication of breaking down the subject/object distinction pervasive in Western philosophy and psychology as well as solving the psychological riddle of how perception is meaningful. The meaningfulness of perception is reflected in his concept of *affordance* which is currently the source of some controversy. AFFORDANCES are the properties of the environment, taken with reference to creatures living in it, that make possible or inhibit various kinds of activity: surfaces of a certain height, size, and inclination afford sitting on by humans, those of a different height and size afford stepping up on, objects moving at a certain speed afford catching, and so forth. For Gibson, perception of these possibilities for action are primary, and they are specified by information in the optic array.

The concept of affordance is implicated in another controversial concept of Gibson's formulation, that of direct perception. Gibson argued that perception is direct in the sense that perceiving a property, for instance an affordance, is based on detection of the information specifying that property. (For affordances the meaning is appreciated in the very detection of the information.) Critics of his theory interpret direct perception as implying that perception is automatic and argue that it is easy to find examples where it is not. This is a misunderstanding. Direct perception does not imply automaticity, rather the processes involved are

different from the traditional ones; they are not association or computation but exploration, detection of invariant relations, and perceptual learning.

Many of Gibson's empirical discoveries were incorporated into mainstream theories of perception during his lifetime. From early in his career adaptation to prolonged inspection of curved and tilted lines (e.g., Gibson 1937) became a prototype of subsequent research concerned with perceptual and perceptual-motor adaptation to visual-motor rearrangements. TEXTURE gradients have long been accepted as one of the "cues" of DEPTH PERCEPTION. The investigation of the use of motion transformations for guiding locomotion and the analysis of active perception in general, particularly in computer science, are very active research areas. Gibson's theoretical influence has been extended by many of his former colleagues and students whose research is motivated by his ecological framework. Many groups and research problems illustrate this influence: Lee (1980), Warren, Morris, and Kalish (1988), and others have investigated the geometric nature of motion-generated information available for the guidance of locomotion. Turvey, Shaw, and others (e.g., Turvey et al. 1981) have integrated Gibson's ideas with those of Nicolai Bernshtein, the Russian action physiologist, in investigations and analyses of both visual and haptic perception. Edward Reed has extended his views to what he terms ecological philosophy, described in three recent books (Reed 1996a, 1996b, 1997). Gibson's closest and most influential colleague was his wife, Eleanor Jack Gibson, who has elaborated a theory of perceptual learning and development, complementary to his theory of perception (E. J. Gibson 1969). Most recently she and her colleagues (e.g., Adolph, Eppler, and Gibson 1993; A. D. Pick 1997; Walker-Andrews 1988; and others) have been applying the concept of affordance in the study of PERCEPTUAL DEVELOPMENT in a way that simultaneously refines the concept itself. Such investigations have shown the promise and utility of Gibson's radical formulation. Such success will really be complete when it permits and encourages further development of his theoretical concepts without the shackling which he feared.

This article was to have been written by Gibson's close friend and younger colleague, Edward Reed. His untimely death in February, 1997, has deprived the field of a brilliant and humane scholar.

Gödel's Theorems

Kurt Gödel was one of the most influential logicians of the twentieth century. He established a number of absolutely central facts, among them the semantic completeness of first order logic and the relative consistency of the axiom of choice and of the generalized continuum hypothesis. However, the theorems that have been most significant—for the general discussion concerning the foundations of mathematics—are his two *incompleteness theorems* published in 1931; they are also referred to simply as Gödel's theorems or *the Gödel theorems.*

The early part of the twentieth century saw a dramatic development of logic in the context of deep problems in the foundations of mathematics. This development provided for the first time the basic means to reflect mathematical practice in formal theories; see FORMAL SYSTEMS. One fundamental question was: Is there a formal theory such that mathematical truth is co-extensive with provability in that theory? Russell's type theory *P* of *Principia Mathematica* and axiomatic set theory as formulated by Zermelo seemed to make a positive answer plausible. A second question emerged from the research program that had been initiated by Hilbert around 1920 (with roots going back to the turn of the century): Is the consistency of mathematics in its formalized presentation provable by restricted mathematical, so-called finitist means? The incompleteness theorems gave negative answers to both questions for the particular theories mentioned. To be more precise, a negative answer to the second question is provided only if finitist mathematics itself can be formalized in these theories; that was not claimed by Gödel in 1931, only in his (1933) did he assert it with great force.

The first incompleteness theorem states (making use of an improvement due to Rosser):

If P is consistent, then there is a sentence σ in the language of *P*, such that neither σ nor its negation ¬ σ is provable in *P*.

σ is thus *independent* of *P*. As σ is a number theoretic statement it is either true or false for the natural numbers; in either case, we have a statement that is true and not provable in *P*. This incompleteness of *P* cannot be remedied by adding the true statement to *P* as an axiom: for the theory so expanded, the same incompleteness phenomenon arises.

Gödel's second theorem claims the unprovability of a (meta-) mathematically meaningful statement:

If P is consistent, then *cons,* the statement in the language of *P* that expresses the consistency of *P*, is not provable in *P*.

Some, for example Church, raised the question whether the proofs in some way depended on special features of *P*. In his Princeton lectures of 1934, Gödel tried to present matters in a more general way; he succeeded in addressing Church's concerns, but continued to strive for even greater generality in the formulation of the theorems. To understand in what direction, we first review the very basic ideas underlying the proofs and then discuss why Turing's work is essential for a general formulation.

Crucial are the *effective presentation* of *P*'s syntax and its *(internal) representation.* Gödel uses a presentation by primitive recursive functions, that is, the basic syntactic objects (strings of letters of *P*'s alphabet and strings of such strings) are "coded" as natural numbers, and the subsets corresponding to formulas and proofs are given by primitive recursive characteristic functions. Representability conditions are established for all syntactic notions *R*, that is, really for all primitive recursive sets (and relations): if *R(m)* holds then *P* proves $r(\overline{m})$, and if not *R(m)* holds then *P* proves $\neg r(\overline{m})$, where *r* is a formula in the language of *P* and *m* the numeral for the natural number *m*. Thus, the metamathematical talk about the theory can be represented within it. Then the self-referential statement σ (in the language of *P*) is constructed in conscious analogy to the liar

sentence; σ expresses that it is not provable in *P*. An argument similar to that showing the liar sentence not to be true establishes that σ is not provable in *P*, thus we have part of the first theorem. The second theorem is obtained, very roughly speaking, by formalizing the proof of the first theorem concerning σ, but additional derivability conditions are needed: this yields a proof in *P* of (cons → σ). Now, clearly, cons cannot be provable in *P*, otherwise σ were provable, contradicting the part of the first theorem we just established. The proof of the second theorem was given in detail only by Hilbert and Bernays (1939). A gem of an informal presentation of this material is (Gödel 1931b); for a good introduction to the mathematical details see Smorynski (1977).

Gödel viewed in (1934) the primitive recursiveness of the syntactic notions as "a precise condition which in practice suffices as a substitute for the unprecise requirement . . . that the class of axioms and relation of immediate consequence be constructive," that is, have an effectively calculable characteristic function. What was needed, in principle, was a precise concept capturing the informal notion of an effectively calculable function, and that would allow a perfectly general characterization of formal theories. Such a notion emerged from the investigations of Church and TURING; see CHURCH-TURING THESIS. Only then was it possible to state and prove the Incompleteness Theorems for all formal theories satisfying representability (for all recursive relations) and derivability conditions. In the above statement of the theorems, the premise "*P* is consistent" can now be replaced by "*P* is any consistent formal theory satisfying the representability conditions," respectively "*P* is any consistent formal theory satisfying the representability and derivability conditions." It is this generality of his results that Gödel emphasized again and again; for example, in his (1964) work: "In consequence of later advances, in particular of the fact that, due to A. M. Turing's work, a precise and unquestionably adequate definition of the general concept of formal system can now be given, the existence of undecidable arithmetical propositions and the non-demonstrability of the consistency of a system in the same system can now be proved rigorously for *every* consistent formal system containing a certain amount of finitary number theory."

Gödel exploited this general formulation of his theorems (based on Turing's work) and analyzed their broader significance for the philosophy of mathematics and mind most carefully in (1951). The first section is devoted to a discussion of the Incompleteness Theorems, in particular of the second theorem, and argues for a "mathematically established fact" which is of "great philosophical interest" to Gödel: either the humanly evident axioms of mathematics cannot be comprised by a finite rule given by a Turing machine, or they can be and thus allow the successive development of all of demonstrable mathematics. In the latter case human mathematical abilities are in principle captured by a Turing machine, and thus there will be absolutely undecidable problems. That is what can be strictly inferred from Gödel's theorems, counter to Lucas, Penrose, and others. Gödel thought that the first disjunct held, as he believed that the second disjunct had to be false; he emphasized repeatedly, for example in (1964), that his

results do not establish "any bounds for the powers of human reason, but rather for the potentialities of pure formalism in mathematics." Indeed, in the Gibbs lecture Gödel reformulated the first disjunct as this dramatic and vague statement: "the human mind (even within the realm of pure mathematics) infinitely surpasses the powers of any finite machine."

Golgi, Camillo

Camillo Golgi (1843–1926) was one of a generation of great neurohistologists that included Kölliker, Gerlach, Nissl, and CAJAL. For these scientists, the cellular nature of nervous tissue was still enigmatic and controversial, decades after Schleiden and Schwann had promulgated the theory that cells are the basic architectonic units of living tissues. What we now somewhat nonchalantly identify as nerve cells had been visualized as early as 1836 (by Valentin); but, with the techniques then available, the relationship between cell bod-

ies and their protoplasmic extensions could not be clear. A natural interpretation, bizarre as it may now seem, was that nerve cells were nodes, perhaps nutritive in function, embedded within a continuous reticulum of nerve fibers.

Golgi's unique and enduring contribution is generally cited as the discovery of the silver dichromate stain for nerve tissue, which for the first time allowed visualization of nerve cells in their entirety. The actual discovery is surrounded with a certain romanticism, an admixture of luck and perseverance. Golgi, the son of a medical practitioner, had taken his degree in medicine (1865), and spent six years (1865–71) tending patients at the Ospedale di San Matteo in Pavia while also doing research in brain histology in the laboratory of his younger friend and mentor, Giulio Cesare Bizzozero. The actual discovery, however, came while he was first resident physician in the home for incurables at Abbiategrasso. Working in the evenings by candlelight in the kitchen of his hospital apartment (da Fano 1926), he continued the research that led to the new technique. The resulting article, published in 1873 ("On the structure of the gray matter of the brain"), has a refreshing simplicity: "Using the method I have developed for staining brain elements . . . I was able to discover several facts about the structure of the grey brain matter which I believe worth making known" (in Corsi 1988).

The silver stain, although used to advantage by Golgi himself (who subsequently moved to the faculty at Pavia, as professor of general pathology and histology, where he remained until his retirement in 1918), was at first dismissed by the mainstream school of German histologists. In 1887 the Golgi stain was itself discovered by Ramon y Cajal, who used it to impressive advantage in the first great investigations of functional neuroanatomy. Throughout the twentieth century, the Golgi stain remained important in investigations of normative structure and of changes associated with development, pathology, or plasticity. It has to some extent been superseded by intracellular injection of tracers (such as biocytin or horseradish peroxidase), but remains a valuable method for visualizing larger populations of cells and when experimental injection is not feasible (i.e., in most human material). In tribute to the elegance of the original silver methods, high-quality cellular images, immunocytochemical or intracellular, are still evaluated as "pseudo-Golgi" or "Golgi-like."

Golgi further deserves acknowledgment for his role in the early polemics surrounding the NEURON doctrine. This debate was articulated dramatically, almost scandalously from the modern perspective, in the Nobel addresses for 1906, when Golgi and Cajal were jointly awarded the prize in physiology and medicine. Golgi defended the reticularist position, while Cajal championed the neuron doctrine (respectively representing the "continualists" and the "contiguists"; Van der Loos 1967). Golgi's position, in light of the facts, has come to be viewed as archaic, and an unfortunate example of dogma winning out over observation. In his defense, it is worth remembering that synaptic morphology —and in particular the discontinuity of the pre- and post-synaptic elements—was not definitively demonstrated until electron microscopic studies in the 1950s (see Peters, Palay, and de Webster 1991). Moreover, at least some of Golgi's

reservations can be seen as an arguably legitimate concern about the neuron doctrine in its most stringent formulation. Thus, he makes the interesting distinction between a "nerve cell," which corresponds to a distinct histological entity, and a "neuron," the definition of which, he suggests, should include its functional operation. In the functional domain, the concept of the "neuron" is indeed elusive and continues to evolve even at the present moment.

Golgi's reticularist stance may have derived from a strong conviction in the unified or holistic nature of brain function, or at least a preoccupation with how unity (of perception, of consciousness) can result from individualized elements. So stated, this is not necessarily dissimilar from modern discussions of the BINDING PROBLEM. It is interesting to read Golgi's prose against the backdrop of current work on functional ensembles linked by temporal response properties ("l'action d'ensemble des cellules nerveuses, que j'ai ainsi définée par opposition à la prétendue action individuelle," Golgi 1908; "the group action of nerve cells which I have defined as being opposite to their alleged individual action," Golgi 1967: 202).

Golgi is also known for his discovery of the "internal reticular apparatus" (smooth endoplasmic reticulum or "Golgi apparatus;" see Peters, Palay, and de Webster 1991), and for his distinction between neurons with long or local axons (respectively, Golgi Type I and Type II, also observed early on by Cajal).

In summary, Golgi's silver stain has become, rightly or not, a favorite illustration of the role of serendipity in scientific discovery. It is an early example of the importance of new techniques for advancing the investigation of brain and cognitive processes. The story is also a lesson in the potential deceptiveness of "concrete" images—whether we read it as a case of missed opportunity and intransigence, or of being right for the wrong reasons.

Grammar, Neural Basis of

Grammar refers to the syntactic structure of sentences that allows the meanings of words to be related to each other to form propositions. Linguistics has been concerned with the way humans' unconscious knowledge of this structure is represented. PSYCHOLINGUISTICS has been concerned with how this knowledge is used in speaking and comprehension. There is no way at present to investigate how the nervous system represents syntactic knowledge, but there are two approaches to the neural basis for syntactic processing. One has been the traditional deficit-lesion correlational approach in patients with brain lesions. The second is the observation of neurophysiological and metabolic activity associated with syntactic processing in normal subjects. Both approaches have made some progress, but there are many gaps in our scientific investigation of the question.

Deficit-lesion correlations are available for patients with disorders of both production and receptive processing of syntactic structures. With respect to the production of syntactic form, the speech of patients with a symptom known as agrammatism is characterized by short phrases with simple syntactic structures and omission of grammatical markers and function words. These patients tend to have lesions that include Broca's area (pars triangularis and opercularis of the left third frontal convolution), which has led some researchers to suggest that this region is responsible for syntactic planning in LANGUAGE PRODUCTION (Zurif 1982). Several studies have shown, however, that lesions in other brain areas can produce agrammatism, suggesting that other left hemisphere areas can be responsible for this function in some individuals (Vanier and Caplan 1990; Dronkers et al. 1994).

Syntactic processing can also be impaired in comprehension, as shown by patients' failure to understand sentences with more complex syntactic structures whose meaning cannot be simply inferred (e.g., *The boy was pushed by the girl*). More detailed studies of disorders of the time-course of syntactic processing in sentence comprehension have also been carried out (Tyler 1985; Swinney and Zurif 1995). The original studies of patients with syntactic comprehension disorders also focused on agrammatic Broca's aphasics (Caramazza and Zurif 1976). However, patients whose lesions lie outside Broca's area also often show impairments of syntactically-based sentence comprehension (Berndt, Mitchum, and Haendiges 1996; Caplan 1987; Caplan and Hildebrandt 1988; Caplan, Baker, and Dehaut 1985; Caplan, Hildebrandt, and Makris 1996; Tramo, Baynes, and Volpe 1988), and patients with agrammatism often show good syntactic comprehension (Berndt, Mitchum, and Haendiges 1996). This has led some researchers to suggest that a more distributed neural system in the left perisylvian cortex, of which Broca's area may be a specialized part, is responsible for this function (Mesulam 1990; Damasio and Damasio 1992). One study (Caplan, Hildebrandt, and Makris 1996) reported a small but clear impairment in syntactic processing in comprehension after right hemisphere strokes, suggesting some role of the nondominant hemisphere in this function.

Physiological and metabolic studies in normal subjects have also provided information about the brain regions involved in syntactic processing in comprehension. Event related potentials (ERPs) have shown components, such as the P600 or "syntactic positive shift" in the central parietal region and the "left anterior negativity," that may be associated with syntactic processing (Hagoort, Brown, and Groothusen 1993; Munte, Heinze, and Mangun 1993; Neville et al. 1991; Rosler et al. 1993). Recently, functional neuroimaging with POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI) has been used to investigate the regional cerebral blood flow (rCBF) associated with sentence-level language processing. Using PET, Mazoyer et al. (1993) reported inconsistent rCBF increases associated with syntactic processing, but it may be that their experimental conditions did not differ in the minimal ways necessary to isolate the neural correlates of the various components of linguistic processing above the single-word level. Stromswold et al. (1996) reported an isolated increase in rCBF in part of Broca's area associated with syntactic processing. Using a slightly different experimental paradigm with fMRI, Just et al. (1996) reported an increase in rCBF in both Broca's area and a second language area—Wernicke's area in the left first temporal gyrus —as well as smaller increases in rCBF in the right hemisphere homologues of these structures. The Just et al. results are consistent with those of Caplan, Hildebrandt, and Makris (1996), but more research is needed to understand the differences across various studies.

In summary, the dominant perisylvian cortex is the region of the brain most involved in syntactic processing and production. Whether there is any further specialization within this region for these functions remains to be established.

Grammatical Relations

In its broadest sense, the term *grammatical relation* (or *grammatical role* or *grammatical function*) can be used to refer to almost any relationship within grammar, or at least within SYNTAX and MORPHOLOGY. In its narrowest sense, grammatical relation is a cover term for grammatical subject, object, indirect object, and the like. To understand what grammatical relations are, in this more specific sense, it will help to contrast them with intuitively similar but distinct syntactic concepts such as thematic roles, Cases, and syntactic positions.

We can see the difference between surface grammatical relations and semantic relations or THEMATIC ROLES (e.g., agent, goal, theme, etc.) by examining examples (1) and (2). In these examples, the noun phrase "that story" has the same thematic role (theme or patient) in both the active and the passive versions of the sentence; however, the grammatical relation of "that story" differs in the two sentences. In the active sentence, "that story" has the grammatical relation of object, whereas in the passive sentence, it has the grammatical relation of subject.

(1) active: This girl wrote that story.

(2) passive: That story was written by this girl.

It is not necessary, however, to appeal to derived contexts in order to distinguish surface grammatical relations and thematic roles. Although the subject of an active sentence is very often an agent, there are sentences without an agent role and in such sentences, some other thematic role such as theme, goal, or experiencer is associated with the grammatical relation of subject:

(3) The ball rolled down the hill.

(4) The woman received the letter.

(5) The boy enjoyed the ice cream.

Grammatical relations are also distinct from Cases (e.g. nominative, accusative, dative, etc.). Although the grammatical relation of subject is often associated with nominative Case, whereas the grammatical relation of object is often associated with accusative Case, there are many examples of other pairings of these grammatical relations and Cases. For example, in Icelandic some verbs take a dative subject and a nominative object:

(6) Barninu   batnaði   veikin.
    the.child-DAT recovered.fromthe.disease-NOM(*ACC)
    'The child recovered from the disease.' (Yip, Maling, and Jackendoff 1987: 223)

Hindi also has verbs that take dative subjects, but most transitive verbs in Hindi take an ergative subject and a nominative

object (in the perfective aspect):

(7) Raam-ne   roTii   khaayii   thii.
    Ram(masc.)-ERG bread(fem)-NOM eat(perf, fem)
    be(past, fem) "Ram had eaten bread." (Mahajan 1990:
    73)

Thus we see that grammatical relations are distinct from Cases.

Finally, grammatical relations can also be distinguished from syntactic positions. If an object is fronted in a topicalization construction, for example, it remains an object despite the fact that it is located above the subject in the syntactic structure.

(8) a. I read *that book.*
    b. *That book,* I read.

Similarly, grammatical relations remain constant across many word orders in languages that allow scrambling. For example, in all of the word order variants of the Hindi sentence below, *Ram* has the grammatical relation of subject and *banana* has the grammatical relation of object:

(9) a. Raam-ne   kelaa   khaayaa.
        Ram-ERG   banana-NOM   ate
        'Ram ate a banana.'
    b. Raam-ne khaayaa kelaa.
    c. Kelaa raam-ne khaayaa.
    d. Kelaa khaayaa raam-ne.
    e. Khaayaa raam-ne kelaa.
    f. Khaayaa kelaa raam-ne. (Mahajan 1990: 19)

So far, we have been discussing only surface grammatical relations; that is, the grammatical relations that hold at surface structure after all movements or other grammatical relation-changing processes have occurred. However, one may also speak of deep or initial grammatical relations. In both the active sentence in (10) and the passive sentence in (11), one may say that *that banana* has the initial grammatical relation of object.

(10) Ram ate that banana.

(11) That banana was eaten by Ram.

Thus there is a closer association between initial grammatical relations and thematic roles than there is between surface grammatical relations and thematic roles.

Almost all linguists use the terms *grammatical relation*, *subject*, *object*, and the like in a descriptive sense. However, theories of grammar differ widely with respect to the question of the theoretical status of grammatical relations. The controversy centers around the question of how many formal devices of what kind the correct theory of grammar includes. Proponents of RELATIONAL GRAMMAR (Perlmutter and Postal 1977; Perlmutter 1983) maintain that grammatical relations are primitive notions in the theory of grammar and that universal generalizations about language are formulated in terms of those primitives. Others maintain that no grammatical rules make crucial reference to grammatical relations, as distinct from thematic roles, Cases, or syntactic positions and that adding grammatical relations to the the-

ory of grammar is unnecessary and therefore undesirable (e.g., Chomsky 1981; Hoekstra 1984; Williams 1984; Bhat 1991). Between these poles, there are several middle and variant positions. Some take the position that although grammatical relations are not primitive notions of grammar, they do play an important role in grammar as derived notions (Anderson 1978). Some argue for the need for finer-grained grammatical relations, such as adding "restricted object" (Bresnan and Kanerva 1989), within the theory of LEXICAL FUNCTIONAL GRAMMAR.

Many works whose titles contain the phrase "grammatical relations" are not so much concerned with this theoretical controversy, but rather with a somewhat broader sense of grammatical relations, pertaining to how Case, agreement, and/or word order identify or distinguish subjects and objects. In this broader sense, a "theory of grammatical relations" is assumed to include a theory of Case and agreement systems that can account for all of the cross-linguistic differences that occur (see TYPOLOGY). Such work often focuses on languages or particular constructions in which the familiar associations between subjects and nominative Case or objects and accusative Case do not hold. For example, they address the question of how or why dative or ergative Case is assigned to subjects in constructions such as (6) or (7), instead of nominative Case; and why nominative Case is instead assigned to the objects in those constructions. One approach to this problem of non-prototypic associations between Cases and grammatical relations has been to propose that at some level, the prototypic association (e.g., between nominative Case and subjects) actually does hold, but that grammatical relations (or structural positions) are inverted at some level in the derivation (e.g., Harris 1976; Marantz 1984). Others maintain that assuming such a close association between Case and grammatical relations (or syntactic positions) is not correct and that there are conditions under which subjects can take other Cases, especially lexical (inherent, quirky) Cases, freeing up the nominative Case which can then be assigned to an object (e.g., Yip, Maling, and Jackendoff 1987).

Other works with "grammatical relations" in the title focus on the question of how to describe and analyze a range of constructions that appear to involve changes in grammatical relations, such as passive, causative, or applicative constructions, or on restrictions on various grammatical processes such as relativization that may be stated in terms of grammatical relations (e.g., Gary and Keenan 1977; Marantz 1984; Baker 1988).

Greedy Local Search

Greedy local search search methods are widely used to solve challenging computational problems. One of the earliest applications of local search was to find good solutions for the traveling salesman problem (TSP). In this problem, the goal is to find the shortest path for visiting a given set of cities. The TSP is prototypical of a large class of computational problems for which it is widely believed that no efficient (i.e., polynomial time) ALGORITHM exists. Technically speaking, it is an NP-hard optimization problem (Cook 1971; Garey and Johnson 1979; Papadimitriou and Steiglitz 1982). A local search method for the TSP proceeds as follows: start with an arbitrary path that visits all cities, such a path will define an order in which the cities are to be visited. Subsequently, one makes small ("local") changes to the path to try to find a shorter one. An example of such a local change is to swap the position of two cities on the tour. One continues making such changes until no swap leads to a shorter path. Lin (1965) and Lin and Kernighan (1973) show that such a simple procedure, with only a slightly more complex local change, leads to solutions that are surprisingly close to the shortest possible path.

The basic local search framework allows for several variations. For example, there is the choice of the initial solution, the nature of the local changes considered, and the manner in which the actual improvement of the current

solution is selected. Lin and Kernighan found that multiple runs with different random initial paths lead to the best solutions. Somewhat surprisingly, starting with good initial paths did not necessarily lead to better final solutions. The reason for this appears to be that the local search mechanism itself is powerful enough to improve on the initial solutions—often quickly giving better solutions than those generated using other methods. Choosing the best set of local changes to be considered generally requires an empirical comparison of various kinds of local modifications that are feasible. Another issue is that of how to select the actual improvement to be made to the current solution. The two extremes are *first-improvement* (also called "hill-climbing"), in which any favorable change is accepted, and *steepest-descent,* in which the *best* possible local improvement is selected at each step. Steepest-descent is sometimes referred to as *greedy* local search, but this term is also used to refer to local search in general.

A local search method does not necessarily reach a global optimum because the algorithm terminates when it reaches a state where no further improvement can be found. Such states are referred to as *local optima.* In 1983, Kirkpatrick, Gelatt, and Vecchi introduced a technique for escaping from such local optima. The idea is to allow the algorithm to make occasional changes that do not improve the current solution, that is, changes that lead to equally good or possibly inferior solutions. Intuitively speaking, these nonimproving moves can be viewed as injecting *noise* into the local search process. Kirkpatrick, Gelatt, and Vecchi referred to their method as *simulated annealing,* because it was inspired by the annealing technique used to reach low energy states in glasses and metals. The amount of "noise" introduced is controlled with a parameter, called the temperature T. Higher values of T correspond to more noise. The search starts off at a high temperature, which is slowly lowered during the search in order to reach increasingly better solutions.

Another effective way of escaping from local minima is the *tabu search* method (Glover 1989). During the search, the algorithm maintains a "tabu" list containing the last L changes, where L is a constant. The local search method is prevented from making a change that is currently on the tabu list. With the appropriate choice of L, this methods often forces the search to make upward (nonimproving) changes, again introducing noise into the search.

Genetic algorithms can also be viewed as performing a form of local search (Holland 1975). In this case, the search process proceeds in parallel. Solutions are selected based on their "fitness" (i.e., solution quality) from an evolving population of candidates. Noise is introduced in the search process via random mutations (see EVOLUTIONARY COMPUTATION).

A recent new area of application for local search methods is in solving NP-complete *decision problems,* such as the Boolean satisfiability (SAT) problem. An instance of SAT is a logical expression over a set of Boolean variables. An example expression is "(*a* or (not *b*)) and ((not *a*) or (not *c*))." The formula has *a, b,* and *c* as Boolean variables. The satisfiability problem is to find an assignment to the Boolean variables such that the various parts of the logical expression are simultaneously satisfied. That is, the overall expression should evaluate to "true." In our example, setting *a* to "true," *b* to "true," and *c* to "false" satisfies the formula. Finding a satisfying assignment for arbitrary formulas is a computationally difficult task (Cook 1971). Note that the obvious algorithm would enumerate all 2^N Boolean truth assignments, where N is the number of Boolean variables. The SAT problem is of particular interest to computer scientists because many other problems can be efficiently represented as Boolean satisfiability problems. The best traditional methods for solving the SAT problem are based on a systematic backtrack-style search procedure, called the Davis, Putnam, and Loveland procedure (Davis and Putnam 1960; Davis, Logemann, and Loveland 1962). These procedures can currently solve hard, randomly generated instances with up to four hundred variables (Mitchell, Selman, and Levesque 1992; Crawford and Auton 1993; Kirkpatrick and Selman 1994). In 1992, Selman, Livesque, and Mitchell showed that a greedy local search method, called GSAT, could solve instances with up to seven hundred variables. Recent improvements on the local search strategy enable us to solve instances with up to three thousand variables (Selman, Kautz, and Cohen 1994). The GSAT procedure starts with a randomly generated truth assignment. It then considers changing the truth value of one of the Boolean variables in order to satisfy more of the given logical expression. It keeps making those changes until a satisfying truth assignment is found or until the procedure reaches some preset maximum number of changes. When it reaches this maximum, GSAT restarts with a new initial random assignment. (For closely related work in the area of scheduling, see Minton et al. 1992.) One inherent limitation of local search procedures applied to decision problems is that they cannot be used to determine whether a logical expression is inconsistent, that is, no satisfying truth assignment exists. In practice, this means that one has to use model-based formulations, where solutions correspond to models or satisfying assignments.

An important difference in applying local search to decision problems, as opposed to optimization problems, is that *near*-solutions are of no particular interest. For decision problems, the goal is to find a solution that satisfies all constraints of the problem under consideration (see also CONSTRAINT SATISFACTION and HEURISTIC SEARCH). In practice, this means that, for example, GSAT and related local search procedures spend most of their time satisfying the last few remaining constraints. Recent work has shown that incorporating random walk-style methods in the search process greatly enhances the effectiveness of these procedures.

Since Lin and Kernighan's successful application of local search to the TSP, and the many subsequent enhancements to the local search method, local search techniques have proved so powerful and general that such procedures have become the method of choice for solving hard computational problems.

Grice, H. Paul

H. Paul Grice (1913–1988), the English philosopher, is best known for his contributions to the theory of meaning and communication. This work (collected in Grice 1989) has had lasting importance for philosophy and linguistics, with implications for cognitive science generally. His three most influential contributions concern the nature of communication, the distinction between speaker's meaning and linguistic meaning, and the phenomenon of conversational IMPLICATURE.

Grice's concept of speaker's meaning was an ingenious refinement of the crude idea that communication is a matter of intentionally affecting another person's psychological states. He discovered that there is a distinctive, rational means by which the effect is achieved: by way of getting one's audience to recognize one's intention to achieve it. The intention includes, as part of its content, that the audience recognize this very intention by taking into account the fact that they are intended to recognize it. A communicative intention is thus a self-referential, or reflexive, intention. It does not involve a series of nested intentions—the speaker does not have an intention to convey something and a further intention that the first be recognized, for then this further intention would require a still further intention that it be recognized, and so on ad infinitum. Confusing reflexive with iterated intentions, to which even Grice himself was prone, led to an extensive literature replete with counterexamples to ever more elaborate characterizations of the intentions required for genuine communication (see, e.g., Strawson 1964 and Schiffer 1972), and to the spurious objection that it involves an infinite regress (see Sperber and Wilson 1986, whose own RELEVANCE theory neglects the reflexivity of communicative intentions). Although the idea of reflexive intentions raises subtle issues (see the exchange between Recanati 1987 and Bach 1987), it clearly accounts for the essentially overt character of communicative intentions, namely, that their fulfillment consists of their recognition (by the intended audience). This idea forms the core of a Gricean approach to the theory of speech acts, including nonliteral and indirect speech acts (Bach and Harnish 1979). Different types of speech acts (statements, requests, apologies, etc.) may be distinguished by the type of propositional attitude (belief, desire, regret, etc.) being expressed by the speaker.

Grice's distinction between speaker's and linguistic MEANING reflects the fact that what a speaker means in uttering a sentence often diverges from what the sentence itself means. A speaker can mean something other than what the sentence means, as in "Nature abhors a vacuum," or something more, as in "Is there a doctor in the house?" Grice invoked this distinction for two reasons. First, he thought linguistic meaning could be reduced to (standardized) speaker's meaning. This reductive view has not gained wide acceptance, because of its extreme complexity (see Grice 1989: chaps. 6 and 14, and Schiffer 1972) and because it requires the controversial assumption that language is essentially a vehicle for communicating thoughts rather than a medium of thought itself. Even so, many philosophers would at least concede that mental content is a more fundamental notion than linguistic meaning, and perhaps even that SEMANTICS reduces to the psychology of PROPOSITIONAL ATTITUDES.

Grice's other reason for invoking the distinction between speaker's and linguistic meaning was to combat extravagant claims, made by so-called ordinary language philosophers, about various important philosophical terms, such as *believes* or *looks*. For example, it was sometimes suggested that believing implies not knowing, because to say, for example, "I believe that alcohol is dangerous" is to imply that one does not know this, or to say "The sky looks blue" is to imply that the sky might not actually be blue. However, as Grice pointed out, what carries such implications is not what one is saying but that one is saying it (as opposed to the stronger "I know that alcohol is dangerous" or "The sky is blue"). Grice also objected to certain ambiguity claims, for instance that *or* has an exclusive as well as inclusive sense, as in "I would like an apple or an orange," by pointing out that it is the

use of *or*, not the word itself, that carries the implication of exclusivity. Grice's Modified Occam's Razor ("Senses are not to be multiplied beyond necessity") cut back on a growing conflation of (linguistic) meaning with use, and has since helped linguists appreciate the importance of separating, so far as possible, the domain of PRAGMATICS from semantics.

Conversational implicature is a case in point. What a speaker implicates is distinct from what the speaker says and from what his words imply. Saying of an expensive dinner, "It was edible," implicates that it was mediocre at best. This simple example illustrates a general phenomenon: a speaker can say one thing and manage to mean something else or something more by exploiting the fact that he may be presumed to be cooperative, in particular, to be speaking truthfully, informatively, relevantly, and otherwise appropriately. The listener relies on this presumption to make a contextually driven inference from what the speaker says to what the speaker means. If taking the utterance at face value is incompatible with this presumption, one may suppose that the speaker intends one to figure out what the speaker does mean by searching for an explanation of why the speaker said what he said.

Although Grice's distinction between what is said and what is implicated is not exhaustive (for what it omits, see Bach 1994), the theoretical strategy derived from it aims to reduce the burden on semantics and to explain a wide range of nonsemantic phenomena at an appropriate level of generality. This strategy has had lasting application to a wide range of problems in philosophy of language as well as other areas of philosophy, such as epistemology and ethics, and to various areas of research in linguistics and computer science, such as the LEXICON, ANAPHORA, DISCOURSE, and PLANNING. Economy and plausibility of theory require heeding Grice's distinction between speaker's and linguistic meaning, and the correlative distinction between speaker's and linguistic reference. Rather than overly attribute features to specific linguistic items, one can proceed on the default assumption that uses of language can be explained in terms of a core of linguistic meaning together with general facts about rational communication.

Haptic Perception

The haptic sensory modality is based on cutaneous receptors lying beneath the skin surface and kinesthetic receptors found in muscles, tendons, and joints (Loomis and Lederman 1986). The haptic modality primarily provides information about objects and surfaces in contact with the perceiver, although heat and vibration from remote sources can be sensed (see also PAIN). Haptic perception provides a rich representation of the perceiver's proximal surroundings and is critical in guiding manipulation of objects.

Beneath the surface of the skin lie a variety of structures that mediate cutaneous (or tactile) perception (see, e.g., Bolanowski et al. 1988; Cholewiak and Collins 1991). These include four specialized end organs: Meissner corpuscles, Merkel disks, Pacinian corpuscles, and Ruffini endings. There is substantial evidence that these organs play the role of mechanoreceptors, which transduce forces applied to the skin into neural signals. The mechanoreceptors can be functionally categorized by the size of their receptive fields (large or small) and their temporal properties (fast adapting, FA, or slowly adapting, SA). The resulting 2×2 classification comprises (1) FAI receptors, which are rapidly adapting, have small receptive fields, and are believed to correspond to the Meissner corpuscles; (2) FAII receptors,

which are rapidly adapting, have large receptive fields, and likely correspond to the Pacinian corpuscles (hence also called PCs); (3) SAI receptors, which are slowly adapting, have small receptive fields, and likely correspond to the Merkel disks; and (4) SAII receptors, which are slowly adapting, have large receptive fields, and likely correspond to the Ruffini endings. Among other cutaneous neural populations are thermal receptors that respond to cold or warmth.

By virtue of differences in their temporal and spatial responses, the various mechanoreceptors mediate different types of sensations. The Pacinian corpuscles have a maximum response for trains of impulses on the order of 250 Hz and hence serve to detect vibratory signals, like those that arise when very fine surfaces are stroked or when an object is initially contacted. The SAI receptors, by virtue of their sustained response and relatively fine spatial resolution, are implicated in the perception of patterns pressed into the skin, such as braille symbols (Phillips, Johansson, and Johnson 1990). The SAIs also appear to mediate the perception of roughness, when surfaces have raised elements separated by about 1 mm or more (Connor and Johnson 1992; see TEXTURE).

The responses of haptic receptors are affected by movements of the limbs, which produce concomitant changes in the nature of contact between the skin and touched surfaces. This dependence of perception on movement makes haptic perception active and purposive. Characteristic, stereotyped patterns of movement arise when information is sought about a particular object property. For example, when determining the roughness of a surface, people typically produce motion laterally between the skin and the surface, by stroking or rubbing. Such a specialized movement pattern is called an exploratory procedure (Lederman and Klatzky 1987).

An exploratory procedure is said to be associated with an object property if it is typically used when information about that property is called for. A number of exploratory procedures have been documented. In addition to the lateral motion procedure associated with surface texture, there is unsupported holding, used to sense weight; pressure, used to sense compliance; enclosure, used to sense global shape and volume; static contact, used to determine apparent temperature; and contour following, used to determine precise shape. The exploratory procedure associated with a property during free exploration also turns out to be optimal, in terms of speed and/or accuracy, or even necessary (in the case of contour following), for extracting information about that property; an exploratory procedure that is optimal for one property may also deliver relatively coarse information about others (Lederman and Klatzky 1987).

The exploratory procedures appear to optimize perception of an object property by facilitating a computational process that derives that property from sensory signals. For example, the exploratory procedure called static contact promotes perception of surface temperature, because it characteristically involves a large skin surface and therefore produces a summated signal from spatially distributed thermal receptors (Kenshalo 1984). Texture perception is enhanced by lateral motion of the skin across a surface, because the scanning motion increases the response of the SA units (Johnson and Lamb 1981). It has been proposed that weight can be judged by wielding an object (as occurs during unsupported holding), because the motion provides information about the object's resistance to rotation, which is related to its mass and volume (Amazeen and Turvey 1996).

With free exploration, familiar common objects can usually be identified haptically (i.e., without vision) with virtually no error, within a period of 1–2 s (Klatzky, Lederman, and Metzger 1985; see also OBJECT RECOGNITION). The sequence of exploratory procedures during identification appears to be driven both by the goal of maximizing bottom-up information and by top-down hypothesis testing. Object exploration tends to begin with general-purpose procedures, which provide coarse information about multiple object properties, and proceed to specialized procedures, which test for idiosyncratic features of the hypothesized object (Lederman and Klatzky 1990).

Although haptic object identification usually has a time-course of seconds, considerable information about objects can be acquired from briefer contact. Intensive properties of objects—those that can be coded unidimensionally (i.e., not with respect to layout in 2-D or 3-D space)—can be extracted with minimal movement of the fingers and in parallel across multiple fingers (Lederman and Klatzky 1997). When an array of surface elements is simultaneously presented across multiple fingers, the time to determine whether an intensively coded target feature (e.g., a rough surface) is present can average on the order of 400 ms, including response selection and motor output. Properties extracted during such early touch can form the basis for object identification: a 200-ms period of contact, without finger movement, is sufficient for identification at levels above chance (Klatzky and Lederman 1995).

A critical role for haptic perception is to support manipulatory actions on objects (see also MOTOR CONTROL). When an object is lifted, signals from cutaneous afferents allow a grip force to be set to just above the threshold needed to prevent slip (Westling and Johannson 1987). During lifting, incipient slip is sensed by the FA receptors, leading to corrective adjustments in grip force (Johannson and Westling 1987). Adjustments also occur during initial contact in response to perceived object properties such as coefficient of friction (Johannson and Westling 1987). Age-related elevations in cutaneous sensory thresholds lead older adults to use grip force that is substantially greater than the level needed to prevent slip (Cole 1991).

Head-Driven Phrase Structure Grammar

Head-driven phrase structure grammar (HPSG) is a lexicalist, constraint-based family of theories of GENERATIVE GRAMMAR to which Sag and Wasow (1998) offers an elementary introduction. Two assumptions underlie the theory of head-driven phrase structure grammars. The first is that languages are systems of types of linguistic objects like *word, phrase, clause, person, index, form-type, content,* rather than collections of sentences. The other is that grammars are best represented as process-neutral systems of declarative constraints (as opposed to constraints defined in terms of operations on objects as in transformational grammar). Representations are structurally uniform: all objects of a particular type have all and only the attributes defined for that type. What attributes are defined for an object type is restricted empirically, not by a priori conditions; they cover phonological, semantic, structural, contextual, formal and selectional (subcategorizational) properties.

A grammar (and for that matter, a theory of universal grammar) is thus seen as consisting of an inheritance hierarchy of such types (an "is-a" hierarchy similar to familiar semantic networks of the sort that have "creature" as a root and progressively more specific nodes on a branch leading to a particular canary "Tweety"). The types are interrelated in two ways. First, some types are defined in terms of other types. Second, the hierarchy allows for multiple inheritance, in that linguistic objects can belong to multiple categories at the same time, just as other conceptual objects do. The constraints in the linguistic hierarchy are all local, so that well-formedness is determined exclusively with reference to a given structure, and not by comparison to any other candidate structures. The LEXICON is a rich subhierarchy within the larger hierarchy constituting the grammar. Having declarative constraints on a hierarchy of interrelated types of linguistic objects is seen as enabling an account of language processing which is incremental and pervasively integrative. Thus, as long as information about grammatical number is consistent, it does not matter whether it comes from a verb or its subject, as shown by the fact that (1–3) are acceptable, whereas (4) is not.

1. The dogs slept in the barn.
2. The sheep which was mine stayed in the pen.
3. The sheep which stayed in the pen were mine.
4. *The sheep which was mine are in the pen.

Linguistic objects are modeled as feature structures. Feature structures are complete specifications of values for all the attributes that are appropriate for the particular sort of object that they model, and they are the entities constrained by the grammar. Feature structure descriptions describe classes of feature structures, by means of familiar attribute-and-value matrices (AVMs) that (partially) describe them. A partial description constrains all the members of whatever class of feature structures it describes, while a total description is a constraint that limits the class to a single member. For the most part, grammar specification deals with generalizations over classes of objects like words and phrase-types, and therefore with (partial) feature structure descriptions. Feature-based unification grammar formalisms like HPSG are thus conceptually lean and computationally tractable, and are being used in increasing numbers of NATURAL LANGUAGE PROCESSING systems.

A feature's value is of one of four possible types: atom, feature structure, set of feature structures, or list of feature structures. (Set values are represented as sequences within curly brackets: SLASH {⟨1⟩⟨2⟩}. The empty set is denoted: { } while { [ ] } denotes a singleton set. List values are represented as sequences within angled brackets: COMPS < NP, VP[*inf*] >. The empty list is denoted: < >, and < [ ] > denotes a singleton list.) Values that are not specified in a feature-structure description are still constrained to be among the legitimate values for the features that the constraints on the types to which it belongs require.

Like other linguistic objects, categories that figure in the SYNTAX have rich internal structure and constituency descriptions. But HPSG is a "WYSIWYG" theory; empty categories are avoided rather than exploited.

The general outlines of the HPSG approach to constituent order derive from the theory of linear precedence rules sketched in GPSG (Gazdar and Pullum 1981; Gazdar et al. 1985), and discussed at some length in Pollard and Sag (1987). As in GPSG, so-called free word order (i.e., free phrase order) is a consequence of not constraining the order of constituents at all. (Genuinely free word order, where (any) words of one phrase can precede (any) words of any other phrase requires a word-order function that allows constituents of one phrase to be recursively interleaved with constituents of another; see Gazdar and Pullum 1981; Pollard and Sag 1987; Dowty 1996; Reape 1994).

As grammar-writing research on a number of languages (especially notably, German and French) has made abundantly clear, word order constraints are not always compatible with the semantic and syntactic evidence for constituency, and the exact form of the resolution to this dilemma constitutes a lively topic in current research.

Constraints on phrase types project meanings, subcategorization requirements, and head properties from subconstituents. The HEAD-feature principle, for example, represented in figure 1, constrains HEAD properties of a phrase (i.e., category information like person, number, case, inflection) to be the same as that of its head daughter.

Constraints on phrase types also provide COMPOSITIONALITY in the semantics by specifying how the semantics of a phrase type is a function of the semantics of its daughter constituents.

Equi and raising structures (like *Kim tried to run* and *Kim seemed to run,* respectively) are both projections of heads that subcategorize for an unsaturated predicative complement, and have the same sorts of constituent structure. Equi verbs like *try,* however, systematically assign one more semantic role than raising verbs like *seem* do. Pollard and Sag (1994) represent this difference by saying that an equi verb subcategorizes for an NP with a referential index (i.e., one that is not an expletive), which is the same as the index

of the subject element that its complement subcategorizes for, and assigns a semantic role to that index, whereas a raising verb just subcategorizes for whatever its infinitive VP complement subcategorizes for, and assigns no semantic role to the index of that element.

The general outlines of the HPSG treatment of unbounded extractions (WH-MOVEMENT) follow the three-part strategy developed in GPSG (Gazdar 1981; Gazdar et al. 1985). An extra constituent is licensed just in case it matches a missing constituent. Something must ensure that the missing constituent is missing. The correspondence between the gap and the extra constituent (the *filler*) is recorded via constraints on local (i.e., depth one) constituency relations over an indefinitely large array of structure.

In HPSG, the extra constituent is licensed in strong (topicalization-type) extractions by the schema or sort declaration that defines head-filler clauses (topicalization structures), and for weak extraction phenomena such as *tough*-constructions, by subcategorization and sort specifications that require a complement daughter to not be lexically realized. Gaps (or traces) are licensed in phrases by constraints or rules that allow dependents to be unrealized when the lexical head that selects them inherits information that a matching element should be missing. As in GPSG, "a linked series of local mother-daughter feature correspondences" (Gazdar et al. 1985: 138), embodied as constraints on phrase-types, entail that the extra constituent and the missing constituent match.

The HPSG account of the binding of indexical elements like *her* and *themselves* is stated in terms of the relative obliqueness of the GRAMMATICAL RELATIONS of the indexical and its antecedent relative to a predicate. Considering its nonconfigurational approach, the HPSG binding theory nonetheless resembles familiar configurational accounts:

- A locally commanded anaphor must be locally o-bound.
- A personal pronoun must be locally o-free.
- A non-pronoun must be o-free.

However, it differs crucially from typical configurational accounts in that it has an inherently narrower scope. Principle A does not constrain all anaphors to be locally o-bound (coindexed to something before them on a predicate's argument-structure list); it constrains only those that are locally o-commanded (i.e., the ones that are noninitial on the list). This makes strong, vulnerable, and apparently correct claims. First, pronouns that are initial elements on argument-structure lists are unconstrained—free to be anaphors, coindexed to anything, and vacuously satisfying principle A, or to be pronouns, substantively satisfying principle B. Thus, the theory predicts that phrases in these "exempt" conditions, which are coindexed to anything anywhere in a higher clause, or even outside the sentence altogether, can be either anaphors or pronouns. This is correct; the reflexive pronouns that contradict the naive versions of principle A are generally replaceable with personal pronouns with the same reference.

Unification-based, declarative models of grammar like HPSG are attractive for natural language processing applications (e.g., as interfaces to expert systems) precisely

$$\begin{bmatrix} \text{SYNSEM | LOCAL | CATEGORY | HEAD } & \boxed{1} \\ \text{HEAD-DTR} & <[\text{SYNSEM | LOCAL | CATEGORY | HEAD } & \boxed{1} \ ]> \end{bmatrix}$$

headed-phrase

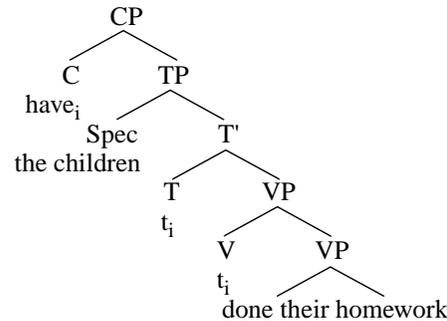
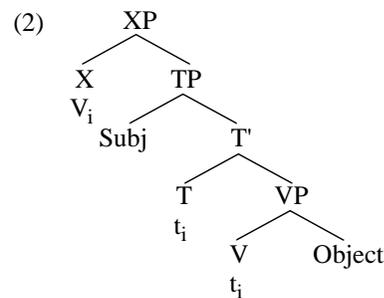
Head Movement

Within the syntactic framework that grew out of Chomsky (1965), elements that appear in unexpected positions are often said to have undergone movement. One case of this is wh-movement where a maximal projection (see X-BAR THEORY) moves to Spec, CP. Heads of maximal projections may also be displaced as seen by the following triple. "The children will not *have* done their homework." "The children *have* not done their homework." "*Have* the children done their homework?" The verb *have* appears in three different positions with respect to negation *not* and the subject *the children*. A head movement account assumes that *have* originates in V (head of VP), moves to T(ense) (head of TP), and then to C (head of CP).

(1) [$_{CP}$C [$_{TP}$ the children T [$_{VP}$ V [$_{VP}$ do their homework]]]].


By positing a process by which heads may be moved, languages that appear to have quite different surface realizations may be seen as having similar abstract underlying representations that are then disrupted by language-specific rules of head movement. For instance, if one assumes that VPs containing the V and the object are universal (see LINGUISTIC UNIVERSALS), one can account for VSO languages (see TYPOLOGY) by positing obligatory movement of the V to a head higher in the syntactic tree in these languages.

(2)


The word order in verb second languages such as German is characterized by obligatory movement of a topic to Spec, CP and head movement of the verb to C (see PARAMETER-SETTING APPROACHES TO ACQUISITION, CREOLIZATION, AND DIACHRONY).

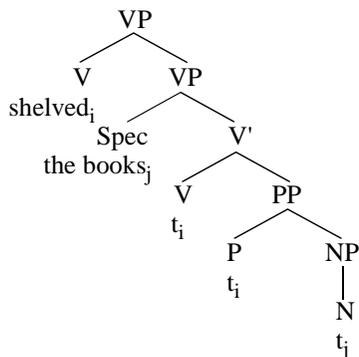
Another use of head movement has been to explain the tight correlation between morpheme orders and phrase structure (the mirror principle of Baker 1985) through local iterative head movement. Although the movement in English discussed earlier transposes words by moving a word into an empty head position, head movement may also move a stem into a head which contains an affix (or force movement of a word which contains this affix in MINIMAL-ISM). For example, in Japanese where the morpheme order is V-Tense-C as in *tabe-ta-to,* "eat-pst-Comp(that)," the verb has undergone the same movement that we saw for English from V to T to C, picking up the head-related MOR-PHOLOGY.

This use of head movement to create morphologically complex words can be further extended to account for processes such as noun incorporation where the noun head of the object NP incorporates into the verb through head movement to form complex verbs like the Mohawk form in (3) (see POLYSYNTHETIC LANGUAGES as well as Baker 1988 and 1996).

(3) wa-hake-'sereht-uny-λ-'
     fact-agr(3sS)+agr(1sO)-car-make-ben-punc
     'He made a car for me'

Head movement as a mechanism to build complex words interacts in obvious ways with questions concerning morphology and the LEXICON (see, e.g., diSciullo and Williams 1988 for arguments against this account of incorporation).

As well as creating morphologically complex words, head movement has been used to represent words that are morphologically simple but semantically complex. Hale and Keyser (1993) have suggested that denominal and deadjectival verbs such as *shelve* and *thin* are formed through head movement. "The children shelved the books" would be derived from a structure similar to "The children put the books on the shelf." The verb and the preposition would be null, however, allowing the movement of *shelve* as the head of the prepositional object NP to move iteratively through the empty P to the empty V. (The structure below contains an extra VP; see Hale and Keyser 1993 for details.)

(4) the children [$_{VP}$ shelved [the books] [$_{PP}$ P [$_{NP}$ N]].


Like other movements, head movement in not unconstrained but must obey a locality condition. Descriptively this locality condition requires movement to the most local possible landing site (the Head Movement Constraint of Travis 1984). Baker (1988) and Rizzi (1990) have subsequently reformulated this locality condition, collapsing it with the locality condition on rules that move maximal projections. The existence of this locality condition on head movement and the similarity of this condition to the condition for movement of maximal projections strengthens the claim that head movement is one instance of a more general movement rule. Further, the fact that this locality condition shows up in noun incorporation and denominal verb formation as well as the English verb movement facts strengthens the claim that they are all part of the same phenomenon. For instance, the following strings are ungrammatical for the same reason:

(5) a. *Have the children will __ done their homework
     b. *wa-hake-'sereht-uny-λ-' wa'-ke-nohare-'
         fact-agr(3sS)+agr(1sO)-car-make-ben-punc fact-agr(1sS)-wash-punc)
         'He made me wash the car' (lit: he me-car-made wash)
     c. *The children shelved the books on __.

In all three cases an intervening head position has been skipped (the T *will,* the V *ohare,* "wash," and the P *on*), violating the Head Movement Constraint.

If heads must always move to head positions, then head movement may be used as a probe to determine phrase structure. For instance, Pollock (1989) has argued that there must be (at least) two head positions between C and V due to the fact that, in French, there are two possible landing sites for the verb—one between the subject and negation (as in the English example above) and one between negation and an adverb. This may be extended as in Cinque (forthcoming) to posit head positions between different classes of adverbs in order to account for the possible placement of the participle *rimesso* (marked with an X) in the following Italian sentence.

(6) Da allora, non hanno X di solito X mica X più X sempre X completamente *rimesso* tutto bene in ordine
     "Since then, they haven't usually not any longer always put everything well in order"

It has also been proposed that head movement cannot proceed from a lexical category (N, V, A, P) through a functional category (T, C, D(et)) back to a lexical category to explain why functional (grammatical) morphemes are not found in, say, causative structures (*make-fut-work; see Li 1990). A typology of head movement has also been proposed (Koopman 1983) that includes one type of head movement with the characteristics of NP-Movement (like passive and raising), and another with the characteristics of WH-MOVEMENT.

Head movement is different from maximal projection movement in that it can be seen to create both morphologically complex as well as (the meaning of) morphologically simple words, arguably putting it into direct competition with lexical and semantic rules. Yet because it shows parallel restrictions and typology to rules that permute maximal projections, it can be said to be part of the computational component of SYNTAX.

Hebb, Donald O.

Donald Olding Hebb (1904–1985) was, during his lifetime, an extraordinarily influential figure in the discipline of psychology. His principled opposition to radical BEHAVIORISM and emphasis on understanding what goes on between stimulus and response (perception, LEARNING, thinking) helped clear the way for the cognitive revolution. His view of psychology as a biological science and his neuropsychological cell-assembly proposal rejuvenated interest in physiological psychology. Since his death, Hebb's seminal ideas exert an ever-growing influence on those interested in mind (cognitive science), brain (neuroscience), and how brains implement mind (cognitive neuroscience).

On graduating from Dalhousie University in 1925, Hebb aspired to write novels, but chose instead the more practical field of education and quickly became a school principal. The writings of JAMES, FREUD, and Watson stimulated his interest in psychology, and as a part-time graduate student at McGill University, Hebb was exposed to Pavlov's program. Unimpressed, Hebb was "softened up for [his] encounter with Kohler's GESTALT PSYCHOLOGY and LASHLEY's critique of reflexology." Hebb went to work with Lashley, and in 1936 completed his doctorate at Harvard on the effects of early visual deprivation on size and brightness perception in the rat. He accepted Wilder PENFIELD's offer of a fellowship at the Montreal Neurological Institute, where he explored the impact of brain injury and surgery, particularly lesions of the frontal lobes, on human intelligence and behavior. From his observations that removal of large amounts of tissue might have little impact on MEMORY and INTELLIGENCE, Hebb inferred a widely distributed neural substrate. At Queens University, Hebb developed human and animal intelligence tests (including the "Hebb-Williams" maze) and concluded that experience played a much greater role in determining intelligence than was typically assumed (Hebb 1942).

In 1942 Hebb rejoined Lashley, who had become director of the Yerkes Laboratory of Primate Biology. There Hebb explored fear, anger, and other emotional processes in the chimpanzee (cf. EMOTION AND THE ANIMAL BRAIN). Stimulated by the intellectual climate at Yerkes, Hebb began writing a book synthesizing different lines of research into a "general theory of behavior that attempts to bridge the gap between neurophysiology and psychology" (Hebb 1949: vii). Hebb returned to McGill as professor of psychology and in 1948 was appointed chair. His book *The Organization of Behavior: A Neuropsychological Theory* wielded a kind of magic in the years after its appearance (Hebb 1949). It attracted many brilliant scientists into psychology, made McGill University a North American mecca for scientists interested in the brain mechanisms of behavior, led to many important discoveries, and steered contemporary psychology onto a more fruitful path.

For Hebb "the problem of understanding behavior is the problem of understanding the total action of the nervous system, and vice versa" (1949: xiv), and his advocacy of an interdisciplinary effort to solve this "neuropsychological" problem was his most general theme. When Hebb's book was published physiological psychology was in decline, and there was a growing movement in psychology to reject physiological concepts (Skinner 1938). *The Organization of Behavior* marked a turning point away from this trend. Metaphors, using nonbiological devices with well-understood properties, figure prominently in the history of attempts to explain behavior and thought. The mental chemistry of the British Associationists, hydraulics of psychotherapy, magnetic fields of Gestalt psychology, and the computer metaphor of information processing psychology were all fruitful to a point, but then limited and misleading. Hebb's appealingly simple alternative was to explain human and animal behavior and thought in terms of the actual device that produces them—the brain. In *The Organization of Behavior,* Hebb presented just such a *neuropsychological* theory.

There were three pivotal postulates: (1) Connections between neurons increase in efficacy in proportion to the degree of correlation between pre- and postsynaptic activity. In neuroscience this corresponds to the "Hebb synapse," the first instances of which were later discovered in LONG-TERM POTENTIATION and kindling, whereas in cognitive science this postulate provides the most basic learning algorithm for adjusting connection weights in artificial NEURAL NETWORK models. (2) Groups of neurons that tend to fire together form a cell-assembly whose activity can persist after the triggering event and serves to represent it. (3) Thinking is the sequential activation of a set of cell-assemblies.

Hebb knew that his theory was speculative, vague, and incomplete. Missing from the model, for example, was neural inhibition (Milner 1957), a concept Hebb later incorporated (1959). But Hebb believed that a class of theory was needed, of which his was merely one specific form—subject to modification or rejection in the face of new evidence. Hebb's ideas were certainly fruitful in generating new evidence, as whole literatures on the role of early experience in PERCEPTUAL DEVELOPMENT (Hunt 1979), sensory deprivation (Zubek 1969), self stimulation (Olds and Milner 1954), the stopped retinal image (Pritchard, Heron, and Hebb 1960), synaptic modifiability (Goddard 1980), and learning without awareness (McKelvie 1987), were provoked or fostered by them.

When philosophy and physiology converged in the nineteenth century, psychology emerged with the promise of a science of mental life (Boring 1950). By providing a neural implementation of the Associationists' mental chemistry Hebb fulfilled this promise and laid the foundation for neoconnectionism, which seeks to explain cognitive processes in terms of connections between assemblies of real or artificial neurons.

Helmholtz, Hermann Ludwig Ferdinand von

Hermann Ludwig Ferdinand von Helmholtz (1821–1894) was born on August 31, 1821, in Potsdam. His father, Ferdinand Helmholtz, was a respected teacher of philology and

philosophy at the gymnasium. His mother was the daughter of a Hanoverian artillery officer with the surname Penne, descended from the Quaker William Penn, founder of Pennsylvania.

After serving as an army surgeon, Helmholtz held a succession of academic positions—lecturer at the Berlin Anatomy Museum, professor of physiology at Konigsberg, professor of physiology at Bonn, professor of physiology at Heidelberg, professor of physics at the Military Institute for Medicine and Surgery in Berlin, first president of the Imperial Physico-Technical Institute in Berlin. He married and had two children, his son Richard becoming a physical chemist. During his extremely distinguished life he was ennobled by the emperor: hence the "von" in his name.

Helmholtz was no less than a hero of nineteenth-century science, making major contributions to physics and the foundations of geometry, and founding the modern science of visual and auditory perception. He formulated the principle of conservation of energy in 1847, and made significant contributions to the philosophy of non-Euclidean geometry. This fueled his rejection of the prevailing Kantian philosophy in favor of a thoroughly empirical approach to the natural and biological sciences. He was the last scholar to combine both in depth.

Helmholtz was the first to see a living human RETINA. The wonderful memory of doing so remained with him for the rest of his life. His discovery was made with the extraordinarily useful instrument, the ophthalmoscope, which he invented in 1851. He explained why the pupil is black—the observing eye and head gets in the way of light reaching the observed retina—so he introduced light onto the retina with a part-reflecting 45° mirror, using thin microscope slides for part-reflecting mirrors, and also a concave lens. Although Helmholtz immediately saw its general medical significance, doctors were slow to adopt it. It became his most famous invention, which set him up as a scientist commanding support for any future work he chose to undertake.

A guiding principle for Helmholtz's physiological psychology was his teacher Johannes Muller's law of specific energies (perhaps better called law of specific qualities): "In whatever way a terminal organ of sense may be stimulated, the result in CONSCIOUSNESS is always of the same kind." Various SENSATIONS are given not by different nerve signals but according to which part of the "sensory" brain is stimulated. The eyes, ears, and the other organs of sense convert patterns of various kinds of physical energies into the same neural coding, now known to be trains of minute electrical impulses called action potentials, varying in frequency according to strength of stimulation. It was Helmholtz who first measured the rate of conduction of nerve, and recorded reaction times to unexpected events. His teacher Johannes Muller thought the speed must be too great to measure, probably greater than the speed of light; but Helmholtz showed him to be wrong with a very simple technique. For noninvasive measures on humans, he touched the shoulder or the wrist and noted the difference in reaction times. Knowing the difference in length of nerve between shoulder and wrist, it was easy to calculate the conduction rate, and also to find the brain's processing delay time. For a long time Muller could not believe that nerve conduction rate is slower than sound!

Helmholtz followed the English philosopher John Locke (1632–1704) in holding that sensations are symbols for external objects, no more like external objects than words used to describe them. Thus the physical world is separated from experience, and perception is only indirectly related to external events or objects. This, and Muller's law of specific energies, are basic to his theory that visual perceptions are unconscious inferences. This was a generation before Freud's unconscious mind, which also evoked much criticism as it challenged the right to blame, or indeed praise, actions that are unconscious. Yet studying unconscious processes has proved vital for investigating brain and mind, perhaps ultimately to understanding consciousness. For Helmholtz phenomena of ILLUSIONS are important evidence for understanding perceptions as inferences, depending on assumptions that may be wrong. His basic principle was: "We always think we see such objects before us as would have to be present in order to bring about the same retinal images under normal conditions of observation." So afterimages and even crude pictures are seen as objects.

Apart from the mathematical and experimental sciences as well as philosophy, he was talented in languages and in music, playing the piano. He conveyed science and something of the arts to the public with notable popular lectures that remain interesting to read. Remarkably active throughout his life, he suffered occasional migraines, which interrupted his work, and hay fever, which spoiled his holidays. He traveled widely, often to the British Isles, and was a particular friend of the physicist Lord Kelvin, meeting in Glasgow, Scotland. He attributed his success to the unusual range of his knowledge, which indeed was exceptional.

Helmholtz's death on September 8, 1894, a few days after his seventy-third birthday, resulted from an accidental fall while on a ship bound for America, which, sadly, he never visited. Neither of his biographies mentions his account of perception as unconscious inference, which after a long delay is now seen as centrally important in current cognitive psychology. There should be a fuller and more readable life of this major scientist and philosopher, who gave psychology a scientific basis that is still not fully appreciated, and championed thoroughgoing empiricism for understanding physics and biology, and even the misleading yet highly suggestive phenomena of illusions.

Hemispheric Specialization

The modern era of neuroscientific investigation into the asymmetry of the cerebral hemispheres began in the 1860s when localization of function within the cerebral cortex was thrust into the forefront of scientific thought by Paul BROCA. Broca etched out his place in history by announcing that language resided in the frontal lobes and that the left hemisphere played the predominant role. Although neither of these ideas originated with Broca, the recognition that the brain may be functionally asymmetric opened up new avenues of cognitive and neurobiological investigation that have persisted for well over a century. This summary paper will briefly describe a number of lateralized cognitive functions, including language, FACE RECOGNITION, fine MOTOR CONTROL, visuospatial skills, and EMOTIONS, and will examine whether structural asymmetries in the organization of cerebral cortex are related to these functional specializations. The interested reader is referred to several thorough reviews on the topic of lateralization (see further readings).

Language Lateralization

Language is perhaps the most notable and strongly lateralized function in the human brain. Much of our knowledge of the organization of language in the brain is based on the correlation of behavioral deficits with the location of lesions in the neocortex of patient populations. Several language areas are found to be located within the left hemisphere and the behavioral outcome of injury to these particular cerebral locations is generally predictable (e.g., Broca's APHASIA, Wernicke's aphasia, conduction aphasia). In other cases uniquely specific linguistic deficits can result. For example, one case has been reported in which the subject showed an unusual disability at naming fruits and vegetables despite normal performance on a variety of other lexical/semantic tasks following injury to the frontal lobe and BASAL GANGLIA (Hart, Berndt, and Caramazza 1985). Recent reports describe two more patients who are able to produce a normal complement of verbs, but are extremely deficient in noun production, while a third case shows exactly the reverse deficit. Despite the variety of deficits and lesion locations, all are associated with the left hemisphere (Damasio and Tranel 1993).

Modern research techniques including regional cerebral blood flow, POSITRON EMISSION TOMOGRAPHY (PET), functional MAGNETIC RESONANCE IMAGING (fMRI), and intraoperative cortical stimulation, have continued to localize cortical regions that are activated during language tasks and further support the left hemisphere's special role in language functions.

Although it is true that individuals can be right hemisphere, or bilaterally, dominant for language, 90 percent of the adult population (both left- and right-handed) have language functions that are predominantly located within the left hemisphere. Even in seemingly anomalous situations the left hemisphere maintains its "specialized" role in language functions. Studies of bilingual subjects indicate that both languages are located in the same hemisphere, but may be dif-

ferentially distributed (Mendelsohn 1988). In addition, language lateralization is not dependent on the vocal-auditory modality. Disturbances of SIGN LANGUAGE in deaf subjects are also consistently associated with left hemisphere damage, and signing deficits are typically analogous to the language deficits one observes in hearing subjects with the same lesion location (Bellugi, Poizner, and Klima 1989).

In early decorticate patients with one hemisphere missing, language development proceeds relatively normally in either hemisphere (Carlson et al. 1968). Language development in the right hemisphere, while retaining its phonemic and semantic abilities, has deficient syntactic competence that is revealed when meaning is conveyed by syntactic diversity, such as repeating stylistically permuted sentences and determining sentence implication (Dennis and Whitaker 1976). These results suggest that although the right hemisphere is capable of supporting language, language usage does not reach a fully normal state.

In adults who have had language develop in the dominant hemisphere, but later became available for the testing of language in their right hemisphere due to commissurotomy or hemispherectomy, the right hemisphere appears capable of understanding a limited amount of vocabulary, but is usually unable to produce speech. In recent years speech production by the right hemisphere of commissurotomy patients has also been reported, albeit in an extremely limited context (Baynes, Tramo, and Gazzaniga 1992).

Motor Control and the Left Hemisphere

Nine out of ten individuals demonstrate a clear preference for using the right hand. Broca inferred that the hemisphere dominant for language would also control the dominant hand; however, it soon became clear that this was not universally true. Most studies suggest that over 95 percent of right-handers are left-hemisphere dominant for language; however, only 15 percent of left-handers show the expected right-hemisphere dominance. Of left-handers, a full 70 percent are left-hemisphere dominant, while the remaining 15 percent have bilateral language abilities.

Disorders of skilled movement are referred to as *apraxia*. These disorders are characterized by a loss of the ability to carry out familiar purposeful movements in the absence of sensory or motor impairment. The preponderance of apraxia following left hemisphere damage has led many researchers to suggest that this hemisphere may be specialized for complex motor programming. Although lesion studies argue for the left hemisphere's dominance of complex motor control, the lateralization of this function is not nearly as strong as that seen for language. In addition, studies of commissurotomy patients suggest that the right hemisphere is capable of independently directing motor function in response to visual nonverbal stimuli without the help of the left hemisphere (Geschwind 1976).

Right Hemisphere Specializations

The right hemisphere also plays a predominant role in several specialized tasks. Right hemisphere lesion patients have greater difficulties localizing points, judging figure from

ground, and performing tasks that require stereoscopic depth discriminations than do patients suffering damage to the left hemisphere. Additionally, commissurotomy patients show a right hemisphere advantage for a number of visuo-perceptual tasks (Gazzaniga 1995). Many investigators have also reported a right hemisphere advantage for visuopercep-tual tasks in normal subjects, but these results are controver-sial. On the whole visuoperceptual abilities do not appear to be strongly lateralized as both hemispheres are capable of performing these types of low level perceptual tasks. Sev-eral suggestions have been made to account for the asym-metries that are present. One suggestion is that there is no right hemisphere advantage for visuoperception, but a left hemisphere disadvantage due to that hemisphere's preoccu-pation with language functions (Corballis 1991; Gazzaniga 1985). Other authors have reported a difference in the abil-ity of each hemisphere to process global versus local pat-terns or in terms of a hemispheric specialization for different spatial frequencies. The right hemisphere is typi-cally much better at representing the whole object while the left hemisphere shows a slight advantage for recognizing the parts of an object (Hellige 1995).

One specific task that does show convincing evidence for a right hemisphere advantage is face perception. Prosopag-nosia, the inability to recognize familiar faces, occurs more often following damage to the right hemisphere than the left (although most cases result from bilateral damage). In addi-tion, commissurotomy patients have a right hemisphere advantage in their ability to recognize upright faces (Gazza-niga and Smylie 1983; Puce et al. 1996).

In support of a facial processing asymmetry, a number of cognitive studies have indicated that normal subjects attend more to the left side of a face than the right and that the information carried by the left side of the face is more likely to influence a subject's response. Finally, numerous imaging studies have demonstrated right hemispheric activation using a variety of facial stimuli.

The right hemisphere may also be superior at tasks requiring spatial attention (Mangun et al. 1994). Hemine-glect patients typically do not attend to one side of space and do not recognize the presence of individuals in the other hemifield. Additionally, they ignore one side of their body and copy drawings in a manner that entirely ignores half of the picture. This attentional deficit is more often observed following right hemisphere damage.

Studies of normal subjects, psychiatric patients, and lesion patients indicate that the right hemisphere is domi-nant in the recognition and expression of emotion and is preferentially activated during the experience of emotion. Lesions of the right hemisphere are also often associated with affective disorders. Many of the lesion results remain controversial, but experimental studies do demonstrate a left visual field/right hemisphere superiority for the recognition of emotions.

Structural Asymmetry

If the hemispheres are not symmetrical in their functioning then the physical structure of the brain may also be asym-metrical. Although many contradictory reports regarding the weight and volume of the two cerebral hemispheres were published following the discovery of the left hemi-sphere's role in language, it was not long before the differ-ences between the length of the left and right sylvian (lateral) fissures were described. Related to this difference in sylvian fissure length are the casual reports by von Economo and Horn in 1930 and later Pfeifer (1936) that the planum temporale, the dorsal surface of the temporal lobe, is typically larger in the left hemisphere than the right. This very specific size difference between the two hemispheres became a focus of research in the late 1960s after it was described that the left planum temporale (the dorsal surface of the temporal lobe) is significantly larger than the right in 65 percent of the population (GESCHWIND and Levitsky 1968). Based on these studies, it was com-monly accepted that a difference in the size of cortical regions could account for the left hemisphere's specializa-tion for language.

A recent reanalysis of this question using computer-generated three-dimensional reconstruction techniques has revealed a different story. The right lateral fissure rises dra-matically at its caudal extent which results in an apparent foreshortening of the planum in the right hemisphere when it is studied using the previously applied methods (i.e., photographic tracings and slice reconstruction). Three-dimensional measurements that accurately map the highly convoluted cortical surface reveal no size difference between the left and right planum temporale (Loftus et al. 1993). Thus these anatomical differences may not reflect size differences between the hemispheres, but rather differ-ences in gross cortical folding.

Many modern authors have also continued to report the difference in the length of the sylvian fissure that borders the lateral aspect of the planum on the dorsal surface of the temporal lobes (Rubens et al. 1976). Subsequently these findings have been corroborated in certain primate species, human fossils, infants, and, interestingly enough, in the male cat (Tan 1992).

Lateralized Cortical Circuitry

Although many studies have examined gross size differ-ences between the two hemispheres, relatively few have directly examined whether connectional or organizational specializations underlie lateralized functions. Not surpris-ingly, both neurochemical and structural differences have been found between the hemispheres.

Columnar organization also varies between the left and right posterior temporal areas. The left hemisphere has been reported to be organized into clear columnar units, while col-umns in the right hemisphere appear to be much less distinct (Ong and Garey 1990; cf. COLUMNS AND MODULES). This difference may be related to previous reports that the left temporal lobe has greater columnar widths and intercolum-nar distances. Sex differences in the density of neurons within cortical lamina have also been documented in poste-rior temporal regions (Witelson, Glezer, and Kigar 1995), and these results are beginning to support cognitive data sug-gesting that language functions in women are less lateralized than those in men (Strauss, Wada, and Goldwater 1992).

Differences in the fine dendritic structure of pyramidal cells in each hemisphere have also been reported within the frontal lobes (Scheibel 1984), and it has been suggested that the total dendritic length of left hemisphere pyramidal cells is greater than that of right hemisphere pyramidal cells and that this asymmetry may decrease with age (Jacobs and Scheibel 1993).

Cell size asymmetries have also been documented in these same areas. The cell size differences appear to be restricted to the largest of the large pyramidal cells within layer III of Broca's area and are not apparent in adjacent cortical regions (Hayes and Lewis 1995). This same size difference also exists in posterior language regions, but is spread throughout auditory areas, including the primary auditory cortex (Hutsler and Gazzaniga 1995). What is the functional meaning of larger cell sizes? The answer is unclear, but differences in cell body size may indicate differences in the length of a cell's axon or degree of bifurcation. Thus, pyramidal cell size may be related to connectivity differences between the two hemispheres. Recent studies of temporal lobe connectivity using newly-developed tract-tracing methods may support this notion. These studies demonstrate patchy connectivity within the posterior segment of Brodmann's area 22 (Wernicke's area) of both the left and right hemisphere. Additionally, the size of individual patches is quite symmetric, but the distance between individual patches of the left hemisphere is consistently greater than that found in the right (Schmidt et al. 1997). These connectional differences may play a role in the anatomical underpinnings of temporal processing differences between the two hemispheres that could be critical in asymmetric cognitive functions such as language analysis.

Although one might expect that symmetrical structure should be the norm in the human brain, symmetrical organization of the body may largely be due to the requirements of locomotion (Corballis 1991). In addition to the symmetrical placement of the limbs, sense organs may be placed symmetrically so that an organism can attend and respond equally to both sides of the world. Brain organization for these functions might mirror the body organization, but the hemispheric distribution of many cognitive functions may not be constrained in this way. Although there could be some advantage to having dual representations of functions not involved with locomotion (for instance, in the case of damage to one side of the brain), these benefits are likely outweighed by the disadvantages of delayed transmission across long fibers of the corpus callosum. When viewed in this context, it makes sense that certain functions would become largely the domain of one cerebral hemisphere and that damage to the normal brain, either through unilateral lesions or commissurotomy, would reveal a remarkable array of behavioral results.

Heuristic Search

Heuristic search is the study of computer algorithms designed for PROBLEM SOLVING, based on trial-and-error exploration of possible solutions. Problem solving tasks include "pathfinding problems," game playing, and CONSTRAINT SATISFACTION.

The task of navigating in a network of roads from an initial location to a desired goal location, with the aid of a roadmap, is an example of a pathfinding problem. The "states" of the problem are decision points, or intersections of two or more roads. The "operators" are segments of road between two adjacent intersections. The navigation problem can be viewed as finding a sequence of operators (road segments) that go from the initial state (location) to the goal state (location). In a game such as CHESS, the states are the legal board configurations, and the operators are the legal moves.

A search algorithm may be systematic or nonsystematic. A systematic algorithm is guaranteed to find a solution if one exists, and may in fact guarantee a lowest-cost solution. Nonsystematic algorithms, such as GREEDY LOCAL SEARCH, EVOLUTIONARY COMPUTATION, and other stochastic approaches, are not guaranteed to find a solution. We focus on systematic algorithms here.

The simplest systematic algorithms, called "brute-force search" algorithms, do not use any knowledge about the problem other than the states, operators, and initial and goal states. For example, "breadth-first search" starts with the initial state, then considers all states one operator away from the initial state, then all states two operators away, and so on until the goal is reached. Uniform-cost search, or Dijkstra's algorithm (Dijkstra 1959), considers the different costs of operators, or lengths of road segments in our example, and visits the states in increasing order of their distance from the start. A drawback of both these algorithms is that they require enough memory to hold all the states considered so far, which is prohibitive in very large problems (see the following).

"Depth-first search" more closely approximates how one would search if actually driving in the road network, rather than planning with a map. From the current location, depth-first search extends the current path by following one of the roads until a dead end is reached. It then backtracks to the last decision point that has not been completely explored, and chooses a new path from there. The advantage of depth-first search is that it only requires enough memory to hold the current path from the initial state.

"Bi-directional search" (Pohl 1971) searches forward from the initial state and backward from the goal state simultaneously, until the two searches meet. At that point, a complete path from the initial state to the goal state has been found.

A drawback of all brute-force searches is the amount of time they take to execute. For example, a breadth-first search of a road network will explore a roughly circular region whose center is the initial location, and whose radius is the distance to the goal. It has no sense of where the goal is until it stumbles upon it.

Heuristic search, however, is directed toward the goal. A heuristic search, such as the "A* algorithm" (Hart, Nilsson, and Raphael 1968), makes use of a "heuristic evaluation function," which estimates the distance from any location to the goal. For example, the straight-line distance from a given location to the goal is often a good estimate of the actual road distance. For every location visited by A*, it estimates the total distance of a path to the goal that passes through that location. This is the sum of the distance from the start to the location, plus the straight-line distance from the location to the goal. A* starts with the initial location, and generates all the locations immediately adjacent to it. It then evaluates these locations in the above way. At each step, it generates and evaluates the neighbors of the unexplored location with the lowest total estimate. It stops when it chooses a goal location.

A* is guaranteed to find a solution if one exists. Furthermore, if the heuristic function never overestimates actual cost, A* is guaranteed to find a shortest solution. For example, because the shortest path between two points is a straight line, A* using the straight-line distance heuristic function is guaranteed to find a shortest solution to the road navigation problem.

The bane of all search algorithms is called "combinatorial explosion." In road navigation, the total number of intersections is quite manageable for a computer. Consider, however, the traveling salesman problem (TSP). Given a set of N cities, the TSP is to find a shortest tour that visits all the cities and returns to the starting city. Given N cities, there are $(N-1)!$ different orders in which the cities could be visited. Clever algorithms can reduce the number of possibilities to 2^N, but even if N is as small as 50, 2^N is approximately 10^{15}. Even if a computer could examine a million possibilities per second, examining 10^{15} possibilities would take 31.7 years.

An algorithm that is well suited to problems such as the TSP is called depth-first branch-and-bound. A TSP solution is a sequence of cities. Depth-first branch-and-bound systematically searches the possible tours depth-first, adding one city at a time to a partial tour, and backtracks when a tour is completed. In addition, it keeps track of the length of the shortest complete tour found so far, in a variable α. Whenever a partial tour is found in which the sum of the trip segments already included exceeds α, we need not consider any extensions of that partial tour, inasmuch as the total cost can only be greater. In addition, a heuristic evaluation function can be used to estimate the cost of completing a partial tour. If the heuristic function never overestimates the lowest completion cost, whenever the cost of the segments so far, plus the heuristic estimate of the completion cost, exceeds α, we can backtrack. All known algorithms that are guaranteed to find an optimal solution to such "combinatorial problems" are variants of branch-and-bound.

Hidden Markov Models

A *hidden Markov model* (HMM) is a widely used probabilistic model for data that are observed in a sequential fashion (e.g., over time). A HMM makes two primary assumptions. The first assumption is that the observed data arise from a mixture of K probability distributions. The second assumption is that there is a discrete-time Markov chain with K states, which is generating the observed data by visiting the K distributions in Markov fashion. The "hidden" aspect of the model arises from the fact that the state-sequence is not directly observed. Instead, one must infer the state-sequence from a sequence of observed data using the probability model. Although the model is quite simple, it has been found to be very useful in a variety of sequential modeling problems, most notably in SPEECH RECOGNITION (Rabiner 1989) and more recently in other disciplines such as computational biology (Krogh et al. 1994). A key practical feature of the model is the fact that inference of the hidden state sequence given observed data can be performed in time linear in the length of the sequence. Furthermore, this lays the foundation for efficient estimation algorithms that can determine the parameters of the HMM from training data.

A HMM imposes a simple set of dependence relations between a sequence of discrete-valued state variables S and observed variables Y. The state sequence is usually assumed to be first-order Markov, governed by a $K \times K$ matrix of transition probabilities of the form $p(S_{t+1} = i \mid S_{t+1} = j)$, that is, the conditional probability that the system will transit to state i at time $t + 1$ given that the system is in state j at time t (Markov 1913). The K probability distributions associated with each state, $p(Y_t \mid S_t = i)$, describe how the observed data Y are distributed given that the system is in state i. The transition probability matrix and the parameters of the K probability distributions are usually assumed not to vary over time. The independence relations in this model can be summarized by the simple graph in figure 1. Each state depends only on its predecessor, and each observable depends only on the current state. A large number of variations of this basic model exist, for example, constraints on the transition matrix to contain "null" transitions, generalizations of the first-order Markov dependence assumption, generalizations to allow the observations Y_t to depend on past observations Y_{t-2}, Y_{t-3}, . . . , and different flexible parametrizations of the K probability distributions for the observable Ys (Poritz 1988; Rabiner 1989).

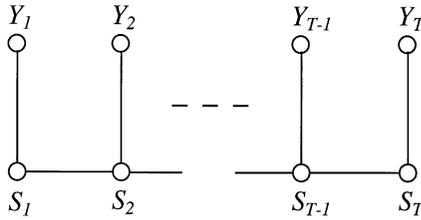
The application of HMMs to practical problems involves the solution of two related but distinct problems. The first is the *inference* problem, where one assumes that the parameters of the model are known and one is given an observed data sequence $\{Y_1, . . . , Y_T\}$. How can one calculate $p(Y_1, . . . , Y_T \mid \text{model})$, as in speech recognition (for example) when finding which word model, from a set of word models, explains the observed data best? Or how can one calculate the most likely sequence of hidden states to have generated $\{Y_1, . . . , Y_T\}$, as in applications such as decoding error-correcting codes, where the goal is to determine which specific sequence of hidden states is most likely to have generated the data. Both questions can be answered in an exact and computationally efficiently manner by taking advantage of the independence structure of the HMM. Finding $p(Y_1, . . ., Y_T \mid \text{model})$ can be solved by the forward-backward procedure, which, as the name implies, amounts to a forward pass through the possible hidden state sequences followed by a backward pass (Rabiner 1989). This procedure takes on the order of TK^2


Figure 1. A graphical representation of the dependencies in a Hidden Markov Model.

operations (linear in the length of the observed sequence). Similarly, the most likely sequence of hidden states for a given observation sequence can be found by the well-known Viterbi algorithm, which is a general application of DYNAMIC PROGRAMMING to this problem (Forney 1973). It also involves a forward and backward pass through the data and also takes order of TK^2 operations.

The second general problem to be solved in practice is that of *estimation,* that is, finding values for the HMM parameters; the $K \times K$ transition matrix, the parameters of the K observable probability distributions, and an initial probability distribution over the states. Implicit is the assumption that K is known (usually assumed to be the case in practice). Given K, the most widely used technique for estimation of HMM parameters is the Baum-Welch algorithm (Baum et al. 1970). The general idea behind the algorithm is as follows. Assume that the parameters are fixed at some tentative estimate. Use the forward-backward algorithm described earlier to infer the probabilities of all the possible transitions $p(S_{t+1} = j \mid S_t = i)$ between hidden states and all probabilities of observed data $p(Y_t \mid S_t = i)$, keeping the tentative parameters fixed. Now that one has estimates of the transitions and observation probabilities, it is possible to reestimate a new set of parameters in closed form. Remarkably, it can be shown that $p(Y_1, \ldots, Y_T \mid \theta_{new}) \geq p(Y_1, \ldots, Y_T \mid \theta_{old})$, that is, the likelihood of the new parameters is at least as great as that of the old, where θ denotes the particular HMM parameter set. Thus, iterative application of this two-step procedure of forward-backward calculations and parameter estimation yields an algorithm that climbs to a maximum of the likelihood function in parameter space. It turns out that this procedure is a special case of a general technique (known as the expectation-maximization or EM procedure; McLachlan and Krishnan 1997) for generating maximum-likelihood parameter estimates in the presence of hidden variables. Variations of the EM algorithm are widely used in machine learning and statistics for solving UNSUPERVISED LEARNING problems. The HMM parameter space can have many local maxima, making estimation nontrivial in practice. The Baum-Welch and EM procedures can also be generalized to maximum a posteriori and Bayesian estimation, where prior information and posterior uncertainty are explicitly modeled (e.g., Gauvain and Lee 1994).

It can be also be useful to look at HMMs from other viewpoints. For example, figure 1 can be interpreted as a simple Bayesian network and, thus, a HMM can be treated in complete generality as a particular member of the Baye-

sian network family (Smyth, Heckerman, and Jordan 1997). An advantage of this viewpoint is that it allows one to leverage the flexible inference and estimation techniques of BAYESIAN NETWORKS when investigating more flexible and general models in the HMM class, such as more complex sequential dependencies and multiple hidden chains.

High-Level Vision

Aspects of vision that reflect influences from memory, context, or intention are considered "high-level vision," a term originating in a hierarchical approach to vision. In currently popular interactive hierarchical models, however, it is almost impossible to distinguish where one level of processing ends and another begins. This is because partial outputs from lower-level processes initiate higher-level processes, and the outputs of higher-level processes feed back to influence processing at the lower levels (McClelland and Rumelhart 1986). Thus, the distinctions between processes

residing at high, intermediate, and low levels are difficult to draw. Indeed, substantial empirical evidence indicates that some high-level processes influence behaviors that are traditionally considered low-level or MID-LEVEL VISION. With this caveat in mind, the following topics will be considered under the heading "high-level vision": object and face recognition, scene perception and context effects, effects of intention and object knowledge on perception, and the mental structures used to integrate across successive glances at an object or a scene.

One major focus of theory and research in high-level vision is an attempt to understand how humans manage to recognize and categorize familiar objects quickly and reliably. An adequate theory of OBJECT RECOGNITION must account for (1) the accuracy of object recognition over changes in object size, location, and orientation (preferably, this account would not posit a different memory record for each view of every object ever seen); (2) the means by which the spatial relationships between the parts or features of an object are represented (given that objects and spaces seem to be coded in different VISUAL PROCESSING STREAMS, with object processing occurring in ventral pathways and space processing occurring in dorsal pathways); and (3) the attributes of both basic-level and subordinate-level recognition (e.g., recognition of a finch as both a bird and as a specific kind of bird). Current competing object recognition theories differ in their approach to each of these factors (see Biederman 1987; Tarr 1995). According to Biederman (1987), objects are parsed into parts at concave portions of their bounding contours, and the parts are represented in memory by a set of abstract components (generalized cylinders); the claim is that these components can be extracted from an image independent of changes in orientation (up to an accidental view rendering certain component features invisible). On Biederman's view, (1) object recognition should be robust to orientation changes as long as the same components can be extracted from the image; and (2) very few views of each object need be represented in memory. Tarr (1995) adopts a different theoretical approach, proposing that specific views of objects are represented by salient features, and that object recognition is orientation-dependent. On Tarr's approach, multiple views of each object are stored in memory, and objects seen in new views must undergo some time-consuming process before they are recognized. The empirical evidence suggesting that object recognition is orientation-dependent is accumulating, favoring the multiple-views approach. However, evidence indicates that the concave portions of bounding contours are more important for recognition than other contour segments, supporting the idea that part structure is critically important for object recognition, consistent with an approach like Biederman's.

A related, but independent, research focus is FACE RECOGNITION. Behavioral evidence obtained from both normal and brain damaged populations suggests that different mechanisms are used to represent faces and objects, and in particular, that holistic, configural processing seems to be more critical for face than for object recognition (e.g., Farah, Tanaka, and Drain 1995; Moscovitch, Winocur, and Behrmann 1997).

A second major problem in high-level vision is the question of how scenes are perceived and, in particular, how the semantic and spatial context provided by a scene influences the identification of the individual objects within the scene. Any effects of scene context require the interaction of spatially local and spatially global processing mechanisms; the means by which this is accomplished have yet to be identified. Research indicates that scene-consistent objects are identified faster and more accurately when placed in a contextually appropriate spatial location rather than one that is contextually inappropriate (Biederman, Mezzanotte, and Rabinowitz 1982). In addition, recent evidence (Diwadkar and McNamara 1997) suggests that scene memory is viewpoint dependent, just as object memory is orientation-dependent. Such dependencies and similarities in the processing of scenes and objects raise questions about the extent to which the mechanisms for processing scenes and objects overlap, despite the apparent specialization of the two different visual processing streams. Nevertheless, much research continues to argue for fundamental differences in the representation of spaces and objects. An example is evidence that when no semantic context is present, memory for spatial configuration is excellent under conditions in which memory for object identity is impaired (Simons 1996). It is worth pointing out that whereas context effects are prevalent in visual perception, their influence may not extend to motor responses generated on the basis of visual input (Milner and Goodale 1995). Experiments measuring motor responses raise the possibility that the different visual processing streams associated with ventral and dorsal anatomical pathways are specialized for vision and action, respectively, rather than for the visual perception of objects and spaces, as originally hypothesized.

A third question central to investigations of high-level vision concerns the mechanisms by which successive glances at an object or a scene are integrated. Phenomenologically, perception of objects and scenes seems to be holistic and fully elaborated rather than piecemeal, abstract, and schematic. Contrary to the phenomenological impressions, evidence indicates that perception is not "everywhere dense" (Hochberg 1968); instead, visual percepts are largely determined by the stimulation obtained at the locus of fixation or attention, even when inconsistent information lies nearby (Hochberg and Peterson 1987; Peterson and Gibson 1991; Rensink O'Regan, and Clark 1997). It has been shown that the structures used to integrate the information obtained in successive glances are abstract and schematic in nature (Irwin 1996); hence, they can tolerate the integration of inconsistent information. Similarly, visual memories, assessed via mental IMAGERY research, are known to be schematic compared to visual percepts (Kosslyn 1990; Peterson 1993). One of the abiding questions in high-level vision is, given such circumstances, how can one account for the phenomenological impressions that percepts are detailed and fully elaborated? A recent appealing proposal is that the apparent richness of visual percepts is an illusion, made possible because eye movements (see EYE MOVEMENTS AND VISUAL ATTENTION) can be made rapidly to real world locations containing the perceptual details required to answer perceptual inquiries (O'Regan 1992). On this view,

the world serves as an external memory, filling in and supplementing abstract percepts on demand.

Other research in high-level vision investigates various forms of TOP-DOWN PROCESSING IN VISION. Included in this domain are experiments concerning the effects of observers' intentions on perception (where intentions are manipulated via instructions; Hochberg and Peterson 1987) and investigations of how object knowledge affects the perception of moving or stationary displays. For example, detection thresholds are lower for known objects than for their scrambled counterparts (Purcell and Stewart 1991). In addition, object recognition cues contribute to DEPTH PERCEPTION, along with the classic depth cues and the configural cues of GESTALT PERCEPTION (Peterson 1994). For moving displays, influences from object memories affect the direction in which ambiguous displays appear to move (McBeath, Morikowa, and Kaiser 1992). Moreover, although apparent motion typically seems to take the shortest path between two locations, Shiffrar and Freyd (1993) found that, under certain timing conditions, object-appropriate pathways are preferred over the shortest pathways. Much early research investigating the contributions to perception from knowledge, motivation, and intention was discredited by later research showing that the original results were due to response bias (Pastore 1949). Hence, it is important to ascertain whether effects of knowledge and intentions lie in perception *per se* rather than in memory or response bias. One way to do this is to measure perceptual processes online; another way is to measure perception indirectly by asking observers to report about variables that are perceptually coupled to the variable to which intention or knowledge refers (Hochberg and Peterson 1987). Many of these recent experiments have succeeded in localizing the effects of intention and knowledge in perception *per se* by using one or more of these methods; hence, representing an advance over previous attempts to study top-down effects on perception.

It is important to point out that not all forms of knowledge or memory can influence perception and not all aspects of perception can be influenced by knowledge and memory. Consider the moon illusion, for example. When the moon is viewed near the horizon, it appears much larger than it does when it is viewed in the zenith; yet the moon itself does not change size, nor does it cover areas of different size on the viewer's retina in the two viewing conditions. The difference in apparent size is an illusion, most likely caused by the presence of many depth cues in the horizon condition and by the absence of depth cues in the zenith condition. However, knowledge that the apparent size difference is an illusion does not eliminate or even reduce the illusion; the same is true for many illusions. The boundaries of the effects of knowledge and intentions on perception have yet to be firmly established. One possibility is that perception can be altered only by knowledge residing in the structures normally accessed in the course of perceptual organization (Peterson et al. 1996).

In summary, research in high-level vision focuses on questions regarding how context, memory, knowledge, and intention can influence visual perception. In the course of investigations into the interaction between perception and these higher-order processes, we will undoubtedly learn more about both. The result will be a deeper understanding of high-level vision and its component processes.

Hippocampus

The hippocampus is a brain structure located deep within the temporal lobe, surrounded by the lateral ventricle, and connected to subcortical nuclei via the fornix and to the neocortex via the parahippocampal region. Considerations of the information-processing functions of the hippocampus highlight its position as the final convergence site for outputs from many areas of the CEREBRAL CORTEX, and its divergent outputs that return to influence or organize cortical memory representations (figure 1).

The neocortex provides information to the hippocampus only from the highest sensory processing areas, plus multimodal and LIMBIC SYSTEM cortical areas and the olfactory cortex. These inputs follow a coarse rostral-to-caudal topography arriving in the parahippocampal region, composed of the perirhinal, parahippocampal, and entorhinal cortices (Burwell, Witter, and Amaral 1995). The latter areas project onto the hippocampus itself at each of its main subdivisions, the dentate gyrus, the CA3 and CA1 components of Ammon's horn, and the subiculum (figure 1). The main flow of information through the hippocampus involves serial connections from the dentate gyrus to CA3, CA3 to CA1, and then CA1 to the subiculum (Amaral and Witter 1989). The intrinsic hippocampal pathway partially preserves the topographical gradients of neocortical input, but there is also considerable divergence and associational connections particularly at the CA3 stage. Outputs of the subiculum, and to a lesser extent CA1, are directed back to the parahippocampal region, which in turn projects back onto the neocortical and olfactory areas that were the source of cortical inputs. These aspects of hippocampal organization maximize the potential for association of information from many cortical streams, and the potential for such associations to influence cortical processing broadly. Furthermore, the capacity for associative plasticity in the form of LONG-TERM POTENTIATION at dentate and CA1 synapses is well established, and has been related to normal rhythmic (theta) bursting activity in the hippocampus and to hippocampal memory function.

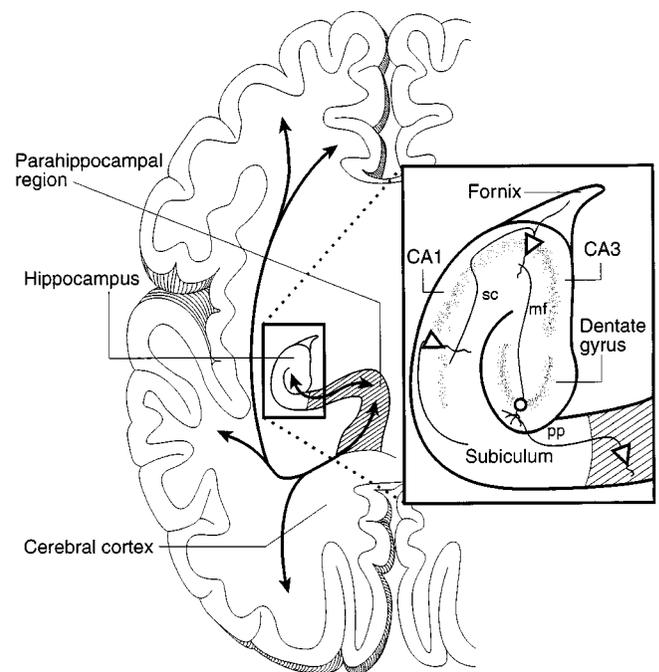
In 1957 Scoville and Milner described a patient known as H. M. who suffered profound amnesia following bilateral


Figure 1.

removal of substantial portions of both the hippocampus and parahippocampal region. H. M. demonstrated an almost complete failure to learn new material, whereas his remote autobiographical memories and short term memory were completely intact, leading to the view that the hippocampal region plays a specific role in the consolidation of short term memories into a permanent store. In addition, the amnesic impairment is also selective to declarative or explicit memory (cf. IMPLICIT VS. EXPLICIT MEMORY), the capacity for conscious and direct expression of both episodic and semantic memory (Corkin 1984; Squire et al. 1993; see also EPISODIC VS. SEMANTIC MEMORY). Conversely, amnesiacs demonstrate normal MOTOR LEARNING and CONDITIONING, and normal sensory adaptations and "priming" of perceptual stimuli; such forms of implicit memory occur despite their inability to recall or recognize the learning materials or the events surrounding the learning experience (see MEMORY, HUMAN NEUROPSYCHOLOGY). The development of a nonhuman primate model has demonstrated a parallel dissociation between severely impaired recognition memory and preserved acquisition of motor skills and perceptual discriminations following damage to the same hippocampal areas removed in H. M. (see MEMORY, ANIMAL STUDIES).

A central open question is precisely what role the hippocampus plays in declarative memory processing. Studies of the consequences of hippocampal damage in animals have generated several proposals about hippocampal function, each suggesting a specific form of hippocampal-dependent and hippocampal-independent memory. Perhaps the most prominent of these is the hypothesis that the hippocampus constitutes a COGNITIVE MAP, a representation of allocentric space (O'Keefe and Nadel 1978). This notion captures the multimodal nature of hippocampal inputs and

accounts for deficits in place learning observed following hippocampal damage. However, this view does not account for the global amnesia observed in humans or for impairments observed on some nonspatial learning tasks in animals with hippocampal damage. A reconciliation of its declarative and spatial functions may be possible by considering a fundamental role for the hippocampus in representing relations among items in a memory network and in "flexibility" of memory expression by which all items can be accessed through any point in the network (Dusek and Eichenbaum 1997). Recent findings using both monkeys and rats have shown that animals with hippocampal damage are severely impaired when challenged to express learned relations between items in a flexible way, and the lack of such flexibility is characteristic of human amnesia (see Eichenbaum 1997; Squire 1992).

Complementary evidence about the memory processing accomplished by the hippocampus has been derived from studies of the firing patterns of cortical and hippocampal neurons in behaving animals. Recordings at successive cortical stages leading to the hippocampus reflect increasing sensory convergence, from the encoding of specific perceptual features or movement parameters in early cortical areas to that of increasingly complicated and multimodal objects and behaviors at higher cortical stages. Consistent with the view that the hippocampus is the ultimate stage of hierarchical processing, the functional correlates of hippocampal cells are "supramodal" in that they appear to encode the abstract stimulus configurations that are independent of any particular sensory input. Most prominent among the functional types of hippocampal principal neurons are cells that fire selectively when a rat is in a particular location in its environment as defined by the spatial relations among multiple and multimodal stimuli (O'Keefe 1976). The firing of such "place cells" is characteristically not dependent upon any particular stimulus element and is not affected even if all the stimuli are removed, so long as the animal behaves as if it is in the same environment. However, hippocampal neuronal activity is not limited to the encoding of spatial cues, but has also been related to meaningful movement trajectories and actions in rats as well as conditioned motor responses in restrained rabbits and monkeys. In addition, across a variety of learning tasks hippocampal neurons are activated by relevant olfactory, visual, tactile, or auditory cues, and these encodings prominently reflect nonallocentric spatial, temporal, and other relations among the cues that guide performance (Wood, Dudchencko, and Eichenbaum, 1999; Deadwyler and Hampson 1997). These findings extend the range of hippocampal coding to reflect its global involvement in memory and serve to reinforce the conclusion that the hippocampus supports relational representations.

Efforts to understand how hippocampal circuitry mediates memory processing have focused on special aspects of hippocampal architecture: a high convergence of sensory information onto the hippocampus, sparse connectivity within the broad serial divergence and associative connections across the cell population, recurrent connections that characterize dentate gyrus and CA3 pyramidal cells, the small fraction of excited afferent fibers required to drive CA1 cells, and rapid adjustments of synaptic weights at each stage via long term potentiation. These anatomical and physiological features have been simulated in artificial associative networks employed to accomplish distributed recodings of inputs and to perform basic computations that are reflected in hippocampal neural activity (see Gluck 1996). Some models have focused on the central features of cognitive maps, such as the ability to solve problems from partial information, take shortcuts, and navigate via novel routes. Other models have focused on sequence prediction that employs the recall of temporal patterns to accomplish spatial and nonspatial pattern completion and disambiguation, and more generally show how such network memory representations can provide the flexibility of memory expression conferred by the hippocampus.

Human-Computer Interaction

Human-computer interaction (HCI) studies how people design, implement, and use computer interfaces. With computer-based systems playing increasingly significant roles in our lives and in the basic infrastructure of science, business, and society, HCI is an area of singular importance. A key to understanding human-computer interaction is to appreciate that interactive interfaces mediate redistribution of cognitive tasks between people and machines.

Designed to aid cognition and simplify tasks, interfaces function as COGNITIVE ARTIFACTS. Two features distinguish interfaces from other cognitive artifacts: they provide the most plastic representational medium we have ever known, and they enable novel forms of communication. Interfaces are plastic in the sense that they can readily mimic representational characteristics of other media. This plasticity in combination with the dynamic character of computation makes possible new interactive representations and forms of communication that are impossible in other media.

The historical roots of human-computer interaction can be traced to a human information-processing approach to cognitive psychology. Human information processing (Card, Moran, and Newell 1983; Lindsay and Norman 1977) explicitly took the digital computer as the primary metaphorical resource for thinking about cognition. HCI as a field grew out of early human information-processing research and still reflects that lineage. Just as cognitive psychology focused on identifying the characteristics of individual cognition, human-computer interaction has, until very recently, focused almost exclusively on single individuals interacting with applications derived from decompositions of work activities into individual tasks. This theoretical approach has dominated human-computer interaction for over twenty years, leading to a computing infrastructure built around the personal computer and based on the desktop interface metaphor.

The desktop metaphor and associated graphical user interface evolved from Sutherland's Sketchpad (Sutherland 1963), a seminal system that introduced the interactive graphical interface in the early 1960s. The desktop metaphor and underlying technologies on which it is based were cast in modern form in a number of university and industrial research centers, most notably Xerox Parc. We now see the legacy of that work in the ubiquitous graphical interface of current commercial systems. Their interfaces bear startling resemblances to those of the early Xerox Alto (Lampson 1988). What has changed since the days of the Alto, in addition to the continual doubling of computing power every eighteen months and all that this doubling makes possible, is that we now have more principled understandings of how to create effective interfaces. This is primarily a result of the development and acceptance of user-centered approaches (Norman and Draper 1986; Nielsen 1993; Nickerson and Landauer 1997) to system design.

Research in human-computer interaction (Helenader, Landauer, and Prabhu 1997), as in most of the cognitive sciences, draws on many disciplines in that it involves both people and computer technologies. The goal of creating effective and enjoyable systems for people to use makes HCI a design activity (Winograd 1996). As designed artifacts, interface development involves what Schon (1983) terms *a reflective conversation with materials.* To be effective, though, interfaces must be well suited to and situated in the environments of users. Designers must ensure that they remain centered on human concerns. Thus, although HCI can be viewed simply as an important area of software design, inasmuch as interfaces account for more than 50 percent of code and significant portions of design effort, it is much more than that. Interfaces are the locus for new interactive representations and make possible new classes of computationally based work materials.

There are many spheres of research activity in HCI. Three areas are of special interest. The first draws on what we know about human perception and cognition, coupling it with task analysis methods, to develop an engineering discipline for HCI. For examples, see the early work of Card, Moran, and Newell (1983) on the psychology of human-computer interaction, analysis techniques based on models of human performance (John and Kieras 1997), the evolving subdiscipline of usability engineering (Nielsen 1993), work on human error (Woods 1988; Reason 1990), and the development of toolkits for interface design (Myers, Hollan, and Cruz 1996).

A second research activity explores interfaces that expand representational possibilities beyond the menus and icons of the desktop metaphor. The new field of information visualization (Hollan, Bederson, and Helfman 1997) provides many examples. The Information Visualizer (Card, Robertson, and Mackinlay 1991), a cognitive coprocessor architecture and collection of 3-D visualization techniques, supports navigation and browsing of large information spaces. Numerous techniques are being developed to help visualize large complex systems (Eick and Joseph 1993; Church and Helfman 1993), gather histories of interactions with digital objects (Hill and Hollan 1994; Eick and Joseph 1993), and provide interactive multiscale views of information spaces (Perlin and Fox 1993; Bederson et al. 1996).

A third active research area is computer-supported cooperative work (CSCW). (See Olson and Olson [1997] for a recent survey.) The roots of CSCW can be traced to Engelbart's NLS system (Engelbart and English 1994). Among other things, it provided the first demonstration of computer-mediated interactions between people at remote sites. CSCW takes seriously what Hutchins (1995) has termed *distributed*

cognition to highlight the fact that most thinking tasks involve multiple individuals and shared artifacts.

Overall, as Grudin (1993) has pointed out, we can view the development of HCI as a movement from early concerns with low-level computer issues, to a focus on people's individual tasks and how better to support them, to current concerns with supporting collaboration and sharing of information within organizations. The phenomenal growth of the World Wide Web and the associated changes in the way we work and play are important demonstrations of the impact of interface changes on sharing information. Not to minimize the importance of the underlying technologies required for the Web (networks, file transfer protocols, etc.), it is instructive to realize that they have all been available since the early days of the Arpanet, the precursor to the modern Internet. Changes at the level of the interface, making access to information on systems almost anywhere only a matter of clicking on a link, opened the Web to users and resulted in its massive impact not only on scientific activities but also on commercial and social interaction.

Myriad important issues, ranging from complex issues of privacy and ownership of information to the challenges of creating new representations and understanding how to effectively accomplish what one might term *urban planning for electronic communities,* face the HCI discipline. As long as the evaluative metric continues to be whether interfaces help us accomplish our tasks more effectively and enjoyably and we continue to explore the potential of new interactive representations to allow us to know the world better and improve our relationships with others, the future of HCI will remain bright and exciting.

Human Navigation

Although the term *navigation* originates from the Latin word for ship, the term has come to be used in a very general way. It refers to the practice and skill of animals as well as humans in finding their way and moving from one place to another by any means. Generally moving from place to place requires knowledge of where one is starting, where

the goal is, what the possible paths are, and how one is progressing during the movement.

Knowledge of where one is starting in one sense is obvious; one can see the immediate surrounds. However, this is of little help if the relation of that place to the rest of the spatial layout is not known. This becomes of practical interest in the so-called drop-off situation, where one is dropped off at an unknown position and has to determine the location. Practically, this could happen in a plane crash when flying over unknown territory, or more generally if one is lost for any reason.

In such cases having a map is useful but requires matching the perception of the surrounding environment with a particular position on the map. That problem can be cognitively quite difficult. An observer has a particular viewpoint of the environment that in general is rather limited. The map typically covers a much larger area and, of course, has an infinite number of possible viewpoints. In addition, in many locales the individual features are ambiguous; limited views of any one hill, valley, or stream often look like others. Very experienced map readers have strategies that help them overcome these difficulties (Pick et al. 1995). For example, in trying to figure out where on a topographical map they are, successful readers focus initially on the terrain rather than the map. This makes sense inasmuch as knowing the details of the terrain would constrain the possibilities more than knowledge of the big picture provided by the map. Successful readers look for configurations of features. As noted, any individual feature is ambiguous; configurations provide powerful constraints as to where one might be.

Identifying possible paths from one place to another can be based on prior spatial layout knowledge (see COGNITIVE MAPS), but it can also be accomplished on the basis of maps. Depending on the type of map, constraints on possible paths will also be indicated, for example, roads on urban and highway maps; mountains, streams, and the like on topographic maps; and reefs, islands, water depths, and so forth on nautical charts. Many maps provide a very general and powerful reference system. The geographic coordinate system, as Hutchins (1995) points out, not only enables specification of the location of starting point and destination, but also permits easy determination of paths by graphic or numerical computation.

In many cases such as piloting a ship along a coast line, navigation often involves specifying position in relation to landmarks rather than the coordinate systems of maps or charts. Keeping track of one's progress during travel is particularly problematic when information about position in relation to landmarks is impoverished. One of the most impressive and cognitively interesting examples of sea navigation is that of Micronesian islanders who traditionally traveled from island to island across wide-open stretches of the South Pacific without navigational instruments. Their skill has been carefully studied by anthropologists (e.g., Gladwin 1970; Lewis 1978; Hutchins 1995). The islanders' knowledge of the paths from one island to another is in the form of sailing directions as to courses to steer and features that are observable along the way. By our standards, information in relation to such features is clearly impoverished. However, there are observable features to which Micronesian sailors attend that others might miss, such as slight changes of water color indicating underwater landmarks, changes in the wave patterns indicating disturbance by nearby islands, the sighting of birds flying toward or away from islands at different times of the day, and so on.

Across the open sea there are few constraints on what paths to take, so maintaining a steady course becomes quite important. Micronesian navigators have developed a form of celestial navigation in which direction at night is determined in relation to the position on the horizon at which particular stars rise and set. In fact, stars rising at the same point on the horizon all follow the same track across the sky and set at the same place in what is called a linear constellation (Hutchins 1995). During the day the direction of the sun at different times and the direction of wave patterns can be used to maintain course.

Most intriguing about the Micronesian system is how the islanders keep track of where along the journey they are. The Micronesian navigators conceptualize the trip in terms of a stationary canoe with an out-of-sight reference island moving past it. Thus the bearing from the canoe to such an island changes as the journey progresses. Because the reference islands are generally out of sight, it makes no difference if the island really exists and, in fact, if there is not an actual convenient reference island an imaginary one is used.

Because motion is relative, it makes no logical difference whether one conceptualizes travel as involving a stationary world and a moving canoe or a stationary canoe and a moving world. Hutchins and Hinton (1984) hypothesize a very interesting explanation for why this conceptualization makes sense on the basis of the sensory information available at sea to the Micronesians.

The changing bearing of a reference island is a convenient way to keep track of where one is on a journey, as is plotting one's position on a map or chart. But how does one know how fast the bearing is changing or how far to move one's chart position? If the environment is too impoverished to keep track of position with respect to features, it must be done by somehow keeping track of one's velocity and integrating over time to obtain distance moved, a procedure known as dead reckoning (Gallistel 1990). Crossing undifferentiated expanses of sea or land, dead reckoning must be relied on for registering progress between celestial fixes unless modern navigational instruments are used.

Another relevant case of impoverished environmental information is the very mundane activity of walking without vision. This is, of course, the common situation of blind people. They, like the Micronesian sailors, are able to keep track of their progress by attending to information often ignored by others, for example odors marking particular locations, and changes of air currents and acoustic resonance properties that signify open passageways and the like (Welsh and Blasch 1980). However, internal information also specifies movement, for example by proprioception and/or motor commands. There is some evidence that blind people do not use this source of information to update their position as well as do blindfolded sighted persons (Rieser, Guth, and Hill 1987; but see Loomis et al. 1993). This

advantage of sighted people may be due to optical flow information when walking with vision serving to calibrate nonvisual locomotion (Rieser et al. 1995). Thus movement in nonvisual locomotion presents on a small scale some of the same problems involved in much grander global navigation.

Human Universals

Human universals comprise those features of culture, society, language, behavior, and psyche for which there are no known exceptions to their existence in all ethnographically or historically recorded human societies. Among the many examples are such disparate phenomena as tools, myths and legends, sex roles, social groups, aggression, gestures, grammar, phonemes, EMOTIONS, and psychological defense mechanisms. Broadly defined universals often contain more specific universals, as in the case of kinship statuses, which are universally included among social statuses. In some cases, the content of a universal is highly specific, as in the smile, frown, or other facial expressions of basic emotions (Ekman, Sorenson, and Friesen 1969) and in the more complex "coyness display" (Eibl-Eibesfeldt 1989).

Some universals have a collective referent-being found in all societies, languages, or cultures, but having a contingent relation to individuals. Thus, dance is found in all societies or cultures, but not all individuals dance. Other universals, such as a grasp of elementary logical concepts (not, and, or, kind of, greater/lesser, etc.) or the use of gestures, characterize the psyche or behavior of all (normal) individuals. Some universals—such as the predominance of women in infant socialization (Levy 1989) or the ease with which youngsters acquire language—characterize all (normal) individuals of one sex or age range.

Human universals commanded attention from the founding of academic anthropology, but for much of this century a variety of factors promoted an emphasis of cultural particulars and a deemphasis of universals and the psychobiological features that might underlie them (Brown 1991; Degler 1991; see also CULTURAL RELATIVISM). Seminal midcentury essays on human universals (Murdock 1945; Kluckhohn 1953) were followed by the emergence of COGNITIVE ANTHROPOLOGY, a fruitful field for the discovery and persuasive demonstration of universals (D'Andrade 1995). Cognitive anthropology and the study of universals in general have drawn heavily on developments in linguistics (see LINGUISTIC UNIVERSALS).

Anthropologists and linguists generally assume that claims of universality should be validated by cross-cultural or cross-language research. However, a considerable amount of research in economics, political science, psychology, and sociology implicitly assumes universality without demonstrating it (but see COMPARATIVE PSYCHOLOGY). Thus, many research findings from these fields may or may not have universal validity.

Because of the practical difficulties that are involved, the existence of particular universals is normally demonstrated not by exhaustive examination of the historical and ethnographic records but rather by some form of sampling. In spite of these difficulties, existing lists of universals show substantial overlap (e.g., Brown 1991; Murdock 1945; Hockett 1973; Tiger and Fox 1971).

Among the variations on the basic concept of human universals are conditional (or implicational) universals, statistical universals, near universals, and universal pools. A conditional universal refers to a cross-culturally invariant rule or linkage whereby if condition x obtains, then y will obtain. The evolution of "basic color terms" provides a well-documented example: if a language possesses only three basic color terms, they will be black, white, and red (Berlin and Kay 1969; see also COLOR CATEGORIZATION). The real universality in such cases consists not in the manifest occurrence of specific phenomena but in a pattern of

co-occurrences and its underlying causation (see the discussion of universal mechanisms beneath variable behavior in Tooby and Cosmides 1992).

Similarly, although the manifest cross-cultural frequency of occurrence of a statistical universal need only be greater than chance, it implies a universal explanation rather than a series of culturally specific explanations. For example, given all the possible terms that might be used to refer to the pupil of the eye, in a very disproportionate number of languages the term refers to a little person, presumably because people everywhere see their own reflections in the pupils of other people's eyes (Brown and Witkowski 1981; see also FIGURATIVE LANGUAGE).

Keeping domestic dogs is only a near universal, as there were peoples who, until recently, lacked them. In many cases the explanations for near universals and (absolute) universals are essentially the same. The designation of near universality sometimes merely indicates uncertainty about the (absolute) universality of the item in question.

A universal pool is a fixed set of possibilities from which particular manifestations are everywhere drawn. For example, a classic study found that in a sample of diverse kinship terminologies only a small pool of semantic features (e.g., sex of speaker, sex of relative, lineal versus collateral relative, etc.) were drawn upon to distinguish one kin term from another (Kroeber 1909).

There are only a few general explanations for universals. Some cultural universals, for example, appear to be inventions that, due to their great antiquity and usefulness, have diffused to all societies. The use of fire and the more specific use of fire to cook food are examples. The dog achieved near universality for the same reasons. Other universals appear to be reflections in culture of noncultural features that are ubiquitous and important for one reason or another. Kinship terminologies (which are simultaneously social, cultural, and linguistic) are found among all peoples, and in all cases they reflect (at least in part) the relationships necessarily generated by the facts of biological reproduction. Systems of classification—of plants and animals as well as kin—were among the most important arenas for the development of cognitive studies in anthropology (Berlin 1992; D'Andrade 1995; see NATURAL KINDS).

Yet other universals spring more or less directly from human nature and, thus, are causally formative of societies, cultures, and languages—and even the course of history. The syndrome of cognitive and emotional traits comprising romantic love, for instance, is known everywhere, inspiring poetry as well as reproduction, while giving rise to families and much human conflict (Harris 1995; Jankowiak 1995).

In recent decades, an inclusive framework for explaining those universals embodied in or springing from human nature has emerged from a combination of fields. From ETHOLOGY and animal behavior have come the identification of species-typical behaviors and the developmental processes (combining innateness and learning) that produce them (see, e.g., Eibl-Eibesfeldt 1989; Seligman and Hager 1972; Tiger and Fox 1971); from SOCIOBIOLOGY have come ultimate explanations for such universals as kin altruism and the norm of reciprocity (Hamilton 1964; Trivers 1971); from Chomsky (1959) has come the notion of mental organs or modules that underpin complex, innate features of the human psyche (Hirschfeld and Gelman 1994; see also DOMAIN SPECIFICITY). Elucidating the evolved architecture of the (universal) human mind and its causal role in the construction of society and culture is the domain of EVOLUTIONARY PSYCHOLOGY (Barkow, Cosmides, and Tooby 1992).

Studies within this framework seek to specify the universals of mind that underlie manifest universals and to explain them in both ultimate (evolutionary) and proximate terms. Thus Symons (1979) explains several species-typical sex differences in human sexuality in terms of a theory derived from a wide comparison of animal species. For example, men compete more intensely or violently for mates, desire more variety of sexual partners, and attend more to the physical features (especially signs of youth) of their mates. Both sexes assume that sex is a service or favor that women provide to men. The theory (Trivers 1972) predicts these differences as consequences of the typically larger female investment in each offspring (e.g., the minimum investments are the female's nine months of gestation and the male's insemination). Studies of this sort offer a more comprehensive illumination of human universals than had hitherto been the case.

Hume, David

Impressed by Isaac Newton's success at explaining the apparently diverse and chaotic physical world with a few universal principles, David Hume (1711–1776), while still in his teens, proposed that the same might be done for the realm of the mind. Through observation and experimentation, Hume hoped to uncover the mind's "secret springs and principles." Hume's proposal for a science of the mind was published as *A Treatise of Human Nature* in 1740, and subtitled "An Attempt to introduce the experimental Method of Reasoning into moral subjects." Though it is now one of the most widely read works in Western philosophy, the reception of the *Treatise* in Hume's lifetime was disappointing. In *My Own Life* Hume says that the *Treatise* "fell dead-born from the press." Considered an atheist by the clergy, which controlled university appointments, Hume sought but never received a professorship.

Hume is widely regarded as belonging with Locke and Berkeley to the philosophical movement called British Empiricism (see RATIONALISM VS. EMPIRICISM). The mind contains two kinds of perceptions: impressions and ideas. Impressions are the original lively SENSATIONS and EMOTIONS. Ideas are fainter copies of impressions. Like Locke, Hume rejected the NATIVISM of the rationalists. There are no ideas without prior impressions, so no ideas are innate. Impressions and ideas may be simple or complex. The imagination freely concatenates perceptions; the understanding and the passions organize perceptions by more regular rules of association. MEMORY ideas, for example, preserve the order and position of the impressions from which they derive. Hume's theory of ideas is an empiricist account of concept formation (see CONCEPTS).

Hume held that the ability to form beliefs, in contrast to having sensations and emotions, was a matter of inference. The belief that bread nourishes is an inference from the constant conjunction of the ingestion of bread with nourishment. In what is now called the problem of INDUCTION, Hume argued that this inference is not a deductive inference, because the proof of the conclusion is not guaranteed by the truth of the premises, and any proof based on experience is itself an inductive inference, making it thus a circular proof. Hume's conclusion is a skeptical one. There is no rational justification for CAUSAL REASONING.

Causal inference leading to belief is a matter of custom and habit. The constant conjunction of perceptions experienced lead cognitive agents to have certain lively ideas or beliefs. One cannot help but believe that fire is hot. Hume emphasized that both humans and other animals make such inductive or causal inferences to predict and explain the world, in spite of the fact that such inferences cannot be rationally justified. In the section of the *Treatise* entitled "Of the reason of animals," Hume anticipated COGNITIVE ETHOLOGY by appealing to evidence about nonhuman animals in support of the claim that inferences from past instances are made by members of many species. The possession of language by humans, Hume held, makes it possible for humans to make more precise inferences than other animals, but this is a matter of degree, not of kind.

If beliefs are habitual responses to environmental regularities, how is it that beliefs that deny such regularities are held? Hume's critical examination of religious belief and the belief in the existence of miracles inspired him to offer a fuller account of the nature of belief formation and credulity. Hume noted several belief-enlivening associative mechanisms in addition to constant conjunction. Belief is influenced by such factors as proximity, resemblance, and repetition. A pilgrimage to the Red Sea, for example, will serve to make one more receptive to the claim that the sea parted. Hume's treatment of the factors influencing belief anticipates the studies of Kahneman and TVERSKY (Tversky and Kahneman 1974) on the selective availability of evidence in PROBABILISTIC REASONING.

Hume rejected DESCARTES's claim that the mind is a mental substance on the grounds that there is no impression from which such an idea of mental substance could be derived. Introspection provides access to the mind's perceptions, but not to anything in which those perceptions inhere. "When I enter most intimately into what I call myself, I always stumble on some particular perception or other, of heat or cold, light or shade, love or hatred, pain or pleasure. I never can catch myself at any time without a perception, and never can observe any thing but the perception" (*Treatise,* p. 252). The mind, Hume concludes, "is nothing but a heap or collection of different perceptions."

The bundle theory of the mind has been criticized by recent philosophers of mind. Hume attempted to account for mental representation by the dynamic interaction of mental items—impressions and ideas. It is not clear that Hume was able to characterize such interaction as mental without appealing to the fact that impressions and ideas are the perceptions *of a mind.* According to Hume's critics, Hume helps himself to the concept of mind rather than account for it in

nonmentalistic terms. Dennett (1978) refers to this as Hume's Problem. Haugeland (1984) argues that such mechanistic accounts of the mind, which predate the notion of automatic symbol manipulation, cannot avoid Hume's problem.

The perceptions of the mind include emotions and passions as well as beliefs, and Hume attempted to offer a unified account of all mental operations. Beliefs are lively or vivacious ideas that result from a certain kind of mental preparation, a constant conjunction of pairs of impressions such as impressions of flame joined with impressions of heat. The lively idea of heat gets its vivacity from the habit or custom formed by the experience of the constantly conjoined impression pair. Beliefs, then, are themselves feelings. Both emotions and beliefs are strongly held perceptions, and the mechanisms that actuate one can influence the other. Fear of falling from a precipice may, for example, displace a belief that one is secure. Like recent theorists, Hume held that both probability and the degree of the severity of anticipated pain or pleasure play a role in the resolution of conflicts of emotion and judgment.

Identity Theory

See MIND-BODY PROBLEM; PHYSICALISM

Illusions

A hallucination is a false perception seen by one person, often drugged or mentally ill, in the absence of stimulation, whereas an illusion is a misinterpretation of a stimulus consistently experienced by most normal people. Illusions are characteristic errors of the visual system that may give us clues to underlying mechanisms. There are several types of visual illusion:

Geometrical: Illusions of Angle and Size

Angles: In the Zollner and Hering (1861) illusions, the long parallel lines appear to be tilted away from the orientation of the background fins (figure 1). Blakemore (1973) attributes this to "tilt contrast," caused by lateral inhibition between neural signals of orientation, which will expand the appearance of acute angles. This theory has problems with the Poggendorff (1860) illusion, which still persists when only the obtuse angles are present, but vanishes when only the acute angles are present (see Burmester 1986). In Fraser's (1908) twisted-rope spiral illusion, the circles look like spirals because of the twisted local ropes, abetted by the diamonds in the background. The visual system seems to take "local votes" of orientation and fails to integrate them correctly.

Size: Gregory points out that size constancy scaling allows the correct perception of the size of objects even when their distance, and hence retinal size, changes. He attributes the geometrical illusions of size to an inappropriate application of size constancy. Thus the nearby man in figure 1 looks tiny compared to the distant man, even though the retinal sizes are identical: depth cues from the ground plane allow size constancy perceptually to expand distant objects. More subtly, in the Muller Lyer illusion, the arrow fins provide cues similar to those from receding and advancing corners, and in Roger Shepard's table illusion (figure 2, top), the two table tops are geometrically identical on the page but look like completely different 3-D shapes, because size and shape constancy subjectively expand the near-far dimension along the line of sight to compensate for geometrical foreshortening.

Illusions of Lightness and Color

A gray cross looks darker on a white than on a black surround. On a red surround it looks greenish, probably owing to lateral inhibition from neurons that sense the white or

Figure 1. Illusion of size

Tables (Shepard)

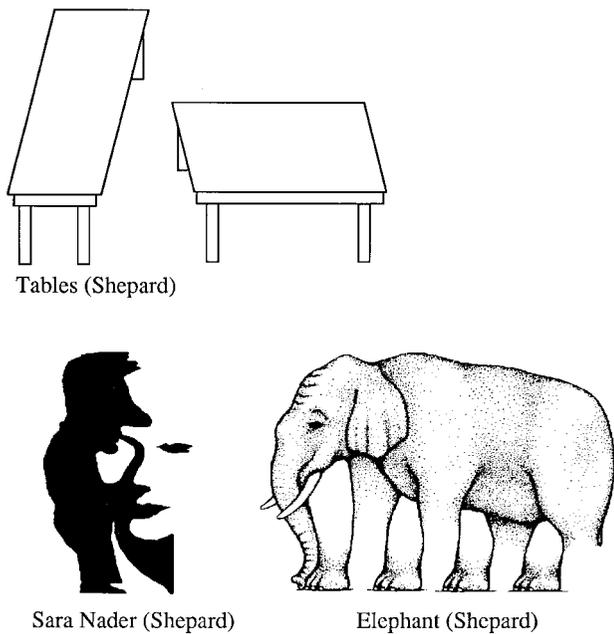
Sara Nader (Shepard)   Elephant (Shepard)


Figure 2. Top: Illusion of size; Bottom: Illusions of interpretation.

Figure 3. Top: Illusions of angle and size; Middle: Illusions of lightness and color; Bottom: Illusions of interpretation.

colored surround. In White's illusion, the grey segments that replace black bars are bordered by much white above and below, so they "ought" to look darker than the gray segments that replace white bars. But in fact they look lighter. This might show that lateral inhibition operates more strongly along the bars than across them, but more likely it is a top-down "belongingness" effect based on colinearity.

Illusions of Interpretation: Ambiguous, Impossible, and Puzzle Pictures

In *ambiguous* pictures, the brain switches between two possible figure-ground interpretations—in figure 3, faces and a vase—even though the stimulus does not change. The shape of the region selected as figure is perceived and remembered; that of the ground is not.

Impossible figures embody conflicting 3-D cues. Penrose's "impossible triangle" (figure 3) is not the projection of any possible physical object. It holds together by means of incorrect connections between its corners, which are correct locally but incorrect globally. Shepard's elephant (figure 2) confuses its legs with the spaces in between. Local votes about depth are not properly integrated. Impossible objects cannot be consistently painted with colors.

In *puzzle* pictures there is one possible interpretation, but reduced cues make it hard to find. (Shepard's Sara Nader, figure 2, is unusual in having two different possibilities). Once found, immediate perceptual learning makes the picture easier to remember, and immediately recognizable the next time it is seen.

The Belgian surrealist painter René Magritte (1898–1967) and the Dutch engraver Maurits Escher (1898–1972) filled their works with splendid visual illusions (http://www.bright-ideas.com/magrittegallery/aF.html and http://lonestar.texas.net/~escher/gallery/). Collections of illusions can be seen on CD-ROM (Scientific American) and on Al Seckel's Web page at http://www.lainet.com/illusions/.

Imagery

The term *imagery* is inherently ambiguous—it can refer to iconography, visual effects in cinematography, mental events, or even to some types of prose. This article focuses on mental imagery. For example, when asked to recall the number of windows in one's living room, most people report that they visualize the room, and mentally scan over this image, counting the windows. In this article we consider not the introspections themselves, but rather the nature of the underlying representations that give rise to them. Because most research on imagery has addressed visual mental imagery, we will focus on that modality.

Unlike most other cognitive activities (such as language and memory), we only know that visual mental image representations are present because we have the experience of seeing, but in the absence of the appropriate sensory input. And here lies a central problem in the study of imagery (the "introspective dilemma"): there is no way that another person can verify what we "see" with our inner eye, and hence the phenomenon smacks of unscientific, fanciful confabulation.

Nevertheless, imagery played a central role in theories of the mind for centuries. For example, the British Associationists conceptualized thought itself as sequences of images. And, WILHELM WUNDT, the founder of scientific psychology, emphasized the analysis of images. However, the central role of imagery in theories of mental activity was undermined when Kulpe, in 1904, pointed out that some thoughts are not accompanied by imagery (e.g., one is not aware of the processes that allow one to decide which of two objects is heavier).

The observation that images are not the hallmark of all thought processes was soon followed by the notion that images as ordinarily conceived (and, indeed, thoughts themselves) may not even exist! John Watson (1913)—the founder of BEHAVIORISM—argued that images actually correspond to subtle movements of the larynx. Watson emphasized the precept that scientific phenomena must be publicly observable, and imagery clearly is not. This line of argument led to diminished interest in imagery until the early 1960s.

Behaviorism ultimately had a salutary effect on the study of imagery; it made it rigorous. Whereas researchers in Wundt's lab were trained in INTROSPECTION, modern researchers are trained in measuring subtle aspects of behavior. In such cases, the behavior is like the track left by a cosmic ray passing through a cloud chamber: It is a kind of signature, a hallmark, that allows us to draw inferences about the phenomena that produced it.

Imagery has effects on the accuracy of LEARNING and MEMORY. In the early 1960s the behaviorist approach to language led to the study of "verbal learning": words were treated as stimuli that could be learned like any other. Paivio and his colleagues (e.g., Paivio 1971) showed that imagery is a major factor that affects the ease of learning words. Not only is a picture worth a thousand words, it is also easier to remember. The same is true for "mental pictures." Words are better learned and remembered if they name an object that can be visualized, such as "boat" or "cat," than they are if they name an abstract idea, such as "justice" or "kindness." The way objects are visualized can, however, affect how easily the words they correspond to are remembered; Bower (1972) found that forming an image of the interaction between a pair of objects made it easier to remember the names of those objects than was the case by simply forming an image of the objects existing separately.

Imagery also affects the detection of perceptual stimuli. Studies of imagery benefited from new techniques developed to investigate perception. For example, SIGNAL DETECTION THEORY (e.g., Green and Swets 1966) has been used to show that forming a visual mental image interrupts vision more than it does hearing, but forming an auditory image interrupts hearing more than vision. Such results reveal that imagery draws on mechanisms used in like-modality perception. However, Craver-Lemley and Reeves (1992) report, this interference occurs only if the image overlaps the target. It is also worth noting that images can be mistaken for percepts, both at the time and in memory (e.g., Johnson and Raye 1981; see Kosslyn 1994 for a review).

One reason that behaviorism failed to hold sway was that a viable alternative was introduced: cognitive psychology. Cognitive psychology likened the mind to software running on a computer, and imagery—along with all other mental processes—was conceptualized in terms of such "information processing." This approach stressed that different sets of processes are used to accomplish different ends. For example, to plan how to arrange furniture in an empty room, one could *generate* an image of the furniture and then mentally *transform* it (rotate it, perhaps imagine stacking a shelf on a crate or desk); one must *maintain* the image as it is being *inspected*. Sometimes imagery involves only some of these processes; for instance, image transformation is irrelevant in remembering the way to get to the train station. Information processing is often studied by measuring response times.

Consider tasks that require image inspection. Do you know the shape of a Saint Bernard's ears? Subjects will require more time to perform this task if they are first told to visualize the dog far off in the distance; before they can answer the question, they will "zoom in" on the part of their image containing the dog's head. Similarly, subjects will require more time to answer this question if they are first told to visualize a Saint Bernard's tail; they will now mentally "scan" across the image of the dog in order to "look" at its ears. Indeed, the time to respond increases linearly with the amount of distance scanned—even though the subject's eyes are closed. Such results suggest that the image representations embody spatial extent (see Kosslyn 1994).

Now consider image generation. Images are generated by activating stored information. Images are created "piece by piece," and thus an image with more parts takes longer to form. Indeed, the time to form an image often increases linearly with the number of parts that are assembled.

Finally, consider image transformation. When objects in images are transformed, they often mimic the movements of real objects. For example, rotating objects appear to shift through a trajectory; the farther one rotates an imaged object, the longer it takes to do so (see MENTAL ROTATION).

Shepard (1984) suggests that this occurs because, due to natural selection, certain laws of physics have been internalized in the brain and act as constraints on the imagery process. Alternatively, it is possible that motor programs guide imagery and, consequently, objects are mentally manipulated in the same manner that real objects would be physically manipulated. In fact, motor parts of the brain have been shown to be activated during some image transformation tasks (e.g., Georgopoulos et al. 1989).

The computer metaphor encouraged a kind of "disembodied mind" approach, which ignored certain classes of data and constraints on theories. Recent years have seen a sharp increase in research on the neural bases of imagery. Such research has addressed each of the processes noted earlier, as well as the issue of how images are internally represented.

It has long been known that some parts of the brain are spatially organized (see Felleman and Van Essen 1991); the pattern of activity on the retina is projected onto these areas (albeit distorted in several ways). Studies reported by five laboratories have now shown that some of these areas, such as primary VISUAL CORTEX, are activated when people visualize. Moreover, the pattern of activation is systematically altered by spatial properties of the image, in a way similar to what occurs in perception. Such results suggest that imagery relies on "depictive" representations, which use space to represent space. This result bears directly on the "imagery debate" of the 1970s and 1980s, which focused on the question of whether a depictive representation is used during imagery. However, this result is not always obtained, and the crucial differences between the tasks that do and do not engender such representations have not yet been identified (Mellet et al. 1998).

Image *generation* is most often disrupted by damage to the posterior left hemisphere (Farah 1984). However, recent studies have shown that images can be generated in at least two ways, one of which uses stored descriptions to arrange parts and relies primarily on left-hemisphere processes, and the other of which uses stored metric spatial information to arrange parts and relies primarily on the right hemisphere (for a review of the literature on this topic, see Behrmann, Kosslyn and Jeannerod 1996).

Patients with brain damage that impairs visual perception sometimes also have corresponding deficits when they *inspect* imaged objects. For example, some patients who have suffered damage to the posterior right parietal lobe display a phenomenon known as "unilateral VISUAL NEGLECT"; they ignore objects to the left side of space. These patients may display the same behavior when visualizing—they ignore objects on the left half of their images (e.g., Bisiach and Luzzatti 1978).

Image *transformations* are accomplished by a complex set of brain areas. However, studies with brain-damaged patients suggest that the right hemisphere plays a crucial role in the transformation process itself (e.g., Corballis and Sergent 1989; Ratcliff 1979).

In conclusion, the recent research on visual mental imagery reveals that imagery is not a unitary phenomenon, but rather is accomplished by a collection of distinct processes. These processes are implemented by neural systems, not discrete "centers." These processes can be combined in different ways (with each combination corresponding to a distinct method or strategy) to allow one to accomplish any given imagery task.

Imitation

There has been an explosion of research in the development, evolution, and brain basis of imitation. Human beings are highly imitative. Recent discoveries reveal that newborn infants have an innate ability to imitate facial expressions. This has important implications for theories of FOLK PSYCHOLOGY, MEMORY, CULTURE, and LANGUAGE.

Classical theories of COGNITIVE DEVELOPMENT postulated that newborns did not understand the similarity between themselves and others. Newborns were said to be "solipsistic," experiencing their own internal sensations and seeing the movements of others without linking the two (Piaget 1962). According to Jean PIAGET, the imitation of facial gestures was first possible at one year of age, a landmark development that was a prerequisite for representational abilities. In sharp contrast, modern empirical work has shown that infants as young as forty-two minutes old successfully imitate adult facial gestures (Meltzoff and Moore 1983). Imitation is innate in humans (figure 1).

Facial imitation presents a puzzle. Infants can see an adult's face but cannot see their own faces. They can feel their own faces move but have no access to the feelings of movement in another person. How is facial imitation possible? One candidate is "active intermodal mapping." The crux of the view is that an infant represents the adult facial expression and actively tries to make his or her own face match that target. Of course, infants do not see their own facial movements, but they can use proprioception to monitor their own unseen actions and to correct their behavior. According to this view, the perception and production of human acts are represented in a common "supramodal" framework and can be directly compared to one another. Meltzoff and Moore (1997) provide a detailed account of the metric used for establishing cross-modal equivalence of human acts and its possible brain basis.

The findings on imitation suggest a common coding for perception and production. Work with adults analyzing brain sites and cognitive mechanisms involved in the imitation, perception, and imagination of human acts suggests they tap common processes (Jeannerod and Decety 1995; Prinz 1990). Neurophysiological studies show that in some cases the same neurons become activated when monkeys perform an action as when they observe a similar action

Figure 1. Photographs of two- to three-week-old infants imitating facial acts demonstrated by an adult. From A. N. Meltzoff and M. K. Moore (1977). *Science* 198 : 75–78.

made by another (Rizzolatti et al. 1996). Such "mirror neurons" may provide a neurophysiological substrate for imitation.

Early imitation has implications for the philosophical problem of other minds. Imitation shows that young infants are sensitive to the movements of themselves and other people and can map self-other isomorphisms at the level of actions (see INTERSUBJECTIVITY). Through experience they may learn that when they act in particular ways, they themselves have certain concomitant internal states (proprioception, emotions, intentions, etc.). Having detected this regularity, infants have grounds for making the inference that when they see another person act in the same way that they do, the person has internal states similar to their own. Thus, one need not accept Fodor's (1987) thesis that the adult THEORY OF MIND must be innate in humans (because it could not be learned via classical reinforcement procedures. Imitation of body movements, vocalizations, and other goal-directed behavior provides a vehicle for infants discovering that other people are "like me," with internal states just like the SELF. Infant imitation may be a developmental precursor to developing a theory of mind (Meltzoff and Moore 1995, 1997; Gopnik and Meltzoff 1997; see also SIMULATION VS. THEORY-THEORY).

What motivates infants to imitate others? Imitation serves many cognitive and social functions, but one possibility is that very young infants use behavioral imitation to sort out the identity of people. Young infants are concerned with determining the identity of objects as they move in space, disappear, and reappear (see INFANT COGNITION). Research shows that young infants use imitation of a person's acts to help them distinguish one individual from another and reidentify people on subsequent encounters (Meltzoff and Moore 1998). Infants use the distinctive actions of people as if they were functional properties that can be elicited through interaction. Thus, infants identify a person not only by featural characteristics (lips, eyes, hair), but by how that individual acts and reacts.

As adults, we ascribe mental states to others. One technique for investigating the origins of theory of mind capitalizes on the proclivity for imitation (Meltzoff 1995a). Using this technique, the adult tries but fails to perform certain target acts. The results show that eighteen-month-olds imitate what the adult "is trying to do," not what that adult literally does do. This establishes that young children are not strict behaviorists, attuned only to the surface behavior of people. By eighteen months of age children have already adopted a fundamental aspect of a folk psychology—actions of persons are understood within a framework involving goals and intentions.

Imitation illuminates the nature of preverbal memory (Meltzoff 1995b). In these tests infants are shown a series of acts on novel objects but are not allowed to touch the objects. A delay of hours or weeks is then imposed. Infants from six to fifteen months of age have been shown to perform deferred imitation after the delay, which establishes preverbal recall memory, not simply recognition of the objects. The findings suggest that infants operate with what cognitive neuroscientists call declarative memory as opposed to procedural or habit memory (Sherry and Schacter 1987; Squire,

Knowlton, and Musen 1993), inasmuch as learning and recall of novel material occurs after one brief observation with no motor training. Research is being directed to determining the brain structures that mediate deferred imitation. Amnesic adults (see MEMORY, HUMAN NEUROPSYCHOLOGY) are incapable of the same deferred imitation tasks accomplished by infants, suggesting that it is mediated by the HIPPOCAMPUS and related anatomical structures (McDonough et al. 1995). Compatible evidence comes from a study showing that children with AUTISM have a deficit in imitation, particularly deferred imitation, compared to mental-age matched controls (Dawson et al. 1998).

Comparative psychologists hotly debate the nature and scope of imitation in nonhuman animals (Heyes and Galef 1996). Imitation among nonhuman animals is more limited than human imitation (Tomasello, Kruger, and Ratner 1993; Tomasello and Call 1997). Animals modify their behavior when observing others, but even higher primates are most often limited to duplicating the goal rather than the detailed means used to achieve it. Moreover, social learning in animals is typically motivated by obtaining food and other extrinsic rewards, whereas imitation is its own reward for the human young. In humans, aspects of language development depend on imitation. Vocal imitation is a principal vehicle for infants' learning of the phonetic inventory and prosodic structure of their native language (Kuhl and Meltzoff 1996; see PHONOLOGY, ACQUISITION OF and SPEECH PERCEPTION).

Human beings are the most imitative species on earth. Imitation plays a crucial role in the development of culture and the distinctively human ability to pass on learned abilities from one generation to another. A current challenge in artificial intelligence is to create a robot that can learn through imitation (Demiris and Hayes 1996). Creating more "humanlike" devices may hinge on embodying one of the cornerstones of the human mind, the ability to imitate.

Implicature

Implicature is a nonlogical inference constituting part of what is conveyed by S[peaker] in uttering U within context C, without being part of what is said in U. As stressed by H. PAUL GRICE (1989), what is conveyed is generally far richer than what is directly expressed; linguistic MEANING radically underdetermines utterance interpretation. Pragmatic principles must be invoked to bridge this gap, for example, (1) (Harnish 1976: 340):

1. Make the strongest relevant claim justifiable by your evidence.

Precursors of (1) were proposed by Augustus De Morgan and John Stuart Mill in the mid-nineteenth century, and by P. F. Strawson and Robert Fogelin in the mid-twentieth (see Horn 1990), but the central contribution is Grice's, along with the recognition that such principles are not simply observed but rather systematically exploited to generate nonlogically valid inferences. From S's assertion that *Some of the apples are ripe,* H[earer] will tend to infer that (for all S knows) not all the apples are ripe, because if S had known all were ripe, she would have said so, given (1).

The first explicit and general account of such inferences is given by Grice (1961: §3), who distinguishes the nonentailment relations operative in (2):

2. a. She is poor but honest.
   a´. There is some contrast between her poverty and her honesty.
   b. Jones has beautiful handwriting and his English is grammatical.
      [Context: recommendation letter for philosophy job candidate]
   b´. Jones is no good at philosophy.
   c. My wife is either in the kitchen or in the bathroom.
   c´. I don't know for a fact that my wife is in the kitchen.

Grice observes that although the inference in (2a,a´) cannot be cancelled *(#She is poor but honest, but there's no contrast between the two),* it is detachable, because the same truth-conditional content is expressible in a way that detaches (removes) the inference: *She is poor and honest.* It is also irrelevant to truth conditions: (2a) is true if "she" is poor and honest, false otherwise. Such detachable but noncancelable inferences that are neither constitutive of what is said nor calculable in any general way from what is said are conventional implicata, related to pragmatic presuppositions (see PRAGMATICS). Indeed, classic instances of conventional implicature involve the standard pragmatic presupposition inducers: focus particles like *even* and *too,* truth-conditionally transparent verbs like *manage to* and *bother to,* and syntactic constructions like clefts. Because conventional implicata are non-truth-conditional aspects of the conventional meaning of linguistic expressions, which side of the semantics/pragmatics border they inhabit depends on whether pragmatics is identified with the non-truth-conditional (as on Gazdar's intentionally oversimplified equation: pragmatics = semantics – truth conditions) or with the nonconventional. (Karttunen and Peters 1979 provide a formal compositional treatment of conventional implicature.)

The inferences associated with (2b,c) are nonconventional, being calculable from the utterance of such sentences in a particular context. In each case, the inference of the corresponding primed proposition is cancelable (either explicitly by appending material inconsistent with it—"*but I don't mean to suggest that . . .*"—or by altering the context of utterance) but nondetachable, given that truth-conditionally equivalent expressions license the same inference. An utterance of (2b) "does not standardly involve the implication . . . attributed to it; it requires a special context to attach the implication to its utterance" (Grice 1961: 130), whereas the default inference from (2c), that S did not know in which of the two rooms his wife was located, is induced in the absence of a marked context (e.g., that of a game of hide-and-seek). (2b) exemplifies particularized conversational implicature, (2c) the more linguistically significant category of generalized conversational implicature. In each case, it is not the proposition or sentence, but the speaker or utterance, that induces the relevant implicatum in the appropriate context.

Participants in a conversational exchange compute what was meant (by S's uttering U in context C) from what was said by assuming the application of the cooperative principle (Grice 1989: 26)—"Make your conversational contribution such as is required, at the stage at which it occurs"—and the four general and presumably universal maxims of conversation on which all rational interchange is grounded:

3. Maxims of Conversation (Grice [1967]1989: 26–27):
   Quality: Try to make your contribution one that is true.

   1. Do not say what you believe to be false.
   2. Do not say that for which you lack evidence.

   Quantity:

   1. Make your contribution as informative as is required (for the current purposes of the exchange).
   2. Do not make your contribution more informative than is required.

   Relation: Be relevant.
   Manner: Be perspicuous.

   1. Avoid obscurity of expression.
   2. Avoid ambiguity.
   3. Be brief. (Avoid unnecessary prolixity.)
   4. Be orderly.

Although implicata generated by the first three categories of maxims are computed from propositional content (what is said), Manner applies to the way what is said is said; thus the criterion of nondetachability applies only to implicata induced by the "content" maxims.

Since this schema was first proposed, it has been challenged, as well as defended and extended, on conceptual and empirical grounds (Keenan 1976; Brown and Levinson 1987), while neo- and post-Gricean pragmaticists have directed a variety of reductionist efforts at the inventory of maxims. The first revisionist was Grice himself, maintaining that all maxims are not created equal, with a privileged status accorded to Quality (though see Sperber and Wilson 1986 for a dissenting view): "False information is not an inferior kind of information; it just is not information . . . . The importance of at least the first maxim of Quality is such that it should not be included in a scheme of the kind I am constructing; other maxims come into operation only on the assumption that this maxim of Quality is satisfied" (Grice 1989: 371).

Of those "other maxims," the most productive is Quantity-1, which is systematically exploited to yield upper-bounding generalized conversational implicatures associated with scalar operators (Horn 1972, 1989; Gazdar 1979; Hirschberg 1985). Grice seeks to defend a conservative bivalent semantics; the shortfall between what standard logical semantics yields and what an intuitively adequate account of utterance meaning requires is addressed by a pragmatic framework grounded on the assumption that S and H are observing CP and the attendant maxims. Quantity-based scalar implicature in particular—my inviting you to infer from my use of *some . . .* that for all I know *not all . . .*—is driven by your knowing (and my knowing your knowing) that I expressed a weaker proposition, bypassing an equally unmarked utterance that would have expressed a stronger proposition, one unilaterally entailing it. What is said in the use of a weak scalar value is the lower bound *(at least some, at least possible),* with the upper bound *(at most some, at most necessary)* implicated as a cancelable inference *(some and possibly all, possible if not necessary).* Negating such predications denies the lower bound: to say that something is not possible is to say that it is impossible (less than possible). When the upper bound is denied *(It's not possible, it's necessary),* grammatical and phonological diagnostics reveal a metalinguistic or echoic use of negation, in which the negative particle is used to object to any aspect of a quoted utterance, including its conventional and conversational implicata, register, morphosyntactic form or pronunciation (Horn 1989; Carston 1996).

One focus of pragmatic research has been on the interaction of implicature with grammar and the LEXICON, in particular on the conventionalization or grammaticalization of conversational implicatures (see Bach and Harnish 1979 on

standardized nonliterality). Another issue is whether Grice's inventory of maxims is necessary and sufficient. One response is a proposal (Horn 1984, 1989; see also Levinson 1987) to collapse the non-Quality maxims into two basic principles regulating the economy of linguistic information. The Q Principle, a hearer-based guarantee of the sufficiency of informative content ("Say as much as you can, modulo Quality and R"), collects Quantity-1 and Manner-1,2. It is systematically exploited (as in the scalar cases) to generate upper-bounding implicata, based on H's inference from S's failure to use a more informative and/or briefer form that S was not in a position to do so. The R Principle, a correlate of the law of least effort dictating minimization of form ('Say no more than you must, modulo Q'), encompasses Relation, Quantity-2, and Manner-3,4. It is exploited to induce strengthening (lower-bounding) implicata typically motivated on social rather than purely linguistic grounds, as exemplified by indirect speech acts (e.g., euphemism) and so-called neg-raising, as in the tendency to pragmatically strengthen *I don't think that f* to *I think that not-f*.

A more radically reductionist model is offered in relevance theory (Sperber and Wilson 1986), in which one suitably elaborated principle of RELEVANCE suffices for the entire gamut of inferential work performed by the Gricean maxims. (The monistic approach of RT is closer to the dualistic Q/R model than it appears, both frameworks being predicated on a minimax or cost/benefit tradeoff that sees the goal of communication as maximizing contextual effects while minimizing processing effort.) RT stresses the radical underspecification of propositional content by linguistic meaning; pragmatically derived aspects of meaning include not only implicatures but "explicatures," that is, components of enriched truth-conditional content.

Although the issues surrounding the division of labor between Gricean implicature and RT-explicature await resolution (see Horn 1992; Récanati 1993), relevance theory has proved a powerful construct for rethinking the role of pragmatic inferencing in utterance interpretation and other aspects of cognitive structure; see Blakemore (1992) for an overview.

Implicit vs. Explicit Memory

Psychological studies of human MEMORY have traditionally been concerned with conscious recollection or explicit memory for specific facts and episodes. During recent years, there has been growing interest in a nonconscious form of memory, referred to as *implicit memory* (Graf and Schacter 1985; Schacter 1987), that does not require explicit recollection for specific episodes. Numerous experimental investigations have revealed dramatic differences between implicit and explicit memory, which have had a major impact on psychological theories of the processes and systems involved in human memory (cf. Roediger 1990; Schacter and Tulving 1994; Ratcliff and McKoon 1997).

The hallmark of implicit memory is a change in performance—attributable to information acquired during a specific prior episode—on a test that does not require conscious recollection of the episode. This change is often referred to as direct or repetition priming. One example of a test used to assess priming is known as stem completion, where people are asked to complete word stems (e.g., TAB) with the first word that comes to mind (e.g., TABLE); priming is inferred from an enhanced tendency to complete the stems with previously studied words relative to nonstudied words (for reviews, see Roediger and McDermott 1993; Schacter and Buckner 1998; Schacter, Chiu, and Ochsner 1993). Priming is not the only type of implicit memory. For instance, tasks in which people learn to perform motor or cognitive skills may involve implicit memory, because skill acquisition does not require explicit recollection of a specific previous episode (for review, see Salmon and Butters 1995).

Implicit memory can be separated or dissociated from explicit memory through experimental manipulations that affect implicit and explicit memory differently (for methodological considerations, see Jacoby 1991; Schacter, Bowers, and Booker 1989), and neurological conditions in which explicit memory is impaired while implicit memory is spared. For example, it has been well established that performance on explicit recall and recognition tests is higher following semantic than following nonsemantic study of an item—the well-known levels of processing effect. In contrast, however, the magnitude of priming on tasks that involve completing word stems or identifying briefly flashed words is often less affected, and sometimes unaffected, by semantic versus nonsemantic study (see reviews by Roediger and McDermott 1993; Schacter, Chin, and Ochsner 1993).

Perhaps the most dramatic dissociation between implicit and explicit memory has been provided by studies of brain-damaged patients with organic amnesia. Amnesic patients are characterized by a severe impairment in explicit memory for recent events, despite relatively normal intelligence, perception, and language. This memory deficit is typically produced by lesions to either medial temporal or diencephalic brain regions. In contrast, a number of studies have demonstrated that amnesic patients show intact implicit memory on tests of priming and skill learning. These observations suggest that implicit memory is supported by different brain systems than is explicit memory (Squire 1992).

The evidence also shows that various forms of implicit memory can be dissociated from one another. A number of studies point toward a distinction between perceptual priming and conceptual priming. Perceptual priming is little affected by semantic versus nonsemantic study processing. It is also modality specific (i.e., priming is enhanced when the sensory modality of study and test are the same), and in some instances may be specific to the precise physical format of stimuli at study and test (cf. Church and Schacter 1994; Curran, Schacter, and Bessenoff 1996; Graf and Ryan 1990; Tenpenny 1995). Conceptual priming, in contrast, is not tied to a particular sensory modality and is increased by semantic study processing; it is observed most clearly on tests that require semantic analysis, such as producing category exemplars in response to a category cue (Hamman 1990). Other evidence indicates that priming and skill learning are dissociable forms of implicit memory. For instance, studies of patients suffering from different forms of dementia indicate that patients with Alzheimer's dementia often show impaired priming on stem completion tasks, yet show normal learning of motor skills; in contrast, patients with Huntington's disease (which affects the motor system) show normal stem completion priming together with impaired learning of motor skills (Salmon and Butters 1995).

Recent studies using newly developed brain imaging techniques, such as POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI) have demonstrated that visual priming on such tests as stem completion is accompanied by decreased blood flow in regions of visual cortex (Squire et al. 1992). Various other neuroimaging studies have produced similar priming-related blood flow decreases (see Schacter and Buckner 1998). These observations are consistent with the idea that visual priming effects depend on a perceptual representation system that includes posterior cortical regions that are involved in perceptual analysis (Tulving and Schacter 1990); priming may produce more efficient processing of test cues, perhaps resulting in decreased neural activity. Other studies have shown that conceptual priming is associated with blood flow reductions in regions of left inferior frontal cortex that are known to be involved in semantic processing (for review, see Schacter and Buckner 1998). In contrast, neuroimaging studies of motor skill learning have shown that the development of skill across many sessions of practice is accompanied by increased activity in regions involved in motor processing, such as motor cortex (Karni et al. 1995). Neuroimaging studies are also beginning to illuminate the networks of structures involved in explicit remembering of recent episodes, including the regions within the prefrontal cortex and medial temporal lobes (e.g., Buckner et al. 1995; Schacter et al. 1996; Tulving et al. 1994; for review, see Cabeza and Nyberg 1997).

The exploration of implicit memory has opened up new vistas for memory research, providing a vivid reminder that many aspects of memory are expressed through means other than conscious, explicit recollection of past experiences. Nonetheless, a great deal remains to be learned about the cognitive and neural mechanisms of implicit memory, and it seems likely that further empirical study and theoretical analysis will continue to pay handsome dividends in the future.

Indexicals and Demonstratives

When you use "I," you refer to yourself. When I use it, I refer to myself. We use the same linguistic expression with the same conventional meaning. It is a matter of who uses it that determines who is the referent. Moreover, when Jon, pointing to Sue, says "she" or "you," he refers to Sue, whereas Sue can neither use "she" nor "you" to refer to herself, unless she is addressing an image of herself. If we change the context—the speaker, time, place, addressee, or audience—in which these expressions occur, we may end up with a different referent. Among the expressions that may switch reference with a change in context are personal pronouns (*my, you, she, his, we, . . .*), demonstrative pronouns (*this, that*), compound demonstratives (*this table, that woman near the window, . . .*), adverbs (*today, yesterday, now, here, . . .*), adjectives (*actual* and *present*),

possessive adjectives (*my pen, their house, . . .*). The reference of other words (e.g., *local, Monday, . . .*) seems also to depend on the context in which they occur. These words capture the interest of those working within the boundaries of cognitive science for several reasons: they play crucial roles when dealing with such puzzling notions as the nature of the SELF, the nature of perception, the nature of time, and so forth.

Reichenbach (1947) characterized this class of expressions *token reflexive* and argued that they can be defined in terms of the locution "this token," where the latter (reflexively) self-refers to the very token used. So, "I" can be defined in terms of "the person who utters this token," "now" in terms of "the time at which this token is uttered," "this table" in terms of "the table pointed to by a gesture accompanying this token," and so on.

One of the major features of token reflexive expressions—also called indexical expressions—that differentiates them from other referential expressions (e.g., proper names: "Socrates," "Paris"; mass terms: "gold," "water"; terms for species: "tiger," "rose"; and so on) is that they are usually used to make reference *in praesentia*. That is, a use of a token reflexive expression exploits the presence of the referent. In a usual communicative interaction the referent is in the perceptual field of the speaker and some contextual clues are used to make the referent salient.

When token reflexive expressions are not used to make reference *in praesentia* they exploit a previously fixed reference. "That man" in "*That man* we saw last night is handsome" does not refer to a present man. The use of token reflexive expressions to make reference *in absentia* forces the distinction between the context of utterance and the context of reference fixing. In our example, to fix the reference the speaker and the hearer appeal to a past context. The gap between the two contexts is bridged by memory.

The general moral seems to be that the paradigmatic use of a token reflexive expression cannot be deferential. Although one often relies on the so-called division of linguistic labor when using nontoken reflexive expressions, one cannot appeal to the same phenomenon when using a token reflexive expression: for example, one can competently use "Spiro Agnew" or "roadrunner" even if one does not know who Spiro Agnew is or is unable to tell a roadrunner from a rabbit. This parallels the fact that when using proper names, mass terms, and the like, context is in play before the name is used: we first fix the context and then use the name, whereas with token reflexive expressions context is at work the very moment we use them. As Perry (1997) suggests, we often use context to disambiguate a mark or noise (e.g., "bank;" "Aristotle" used either as a tag for the philosopher or for Onassis). These are presemantic uses of context. With token reflexive expressions, though, context is used semantically. It remains relevant after the language, words, and meaning are all known; the meaning directs us to certain aspects of context. This distinction reflects on the fact that proper names, mass terms, and so on, unlike token reflexive expressions, contribute to building context-free (eternal) sentences, that is, sentences that are true or false independently of the context in which they are used.

These general features of token reflexive expressions depend on their particular linguistic meaning: "the utterer of this token" is the linguistic meaning (the character, Kaplan 1977, or role, Perry 1977) of "I," whereas "the day in which this token is uttered" is the linguistic meaning of "today," and so on. As such, their linguistic meaning can be viewed as a function taking as argument the context and giving as value the referent (Kaplan 1977).

It is often the case, though, that the linguistic MEANING of expressions like "this," "that," "she," and so on, together with context, is not enough to select a referent. These expressions are often accompanied by a pointing gesture or demonstration and the referent will be what the demonstration demonstrates. Kaplan (1977) distinguishes between *pure indexicals* ("I," "now," "today,". . .) and *demonstratives* ("this," "she," . . .). The former, unlike the latter, do not need a demonstration to secure the reference.

Another way to understand the distinction between pure indexicals and demonstratives is to argue that the latter, unlike pure indexicals, are perception based. When one says "I" or "today," one does not have to perceive oneself or the relevant day to be able to use and understand these expressions competently. To use and understand "this," "she," and the like competently, one ought to perceive the referent or demonstratum. For this very reason, when a pure indexical is involved, the context of reference fixing and the context of utterance cannot diverge: the reference of a pure indexical, unlike the reference of a demonstrative, cannot be fixed by a past perception.

Moreover, a demonstrative, unlike a pure indexical, can be a vacuous term. "Today," "I," and so on never miss the referent. Even if I do not know whether today is Monday or Tuesday and I am amnesiac, if I say "Today I am tired," I refer to the relevant day and myself. By contrast, if hallucinating one says "She is funny," or pointing to a man, "This car is green," "she" and "this car" are vacuous.

Besides, pure indexicals cannot be coupled with sortal predicates, whereas "this" and "that" are often accompanied by sortal predicates to form compound demonstratives like "this *book*" and "that *water*." Sortal predicates can be considered to be *universe narrowers* which, coupled with other contextual clues, help us fix the reference. If when pointing to a bottle one says "This liquid is green," the sortal "liquid" helps us to fix the liquid and not the bottle as referent. Moreover, personal pronouns that work like demonstratives (e.g., "she," "he," "we," . . .) have a built-in or hidden sortal. "She," unlike "he," refers to a female, whereas "we" refers to a plurality of people among whom is the speaker.

Individualism

Individualism is a view about how psychological states are taxonomized that has been claimed to constrain the cognitive sciences, a claim that remains controversial. Individualists view the distinction between the psychological states *of individuals* and the physical and social environments of those individuals as providing a natural basis for demarcating properly scientific, psychological kinds. Psychology in particular and the cognitive sciences more generally are to be concerned with natural kinds whose instances end at the boundary of the individual. Thus, although individualism is sometimes glossed as the view that psychological states are "in the head," it is a more specific and stronger view than suggested by such a characterization. Individualism is sometimes (e.g., van Gulick 1989) called "internalism," and its denial "externalism." Its acceptance or rejection has implications for accounts of MENTAL REPRESENTATION, MENTAL CAUSATION, and SELF-KNOWLEDGE.

The dominant research traditions in cognitive science have been at least implicitly individualistic. Relatively explicit statements of a commitment to an individualistic view of aspects of cognitive science include Chomsky's (1986, 1995) deployment of the distinction between two conceptions of language (the "I"-language and the "E"-language, for "internal" and "external," respectively), Jackendoff's (1991) related, general distinction between "psychological" and "philosophical" conceptions of the mind, and Cosmides and Tooby's (1994) emphasis on the constructive nature of our internal, evolutionary-specialized cognitive modules.

Individualism is controversial for at least three reasons. First, individualism appears incompatible with FOLK PSYCHOLOGY and, more controversially, with a commitment to INTENTIONALITY more generally. Much contemporary cognitive science incorporates and builds on the basic concepts of the folk (e.g., belief, memory, perception) and at least appears to rely on the notion of mental content. Second, despite the considerable intuitive appeal of individualism, arguments for it have been less than decisive. Third, the relationship between individualism and cognitive science has been seen to be more complicated than initially thought, in part because of varying views of how to understand explanatory practice in the cognitive sciences.

One formulation of individualism, expressed in Putnam (1975), but also found in the work of Carnap and early twentieth century German thinkers, is *methodological solipsism*. Following Putnam, Fodor views methodological solipsism as the doctrine that psychology ought to concern itself only with *narrow* psychological states, where these are states that do not presuppose "the existence of any individual other than the subject to whom that state is ascribed" (Fodor 1980: 244). An alternative formulation of individualism offered by Stich (1978), the *principle of autonomy*, says that "the states and processes that ought to be of concern to the psychologist are those that supervene on the current, internal, physical state of the organism" (Stich 1983: 164–165; see SUPERVENIENCE). Common to both expressions is the idea that an individual's psychological states should be *bracketed off* from the mere,

beyond-the-head environments that individuals find themselves in.

Fodor and Stich used their respective principles to argue for substantive conclusions about the scope and methodology of psychology and the cognitive sciences. Fodor contrasted a solipsistic psychology with what he called a naturalistic psychology, arguing that the latter (among which he included JAMES JEROME GIBSON's approach to perception, learning theory, and the naturalism of WILLIAM JAMES) was unlikely to prove a reliable research strategy in psychology. Stich argued for a syntactic or computational theory of mind that made no essential use of the notion of intentionality or mental content. Although these arguments themselves have not won widespread acceptance, many philosophers interested in the cognitive sciences are attracted to individualism because of a perceived connection to FUNCTIONALISM in the philosophy of mind, the idea being that the functional or causal roles of psychological states are individualistic.

A point initially made in different ways by both Putnam and Stich—that our folk psychology violates individualism—was developed by Tyler Burge (1979) as part of a wide-ranging attack on individualism. Putnam had argued that "'meanings' just ain't in the head" by developing a causal theory of reference for natural kind terms, introducing TWIN EARTH thought experiments into the philosophy of mind. Stich identified intuitive cases (including two of Putnam's) in which our folk psychological ascriptions conflicted with the principle of autonomy. Burge introduced *individualism* as a term for an overall conception of the mind, extended the Twin Earth argument from language to thought, and showed that the conflict between individualism and folk psychology did not turn on a perhaps controversial claim about the semantics of natural kind terms. Together with Burge's (1986) argument that DAVID MARR's celebrated computational theory of vision was *not* individualistic, Burge's early arguments have posed the deepest and most troubling challenges to individualism (cf. Fodor 1987: chap. 2; 1994).

Individualism is motivated by several clusters of powerful intuitions. A "Cartesian" cluster that goes most naturally with the methodological solipsism formulation of individualism revolves around the idea that an organism's mental states could be just as they are even were its environment radically different. Perhaps the most extreme case is that of a brain-in-a-vat: were you a brain-in-a-vat, not an embodied person actively interacting with the world, you could have just the same psychological states that you have now, provided that you were supplied with just the right stimulation and feedback from the "vat" that replaces the world you are actually in. A second, "physicalist" cluster that complements the principle of autonomy formulation appeals to the idea that physically identical individuals *must have* the same psychological states—again, no matter how different their environments.

So much for the intuitions; what about the *arguments*? Empirical and methodological (rather than *a priori*) arguments for or against individualism are perhaps of most interest to cognitive scientists (Wilson 1995: chaps. 2–5). Because of the centrality of computation to cognitive sci-

ence, the most powerful empirical arguments appeal to the computational nature of cognition. At times, such arguments have involved detailed examination of particular theories or research programs, most notably Marr's theory of vision (Egan 1992; Segal 1989; Shapiro 1997), the discussion of which forms somewhat of an industry within philosophical psychology. A different sort of challenge to the inference from computationalism to individualism is posed by Wilson's (1994) *wide computationalism*, a view according to which some of our cognitive, computational systems literally extend into the world (and so cannot be individualistic).

Those rejecting individualism on empirical or methodological grounds have appealed to the situated or embedded nature of cognition, seeking more generally to articulate the crucial role that an organism's environment plays in its cognitive processing. For example, McClamrock (1995: chap. 6) points to the role of improvisation in planning, and Wilson (1999) points to the ways in which informational load is shifted from organism to environment in metarepresentation. But despite the suggestiveness of such appeals, the arguments here remain relatively undeveloped; further attention to the relationships between culture, external symbols, and cognition (Donald 1991; Hutchins 1995) is needed.

Further issues: First, faced with the prima facie conflict between individualism and representational theories of the mind, including folk psychology, individualists have often invoked a distinction between wide content and NARROW CONTENT and argued that cognitive science should use only the latter. The adequacy of competing accounts of narrow content, and even whether there *is* a notion of content that meets the constraint of individualism, are matters of continuing debate.

Second, little of the debate over individualism in cognitive science has reflected the increasing prominence of neuroscientific perspectives on cognition. Although one might assume that the various neurosciences must be individualistic, this issue remains largely unexplored.

Finally, largely unasked questions about the relationship between individualism in psychology and other "individualistic" views—for example, in evolutionary biology (Williams 1966; cf. Wilson and Sober 1994) and in the social sciences (e.g., Elster 1986)—beckon discussion as the boundaries and focus of traditional cognitive science are challenged. Answering such questions will require discussion of the place of the cognitive sciences among the sciences more generally, and of general issues in the philosophy of science.

Induction

Induction is a kind of inference that introduces uncertainty, in contrast to DEDUCTIVE REASONING in which the truth of a conclusion follows necessarily from the truth of the premises. The term *induction* sometimes has a narrower meaning to describe a particular kind of inference to a generalization, for example from "All the cognitive scientists I've met are intelligent" to "All cognitive scientists are intelligent." In the broader sense, induction includes all kinds of nondeductive LEARNING, including concept formation, ANALOGY, and the generation and acceptance of hypotheses (abduction).

The traditional philosophical problem of induction is whether inductive inference is legitimate. Because induction involves uncertainty, it may introduce error: no matter how many intelligent cognitive scientists I have encountered, one still might turn up who is not intelligent. In the eighteenth century, DAVID HUME asked how people could be justified in believing that the future will be like the past and concluded that they cannot: we use induction out of habit but with no legitimate basis. Because no deductive justification of induction is available, and any inductive justification would be circular, it seems that induction is a dubious source of knowledge. Rescher (1980) offers a pragmatic justification of induction, arguing that it is the best available means for accomplishing our cognitive ends. Induction usually works, and even when it leads us into error, there is no method of thinking that would work better.

In the 1950s, Nelson Goodman (1983) dissolved the traditional problem of induction by pointing out that the validity

of deduction consists in conformity to valid deductive principles at the same time that deductive principles are evaluated according to deductive practice. Justification is then just a matter of finding a coherent fit between inferential practice and inferential rules. Similarly, inductive inference does not need any general justification but is a matter of finding a set of inductive principles that fit well with inductive practice after a process of improving principles to fit with practice and improving practice to fit with principles. Instead of the old problem of coming up with an absolute justification of induction, we have a new problem of compiling a set of good inductive principles.

The task that philosophers of induction face is therefore very similar to the projects of researchers in psychology and artificial intelligence who are concerned with learning in humans and machines. Psychologists have investigated a wide array of inductive behavior, including rule learning in rats, category formation, formation of models of the social and physical worlds, generalization, learning inferential rules, and analogy (Holland et al. 1986). AI researchers have developed computational models of many kinds of MACHINE LEARNING, including learning from examples and EXPLANATION-BASED LEARNING, which relies heavily on background knowledge (Langley 1996; Mitchell 1997).

Most philosophical work on induction, however, has tended to ignore psychological and computational issues. Following Carnap (1950), much research has been concerned with applying and developing probability theory. For example, Howson and Urbach (1989) use Bayesian probability theory to describe and explain inductive inference in science. Similarly, AI research has investigated inference in BAYESIAN NETWORKS (Pearl 1988). In contrast, Thagard (1992) offers a more psychologically oriented view of scientific induction, viewing theory choice as a process of parallel constraint satisfaction that can be modeled using connectionist networks. There is room for both psychological and nonpsychological investigations of induction in philosophy and artificial intelligence: the former are concerned with how people do induction, and the latter pursue the question of how probability theory and other mathematical methods can be used to perform differently and perhaps better than people typically do. It is possible, however, that psychologically motivated connectionist approaches to learning may approximate to optimal reasoning.

Here are some of the inductive tasks that need to be understood from a combination of philosophical, psychological, and computational perspectives:

1. *Concept learning.* Given a set of examples and a set of prior concepts, formulate new CONCEPTS that effectively describe the examples. A student entering the university, for example, needs to form new concepts that describe kinds of courses, professors, and students.
2. *Rule learning.* Given a set of examples and a set of prior rules, formulate new rules that improve problem solving. For example, a student might generalize that early morning classes are hard to get to. According to some linguists, LANGUAGE ACQUISITION is essentially a matter of learning rules.
3. *Hypothesis formation.* Given a puzzling occurrence such as a friend's not showing up for a date, generate hypoth-

eses about why this happened. Pick the best hypothesis, which might be done probabilistically or qualitatively by considering which hypothesis is the best explanation. Forming and evaluating explanatory hypotheses is a kind of CAUSAL REASONING. Medical diagnosis is one kind of hypothesis formation.
4. *Analogical inference.* To solve a given target problem, look for a similar problem that can be adapted to infer a possible solution to the target problem. ANALOGY and hypothesis formation are often particularly risky kinds of induction, inasmuch as they both tend to involve substantial leaps beyond the information given and introduce much uncertainty; alternative analogies and hypotheses will always be possible. Nevertheless, these risky kinds of induction are immensely valuable to everyday and scientific thought, because they can bring new creative insights that induction of rules and concepts from examples could never provide.

How much of human thinking is deductive and how much is inductive? No data are available to answer this question, but if Harman (1986) is right that inference is always a matter of coherence, then all inference is inductive. He points out that the deductive rule of modus ponens, from *P* and *if P then Q* to infer *Q*, does not tell us that we should infer *Q* from *P* and *if P then Q*; sometimes we should give up *P* or *if P then Q* instead, depending on how these beliefs and *Q* cohere with our other beliefs. Many kinds of inductive inference can be interpreted as maximizing coherence using parallel constraint satisfaction (Thagard and Verbeurgt 1998).

Inductive Logic Programming

Inductive logic programming (ILP) is the area of computer science involved with the automatic synthesis and revision of logic programs from partial specifications. The word

"inductive" is used in the sense of philosophical rather than mathematical induction. In his *Posterior Analytics* Aristotle introduced philosophical induction (in Greek *epagogue*) as the study of the derivation of general statements from specific instances (see INDUCTION). This can be contrasted with deduction, which involves the derivation of specific statements from more general ones. For instance, induction might involve the conjecture that (a) "all swans are white" from the observation (b) "all the swans in that pond are white," where (b) can be derived deductively from (a). In the *Principles of Science* the nineteenth-century philosopher and economist William Stanley Jevons gave some simple demonstrations that inductive inference could be carried out by reversal of deductive rules of inference. The idea of reversing deduction has turned out to be one of the strong lines of investigation within ILP.

In ILP the general and specific statements are in both cases logic programs. A logic program is a set of Horn clauses (see LOGIC PROGRAMMING). Each Horn clause has the form *Head ← Body*. Thus the definite clause active(X) ← *charged(X), polar(X)* states that any *X* that is charged and polar is also active. In this case, active, charged, and polar are called "predicates," and they are properties that are either true or false of X. Within deductive logic programming the inference rule of *resolution* is used to derive consequences from logic programs. According to resolution, given atom *a* and clauses *C, D,* from the clauses $a \vee C$ and $D \vee \bar{a}$ the clause $C \vee D$ can be concluded. A connected set of resolutions is called a proof or deductive derivation.

The inductive derivations in ILP are sometimes thought of as inversions of resolution-based proofs (see "inverse resolution" in Muggleton and de Raedt 1994). Following Plotkin's work in the 1970s, the logical specification of an ILP problem is thought of as consisting of three primary components: *B,* the background knowledge (e.g., things cannot be completely black and completely white), *E* the examples (e.g., the first swan on the pond is white) and *H,* the hypothesis (e.g., all swans are white). The primary relation between these three components is that the background together with the hypothesis should allow the derivation of the examples. This can be written in logical notation as follows:

$$B, H \vdash E$$

Given only such logical specifications, it has long been known that induction is not sound. That is to say, H is not a necessary conclusion from knowing B and E.

A sound treatment is possible by viewing inductive inference as the derivation of statements with associated probabilities. This approach was advocated by the philosopher Carnap in the 1950s and has been taken up more recently in a revised form within ILP. The framework typically chosen is that of Bayesian inference (see BAYESIAN LEARNING). This is a probabilistic framework that allows calculations of the probability of certain events' happening given that other events have happened. Thus suppose we imagine that nature, or a teacher, randomly and independently chooses a series of concepts to be learned, where each concept has an associated probability of coming up. Suppose also that for each concept a series of instances are randomly and inde-

pendently chosen and associated with the label true or false depending on whether they are or are not examples of the chosen concept. From an inductive agent's point of view, prior to receipt of any examples the probability that any particular hypothesis *H* will fit the data is *p(H),* the probability of *H* being chosen by the teacher. Likewise, *p(E)* denotes the probability that the teacher will provide the example sequence *E, p(H | E)* is the probability the hypothesis chosen was *H* given that the example sequence was *E* and *p(E | H)* is the probability that the example sequence was *E* given that the hypothesis chosen was *H.* According to Bayes's theorem

$$p(H|E) \; = \; \frac{p(H)p(E|H)}{p(E)}.$$

The most likely hypothesis *H* given the example *E* is the one that maximizes *p(H | E)*. In fact it is sufficient to maximize *p(H) p(E | H)* because *p(E)* is common to all candidate hypotheses. As with all Bayesian approaches the main issue is how to choose the inductive agent's prior probabilities over hypotheses. In common with other forms of machine learning, this is usually done within ILP systems using a MINIMUM DESCRIPTION LENGTH (MDL) approach, that is, a probability distribution that assigns higher probabilities to textually simple hypotheses.

Within any computational framework such as ILP, a key question involves the efficiency with which the inductive agent converges on the "correct" solution. Here a number of ILP researchers have taken the approach of COMPUTATIONAL LEARNING THEORY, which studies the numbers of examples required for an inductive algorithm to return with high probability an hypothesis which has a given degree of accuracy (this is Valiant's Probably Approximately Correct [PAC] model). One interesting result of these investigations has been that though it has been shown that logic programs cannot be PAC-learned as a class, time-bound logic programs (those in which the derivation of instances are of bounded length) are efficiently learnable within certain Bayesian settings in which the probability of hypotheses decays rapidly (e.g., exponentially or with the inverse square) relative to their size.

One of the hard and still largely unsolved problems within ILP is that of *predicate invention.* This is the process by which predicates are added to the background knowledge in order to provide compact representations for foreground concepts. Thus suppose you were trying to induce a phrase structured grammar for English, and you already have background descriptions for noun, verb, and verb phrase, but no definition for a noun phrase. "Inventing" a definition for noun phrase would considerably simplify the overall hypothesized descriptions. However, the space of possible new predicates that could be invented is clearly large, and its topology not clearly understood.

ILP has found powerful applications in areas of scientific discovery in which the expressive power of logic programs is necessary for representing the concepts involved. Most notably, ILP techniques have been used to discover constraints on the molecular structures of certain biological molecules. These semiautomated scientific "discoveries" include a new

structural alert for mutagenesis and the suggestion of a new binding site for an HIV protease inhibitor. ILP techniques have also been demonstrated capable of building large grammars automatically from example sentences.

The philosopher of science Gillies (1996) has made a careful comparison of techniques used in ILP with Bacon and Popper's conception of scientific induction. Gillies concludes that ILP techniques combine elements from Bacon's "pure" knowledge-free notion of induction and Popper's falsificationist approach. ILP has helped clarify a number of issues in the theory, implementation, and application of inductive inference within a computational logic framework.

Infant Cognition

Questions about the origins and development of human knowledge have been posed for millennia. What do newborn infants know about their new surroundings, and what do they learn as they observe events, play with objects, or interact with people? Behind these questions are deeper ones: By what processes does knowledge grow, how does it change, and how variable are its developmental paths and endpoints?

Studies of cognition in infancy have long been viewed as a potential source of answers to these questions, but they face a problem: How does one find out what infants know? Before the twentieth century, most studies of human knowledge depended either on the ability to reflect on one's knowledge or on the ability to follow instructions and perform simple tasks with focused attention. Infants obviously are unfit subjects for these studies, and so questions about their knowledge were deemed unanswerable by scientists as different as HERMAN VON HELMHOLTZ and Edward Bradford Titchener.

The study of cognition in infancy nevertheless began in earnest in the 1920s, with the research of JEAN PIAGET. Piaget observed his own infants' spontaneous, naturally occurring actions under systematically varying conditions. Some of his most famous observations centered on infants' reaching for objects under different conditions of visibility and accessibility. Infants under nine months of age, who showed intense interest in visible objects, either failed to reach for objects or reached to inappropriate locations when the objects were occluded. Search failures and errors declined with age, a change that Piaget attributed to the emergence of abilities to represent objects as enduring, mechanical bodies. He proposed a domain-general, constructivist theory of cognitive development, according to which the development of object representations was just one manifestation of a more general change in cognitive functioning over the period from birth to eighteen months.

Later investigators have confirmed Piaget's central observations but questioned his conclusions. Studies of motor development suggest that developmental changes in infants' search for hidden objects stem in part from developing abilities to reach around obstacles, manipulate two objects in relation to one another, and inhibit prepotent actions. When these abilities are not required (for example, when infants are presented with an object that is obscured by darkness rather than by occlusion), successful search occurs at younger ages. The causes of developmental changes in search are still disputed, however, with different accounts emphasizing changes in action, ATTENTION, MEMORY, object representations, and physical knowledge.

Recent studies of cognition in infancy have tended to focus on early-developing actions such as kicking, sucking, and looking. Experiments have shown that even newborn infants learn to modify their actions so as to produce or change a perceived event: for example, babies will suck on a pacifier with increased frequency or pressure if the action is followed by a sound, and they will suck harder or longer for some sounds than for others. Studies using this method provide evidence that newborn infants recognize their parents' voices (they suck harder to hear the voice of their mother than the voice of a different woman) and their native language (they suck harder to produce speech in their own community's language). Both abilities likely depend on auditory perception and learning before birth.

A variant of this method is based on the finding that infants' sucking declines over time when followed by the same sound and then increases if the sound changes. This pattern is the basis of studies of infants' auditory discrimination, CATEGORIZATION, and memory, and it reveals remarkably acute capacities for SPEECH PERCEPTION in the first days of life. Indeed, young infants are more sensitive than adults to speech contrasts outside their native language. Studies of older infants, using similar procedures and a headturn response, reveal abilities to recognize the sounds of individual words and predictable sequences of syllables well before speech begins. The relation between these early-developing abilities and later LANGUAGE ACQUISITION is an open question guiding much current research.

Since the middle of the twentieth century, many studies of cognition in infancy have used some aspect of visual attention as a window on the development of knowledge. Even newborn infants show systematic differences in looking time to different displays, preferring patterned to homogeneous pictures, moving to stationary objects, and familiar people to strangers. Like sucking, looking time declines when a single display is repeated and increases when a new display appears. Both intrinsic preferences and preferences for novelty provide investigators with measures of detection and discrimination not unlike those used by traditional psychophysicists. They have produced quite a rich body of knowledge about early PERCEPTUAL DEVELOPMENT. Investigators now know, for example, that one-week-old infants perceive depth and the constant sizes of objects over varying distances, that two-month-old infants have begun to perceive the stability of objects over self motion and consequent image displacements in the visual field, and that three-month-old infants perceive both similarities among animals within a single species and differences across different species.

Perhaps the most intriguing, and controversial, studies using preferential looking methods have focused on more central aspects of cognitive development in infancy. Returning to knowledge of objects, experiments have shown that infants as young as three months look systematically longer at certain events that adults find unnatural or unexpected, relative to superficially similar events that adults find natural. In one series of studies, for example, three-month-old infants viewed an object that was initially fully visible on a horizontal surface, an opaque screen in front of the object rotated upward and occluded the object, and then the screen either stopped at the location of the object (expected for adults) or rotated a full half turn, passing through the space that the object had occupied (unexpected). Infants looked longer at the latter event, despite the absence of any intrinsic preference for the longer rotation. Infants' looking patterns suggested that they represented the object's continuous existence, stable location, and solidity, and that they reacted with interest or surprise when these properties were violated.

In further investigations of these abilities, the limits of early-developing object knowledge have been explored. Thus, four-month-old infants have been found to be more sensitive to the contact relations among object motions (they represent objects as initiating motion on contact with other objects) than to the inertial properties of object motions (they fail to represent objects as moving at constant or smoothly changing velocities in the absence of obstacles). Very young infants also have been shown to detect and discriminate different numbers of objects in visible and partly occluded displays when numbers are small or numerical differences are large. With large set sizes and small differences, in contrast, infants fail to respond reliably to number. Studies of cognition in infancy are most revealing where they show contrasting patterns of success and failure, as in these examples, because the patterns provide insight into the nature of the cognitive systems underlying their performance.

Where infants have shown visual preferences for events that adults judge to be unnatural, controversy has arisen concerning the interpretation of infants' looking patterns. For example, Baillargeon (1993) has proposed that the patterns provide evidence for early-developing, explicit knowledge of objects; Karmiloff-Smith (1992) has proposed that the patterns provide evidence for an initial system of object representation not unlike early-developing perceptual systems; and Haith (Haith and Bensen 1998) has proposed that preferential looking to unnatural events depends on sensory or motor systems attuned to subtle, superficial properties of the events. These contrasting possibilities animate current research.

Alongside these studies is a rich tradition of research on infants' social development, providing further insight into their cognitive capacities. Newborn infants attend to human faces, recognize familiar people, and even imitate some facial gestures and expressions in a rudimentary way. By six months, infants follow people's gaze and attend to objects on which people have acted. By nine months, infants reproduce other people's actions on objects, and they communicate about objects with gestures such as pointing. These patterns suggest that infants have considerable abilities to learn from other people, and they testify to early-developing knowledge about human action. Studies probing the nature of this knowledge, using methods parallel to the preferential looking methods just described, reveal interesting differences. Whereas infants represent inanimate object motions as initiated on contact, they represent human actions as directed to goals; whereas continuity of motion provides the strongest information for object identity, constancy of properties such as facial features provides stronger information for personal identity. Evidence for these differences has been obtained only recently and much remains to be learned, but research already suggests that distinct systems of knowledge underlie infants' reasoning about persons and inanimate objects.

In sum, the descriptive enterprise of characterizing infants' developing knowledge is well under way, both in the preceding domains and in others not mentioned. In contrast, the deeper and more important enterprise of explaining early cognitive development has hardly begun. Most investigators agree that knowledge is organized into domain-specific systems at a very early age, but they differ in their characterizations of those systems and their explanations for each system's emergence and growth. Elman et al. (1996) suggest that infants are endowed with a collection of connectionist

learning systems whose differing architectures and processing characteristics predispose them to treat information from different domains. Spelke and others suggest that infants are endowed with systems of core knowledge that remain central to humans as adults. Carey (1991) proposes that infants are endowed with modular systems for processing perceptual information, but CONCEPTUAL CHANGE occurs as these systems are partly superceded over development by more central systems of representation. As research on infants' learning, knowledge, and perception progresses, these views and others will become more amenable to empirical test.

References to the experiments discussed earlier can be found in Bertenthal (1996), Haith and Bensen (1998), Mandler (1998), and Spelke and Newport (1998). Discussions of infant cognition from diverse theoretical perspectives are listed in the references.

Information Theory

Information theory is a branch of mathematics that deals with measures of information and their application to the study of communication, statistics, and complexity. It originally arose out of communication theory and is sometimes used to mean the mathematical theory that underlies communication systems. Based on the pioneering work of Claude Shannon (1948), information theory establishes the limits to the shortest description of an information source and the limits to the rate at which information can be sent over a communication channel. The results of information theory are in terms of fundamental quantities like entropy, relative entropy, and mutual information, which are defined using a probabilistic model for a communication system. These quantities have also found application to a number of other areas, including statistics, computer science, complexity and economics. In this article, we will describe these basic quantities and some of their applications. Terms like *information* and *entropy* are richly evocative with multiple meanings in everyday usage; information theory captures only some of the many facets of the notion of information. Strictly speaking, information theory is a branch of mathematics, and care should be taken in applying its concepts and tools to other areas.

Information theory relies on the theory of PROBABILITY to model information sources and communication channels. A source of information produces a message out of a set of possible messages. The difficulty of communication or storage of the message depends only on length of the representation of the message and can be isolated from the meaning of the message. If there is only one possible message, then no information is transmitted by sending that message. The amount of information obtained from a mes-

sage is related to its UNCERTAINTY—if something is very likely, not much information is obtained when it occurs. The simplest case occurs when there are two equally likely messages—the messages can then be represented by the symbols 0 and 1 and the amount of information transmitted by such a message is one bit. If there are four equally likely messages, the messages can be represented by 00, 01, 10 and 11, and thus require two bits for its representation. For equally likely messages, the number of bits required grows logarithmically with the number of possibilities. When the messages are not equally likely, we can model the message source by a random variable X, which takes on values 1, 2, . . . with probabilities $p1, p2, \ldots$, with associated entropy defined as

$$H(X) = -\sum_i p_i \log_2 p_i \text{ bits.}$$

The entropy is a measure of the average uncertainty of the random variable. It can be shown (Cover and Thomas 1991) that the entropy of a random variable is a lower bound to the average length of any uniquely decodable representation of the random variable. For a uniformly distributed random variable taking on 2^k possible values, the entropy of the random variable is k bits, and it is easy to see how an outcome could be represented by a k bit number. When the random variable is not uniformly distributed, it is possible to get a lower average length description by using fewer bits to describe the most frequently occurring outcomes, and more bits to describe the less frequent outcomes. For example, if a random variable takes on the values A, B, C, and D with probabilities 0.5, 0.25, 0.125, and 0.125 respectively, then we can use a code 0, 10, 110, 111 to represent these four outcomes with an average length of 1.75 bits, which is less than the two bits required for the equal length code. Note that in this example, the average codeword length is equal to the entropy. In general, the entropy is a lower bound on the average length of any uniquely decodable code, and there exists a code that achieves an average length that is within one bit of the entropy.

Traditional information theory was developed using probabilistic models, but it was extended to arbitrary strings using notions of program length by the work of Kolmogorov (1965), Chaitin (1966), and Solomonoff (1964). Suppose one has to send a billion bits of π to a person on the moon. Instead of sending the raw bits, one could instead send a program to calculate π and let the receiver reconstruct the bits. Because the length of the program would be much shorter than the raw bits, we compress the string using this approach. This motivates the following definition for *Kolmogorov complexity* or *algorithmic complexity:* The Kolmogorov complexity $K_u(x)$ is the length of the shortest program for a universal TURING machine U (see AUTOMATA) that prints out the string x and halts. Using the fact that any universal Turing machine can simulate any other universal Turing machine using a fixed length simulation program, it is easy to see that the Kolmogorov complexity with respect to two different Turing machines differs by at most a constant (the length of the simulation program). Thus the notion of Kolmogorov complexity is

universal up to a constant. For random strings, it can be shown that with high probability, the Kolmogorov complexity is equivalent to the entropy rate of the random process. However, due to the halting problem, it is not always possible to discover the shortest program for a string, and thus it is not always possible to determine the Kolmogorov complexity of a string. But Kolmogorov or algorithmic complexity provides a natural way to think about complexity and data compression and has been developed into a rich and deep theory (Li and Vitanyi 1992) with many applications (see MINIMUM DESCRIPTION LENGTH and COMPUTATIONAL COMPLEXITY).

Transmission of information over a communication channel is subject to noise and interference from other senders. A fundamental concept of information theory is the notion of channel capacity, which plays a role very similar to the capacity of a pipe carrying water—information is like an incompressible fluid that can be sent reliably at any rate below capacity. It is not possible to send information reliably at a rate above capacity. A communication channel is described by a probability transition function $p(y|x)$, which models the probability of a particular output message y when input signal x is sent. The capacity C of the channel can then be calculated as

$$C = \max_{p(x)} \sum_x \sum_y p(x)p(y|x) \log \frac{p(x)p(y|x)}{p(x)\Sigma_x p(y|x)} \qquad (4)$$

A key result of information theory is that if the entropy rate of a source is less than the capacity of a channel, then the source can be reproduced at the output of the channel with negligible error, whereas if the entropy rate is greater than the capacity, the error cannot be made arbitrarily small. This result, due to Shannon (1948), created a sensation when it first appeared. Before Shannon, communication engineers believed that the only way to increase reliability in the presence of noise was to reduce the rate by repeating messages, and that to get arbitrarily high reliability one would need to send at a vanishingly small rate. Shannon proved that this was not necessary; at any rate below the capacity of the channel, it is possible to send information with arbitrary reliability by appropriate coding and decoding. The methods used by Shannon were not explicit, but subsequent research has developed practical codes that allow communication at rates close to capacity. These codes are used in combating errors and noise in most current digital systems, for example, in CD players and modems.

Another fundamental quantity used in information theory and in statistics is the relative entropy or Kullback-Leibler distance $D(p \parallel q)$ between probability mass functions p and q, which is defined as

$$D(p \parallel q) = \sum_i p_i \log \frac{p_i}{q_i} \qquad (5)$$

The relative entropy is a measure of the difference between two distributions. It is always nonnegative, and is zero if and only if the two distributions are the same. However, it is not a true distance measure, because it is not

symmetric. The relative entropy plays a key role in large deviation theory, where it is the exponent in the probability that data drawn according to one distribution looks like data from the other distribution. Thus if a experimenter observes n samples of data and wants to decide if the data that he has observed is drawn from the distribution p or the distribution q, then the probability that he will think that the distribution is p when the data is actually drawn from q is approximately $2^{-nD(p\|q)}$.

We have defined entropy and relative entropy for single discrete random variables. The definitions can be extended to continuous random variables and random processes as well. Because a real number cannot be represented fully with a finite number of bits, a branch of information theory called rate distortion theory characterizes the tradeoff between the accuracy of the representation (the distortion) and the length of the description (the rate). The theory of communication has also been extended to networks with multiple senders and receivers and to information recording (which can be considered as information transmission over time as opposed to information transmission over space).

Information theory has had a profound impact on the technology of the information age. The fact that most information now is stored and transmitted in digital form can be considered a result of one of the fundamental insights of the theory, that the problem of data compression can be separated from the problem of optimal transmission over a communication channel without any loss in achievable performance. Over the half century since Shannon's original work, complex source coding and channel coding schemes have been developed that have come close to fulfilling the bounds that are derived in the theory. These fundamental bounds on description length and communication rates apply to all communication systems, including complex ones like the nervous system or the brain (Arbib 1995). The quantities defined by information theory have also found application in many other fields, including statistics, computer science, and economics.

Informational Semantics

Informational semantics is an attempt to ground meaning—as this is understood in the study of both language and mind—in an objective, mind (and language) independent, notion of information. This effort is often part of a larger effort to naturalize INTENTIONALITY and thereby exhibit semantic—and, more generally, mental—phenomena as an aspect of our more familiar (at least better understood) material world.

Informational semantics locates the primary source of meaning in symbol-world relations (the symbols in question can occur either in the language of thought or in a public language). The symbol-world relations are sometimes described in information-theoretic terms (source, receiver, signal, etc.) and sometimes in more general causal terms. In either case, the resulting semantics is to be contrasted with *conceptual role* (also called *procedural*) semantics, which locates meaning in the relations symbols have to one another (or, more broadly, the way they are related to one another, sensory input, and motor output). Because on some interpretations of information, the information a signal carries is what it indicates about a source, informational semantics is sometimes referred to as *indicator semantics*. The concept of information involved is inspired by, but is only distantly related to, the statistical construct in INFORMATION THEORY (Dretske 1981).

The word "meaning" is multiply ambiguous. Two of its possible meanings (Grice 1989) are: (1) *nonnatural* meaning—the sense in which the word "fire" stands for or means fire; and (2) *natural* meaning—the way in which smoke means (is a sign of, indicates) fire. Nonnatural meaning has no necessary connection with truth: "Jim has the measles" means that Jim has the measles whether or not he has the measles. Natural meaning, on the other hand, requires the existence of the condition meant: if Jim doesn't have the measles, the red spots on his face do not mean (indicate) that he has the measles. Perhaps all they mean is that he has been eating too much candy. Natural meaning, what one event indicates about another, is taken to be a relation between sign and signified that does not depend on anyone recognizing or identifying what is meant. Tracks in the snow can mean there are deer in the woods even if no one identifies them that way—even if they do not mean that *to* anyone.

Information, as this is used in informational semantics, is akin to natural meaning. It is an objective (mind-independent) relation between a sign or signal—tracks in the snow, for instance—and what that sign or signal indicates—deer in the woods. The information a signal carries about a source is what that signal indicates (*means* in a natural way) about that source. Informational semantics, then, is an effort to understand non-natural meaning—the kind of meaning characteristic of thought and language—as arising out of and having its source in natural meaning. The word "meaning" will hereafter be used to refer to nonnatural meaning; "information" and "indication" will be reserved for natural meaning.

Informational semantics takes the primary home of meaning to be in the mind—as the meaning or content of a

thought or intention. Sounds and marks of natural language derive their meaning from the communicative intentions of the agents who use them. As a result, the information of primary importance to informational semantics is that occurring in the brains of conscious agents. Thus, for informational semantics, the very existence of thought and, thus, the possibility of language depends on the capacity of systems to transform information (normally supplied by perception) into meaning.

Not all information-processing systems have this capacity. Artifacts (measuring instruments and computers) do not. To achieve this conversion, two things are required. First, because meaning is fine grained (even though 3 *is* $\sqrt[3]{27}$, thinking or saying that x = 3 is not the same as thinking or saying that x = $\sqrt[3]{27}$) and information is coarse grained (a signal that carries the information that x = 3 necessarily carries the information that x = $\sqrt[3]{27}$), a theory of meaning must specify how coarse grained information is converted into fine grained meaning. Which of the many pieces of information an event (normally) carries is to be identified as its meaning? Second, in order to account for the fact that something (e.g., a thought) can mean (have the content) that x = 3 when x ≠ 3, a way must be found to "detach" information from the events that normally carry it so that something can mean that x = 3 when it does not carry this information (because x ≠ 3).

One of the strategies used by some (e.g., Dretske 1981, 1986; Stampe 1977, 1986) to achieve these results is to identify meaning with the environmental condition with which a state is, or is supposed to be, correlated. For instance, the meaning of a state might be the condition about which it is *supposed* to carry information where the "supposed to" is understood in terms of the state's teleo-function. Others—for example, Fodor (1990)—reject teleology altogether and identify meaning with the sort of causal antecedents of an event on which other causes of that event depend. Still others—for example, Millikan (1984)—embrace the teleology but reject the idea that the relevant functions are informational. For Millikan a state can mean *M* without having the function of carrying this information. By combining teleology with information, informational semantics holds out the promise of satisfying the desiderata described in the last paragraph. Just as the pointer reading on a measuring instrument—a speedometer, for example—can misrepresent the speed of the car because there is something (viz., the speed of the car) it is supposed to indicate that it can fail to indicate, so various events in the brain can misrepresent the state of the world by failing to carry information it is their function to carry. In the case of the nervous system, of course, the information-carrying functions are not (as with artifacts) assigned by designers or users. They come, in the first instance, from a specific evolutionary (selectional) history—the same place the heart and kidneys get their function—and, in the second, from certain forms of learning. Not only do information-carrying functions give perceptual organs and the central nervous system the capacity to misrepresent the world (thus solving the second of the above two problems), they also help solve the grain problem. Of the many things the heart does, only one, pumping blood, is its (biological) function. So too, perhaps, an inter-

nal state has the function of indicating only one of the many things it carries information about. Only one piece of information is it supposed to carry. According to informational semantics, this would be its meaning.

Informational semantics—as well as any other theory of meaning—has the problem of saying of what relevance the meaning of internal states is to the behavior of the systems in which it occurs. Of what relevance is meaning to a science of intentional systems? Is not the behavior of systems completely explained by the nonsemantic (e.g., neurobiological or, in the case of computers, electrical and mechanical) properties of internal events? This question is sometimes put by asking whether, in addition to syntactic engines, there are (or could be) *semantic* engines. The difficulty of trying to find an explanatory role for meaning in the behavior of intentional (i.e., semantic) systems has led some to abandon meaning (and with it the mind) as a legitimate scientific construct (ELIMINATIVE MATERIALISM), others to regard meaning as legitimate in only an instrumental sense (Dennett 1987), and still others (e.g., Burge 1989; Davidson 1980; Dretske 1988; Fodor 1987; Kim 1996) to propose indirect—but nonetheless quite real—ways meaning figures in the explanation of behavior.

Innateness of Language

Although the idea has a large philosophical tradition (especially in the work of the Continental rationalists; see RATIONALISM VS. EMPIRICISM), modern ideas concerning the innateness of language originated in the work of Chomsky (1965 etc.) and the concomitant development of GENERATIVE GRAMMAR. Chomsky's hypothesis is that many aspects of the formal structure of language are encoded in the genome. The hypothesis then becomes an empirical hypothesis, to be accepted or validated according to standard empirical methods.

As with any other hypothesis in the natural sciences, the innateness hypothesis (that there exist genetically specified aspects of language) has to be evaluated alongside competing hypotheses. Clearly, the competing hypothesis is that there are no genetically specified aspects of language. If one accepts that any genetically specified aspects of language exist, then there is no more debate about a general innateness hypothesis, but only a debate about exactly which aspects of language are innate. This debate, in fact, is central to current research in linguistics and PSYCHOLINGUISTICS.

There are many arguments for the innateness hypothesis. But the most significant one in Chomsky's writings, and the one that has most affected the field, is the argument from the POVERTY OF THE STIMULUS (APS; see also Wexler 1991). As Chomsky points out, this argument in the study of language is a modern version of DESCARTES's argument concerning human knowledge of CONCEPTS. The basic thrust of the argument goes as follows:

(1) Human language has the following complex form: G (for Grammar)

(2) The nature of the information about G available to the learner is the following: I (for Input/Information, called Primary Linguistic Data in Chomsky 1965).

(3) No learner could take the information in I and transform it into G.

In other words, the argument from the poverty of the stimulus is that the information in the environment is not rich enough to allow a human learner to attain adult competence.

The arguments to support APS in linguistic theory usually involve linguistic structures that do not seem to be encoded in environmental events. Thus (4a,b) seem to have identical surface structures, yet in (4a) *Mary* is the subject of *please* (she will do the pleasing) and in (4b) *Mary* is the object of *please* (she will be pleased). How will a learner learn this, inasmuch as it seems that the information is not directly provided to the learner in the surface form of the sentence?

(4) a. Mary is eager to please.
   b. Mary is easy to please.

The field of learnability theory (Wexler and Hamburger 1973; Wexler and Culicover 1980) developed as an attempt to provide mathematical preciseness to the APS, and to derive exact consequences. Learnability theory provides an exact characterization of the class of possible grammars, the nature of the input information, and the learning mechanisms, and asks whether the learning mechanism can in fact learn any possible grammar. The basic results of the field include the formal, mathematical demonstration that without serious constraints on the nature of human grammar, no possible learning mechanism can in fact learn the class of human grammars. In some cases it is possible to derive from learnability considerations the existence of specific constraints on the nature of human grammar. These predictions can then be tested empirically.

The strongest, most central arguments for innateness thus continue to be the arguments from APS and learnability theory. This is recognized by critics of the Innateness Hypothesis (e.g., Elman et al. 1996; Quartz and Senjowski 1997). The latter write (section 4.1):

The best known characterization of a developing system's learning properties comes from language acquisition—what syntactic properties a child could learn, what in the environment could serve as evidence for that learning, and ultimately, what must be prespecified by the child's genetic endowment. From these questions, 30 years of research have provided mainly negative results. . . . In the end, theorists concluded that the child must bring most if its syntactic knowledge, in the form of a universal grammar, to the problem in advance. . . . The perception that this striking view of syntax acquisition is based primarily on rigorous results in formal learning theory makes it especially compelling. Indeed, above all, it is this formal feature that has prompted its generalization from syntax to the view of the entire mind as a collection of innately specified, specialized modules. . . . It is probably no overstatement to suggest that much of cognitive science is still dominated by Chomsky's nativist view of the mind.

In addition to the APS, there are a number of other arguments for the innateness hypothesis. These include (1) the similarity of languages around the world on a wide array of abstract features, even when the languages are not in contact, and the features do not have an obvious functional motivation; (2) the rapid and uniform acquisition of language by most children, without instruction (see PHONOLOGY, ACQUISITION OF; SEMANTICS, ACQUISITION OF; SYNTAX, ACQUISITION OF) whereas many other tasks (e.g., problem solving of various kinds) need instruction and are not uniformly attained by the entire population.

Over the years there have been many attempts (currently fashionable ones include Elman et al. 1996; Quartz and Senjowski 1996) to suggest that perhaps learning could explain

LANGUAGE ACQUISITION after all. However, no arguments have been given that overcome the central learnability argumentation for the innateness hypothesis. For example, neither Elman et al. nor Quartz and Senjowski explain via "learning" any of the properties of universal grammar or how they are attained. Quartz and Sejnowski attempt to critique learnability theory, but their critique does not apply to actual studies in learnability theory. For example, they characterize learnability theory as assuming that learners must enumerate every possible language in the class as part of the learning procedure. This is false of Gold (1967) and explicitly argued against in Wexler and Culicover (1980). Wexler and Culicover, who are greatly concerned with the psychological plausibility of the learning procedure, derive their results under some quite severe restrictions, making their learning procedure much more empirically adequate on psychological grounds than the procedures that are considered in so-called learning accounts. (See Gibson and Wexler 1994 for an analysis of psychologically plausible learning mechanisms in the principles and parameters framework in which there is much innate knowledge.) One simply has to say that CONNECTIONIST APPROACHES TO LANGUAGE and its acquisition are simply programmatic statements without any kind of theoretical or empirical support. To be taken seriously as a competitor to the innateness hypothesis, these approaches will have to attain real results.

Intelligence

Intelligence may be defined as the ability to adapt to, shape, and select environments, although over the years many definitions of intelligence have been offered (e.g., see symposia in *Journal of Educational Psychology* 1921; Sternberg and Detterman 1986). Various approaches have been proposed in attempts to understand it (see Sternberg 1990). The emphasis here will be on cognitive-scientific approaches.

Historically, two major competing approaches to understanding intelligence were offered, respectively, by Sir Francis Galton in England and Alfred Binet in France. Galton (1883) sought to understand (and measure) intelligence in terms of psychophysical skills, such as an individual's just noticeable difference (JND) for discriminating weights or the distance on the skin two points needed to be separated in order for them to be felt as having occurred in distinct locations. Binet and Simon (1916), in contrast, conceptualized intelligence in terms of complex judgmental abilities. Binet believed that three cognitive abilities are key to intelligence: (1) direction (knowing what has to be done and how it should be done), (2) adaptation (selection and monitoring of one's strategies for task performance), and (3) control (the ability to criticize one's own thoughts and judgments). The "metacognitive" emphasis in this conception is apparent. Binet's views have had more impact, both because his theory seemed better to capture intuitive notions of intelligence and because Binet devised a test of intelligence that successfully predicted children's performance in school.

Charles Spearman (1923) was a forerunner of contemporary cognitive approaches to intelligence in suggesting three information processes underlying intelligence: (1) apprehension of experience, (2) eduction of relations, and (3) eduction of correlates. Spearman used the four-term ANALOGY problem (A : B :: C : D) as a basis for illustrating these processes, whereby the first process involved encoding the terms; the second, inferring the relation between A and B; and the third, applying that relation from C to D.

The early part of the twentieth century was dominated by psychometric approaches to intelligence, which emphasized the measurement of individual differences but had relatively less to say about the cognitive processing underlying intelligence (see Sternberg 1990 for a review). These approaches for the most part used factor analysis, a statistical technique for discovering possible structures underlying correlational data. For example, Spearman (1927) believed that a single factor, *g* (general ability), captured most of what is important about intelligence, whereas Thurstone (1938) believed in a need for seven primary factors. More recently, Carroll (1993) has proposed a three-tier hierarchical model that is psychometrically derived, but is expressed in information-processing terms, with *g* at the top and successively more narrow cognitive skills at each lower level of the hierarchy.

A change in the field occurred when Estes (1970) and Hunt, Frost, and Lunneborg (1973) proposed what has come to be called the cognitive-correlates approach to intelligence, whereby relatively simple information-processing tasks used in the laboratories of cognitive psychologists were related to scores on conventional psychometric tests of intelligence. Hunt and his colleagues found correlations of roughly –.3 between parameters of rate of information processing in tasks such as a letter-identification task (Posner and Mitchell 1967)—where participants had to say whether letter pairs like A A, A a, or A b were the same either physically or in name—and scores on psychometric tests of verbal abilities. This approach continues actively today, with investigators proposing new tasks that they believe to be key to intelligence, such as the inspection time task, whereby individuals are assessed psychophysically for the time it takes them accurately to discern which of two lines is longer than the other (e.g., Deary and Stough 1996).

An alternative, cognitive-components approach was proposed by Sternberg (1977), who suggested that intelligence could be understood in terms of the information-processing components underlying complex reasoning and problem-solving tasks such as analogies and syllogisms. Sternberg used information-processing and mathematical modeling to decompose cognitive task performance into its elementary components and strategies. Some theorists, such as Hunt (1974) and Carpenter, Just, and Shell (1990), have used computer-simulation methodology in order to identify such components and strategies in complex tasks, such as the Raven progressive matrices.

Building on his earlier work, Sternberg (1985) proposed a triarchic theory of intelligence, according to which these information-processing components are applied to experience to adapt to, shape, and select environments. Intelligence is best understood in terms of performance on either relatively novel cognitive tasks or in terms of automatization of performance on familiar tasks. Sternberg argued that intelligence comprises three major aspects: analytical, creative, and practical thinking.

Howard Gardner (1983, 1995), in contrast, has suggested that intelligence is not unitary, but rather comprises eight distinct multiple intelligences: linguistic, logical-mathematical, spatial, musical, bodily-kinesthetic, interpersonal, intrapersonal, and naturalist. Each of these intelligences is a distinct module in the brain and operates more or less independently of the others. Gardner has offered a variety of kinds of evidence to support his theory—including cognitive-scientific research—although he has not conducted research directly to test his model.

Other theorists have tried directly to link information processing to physiological processes in the brain. For example, Haier and his colleagues (Haier et al. 1988; Haier et al. 1992) have shown via POSITRON EMISSION TOMOGRAPHY (PET) scans that brains of intelligent individuals generally consume less glucose in doing complex tasks such as Raven matrices or the game of TETRIS, suggesting that the greater expertise of intelligent people enables them to expend less effort on the tasks. Vernon and Mori (1992), among others, have attempted directly to link measured speed of neural conduction to intelligence, although there is some question as to the replicability of the findings (Wickett and Vernon 1994).

The field of intelligence has many applied offshoots. For example, a number of cognitive tests have been proposed to measure intelligence (see Sternberg 1993), and a number of different programs have been developed, based on cognitive theory, to modify intelligence (see Nickerson 1994). Some investigators have also argued that there are various kinds of intelligence, such as practical intelligence (Sternberg et al. 1995) and emotional intelligence (Goleman 1995; Salovey and Mayer 1990). The field is an active one today, and it promises to change rapidly as new theories are proposed and new data collected. The goal is not to choose among alternative paradigms, but rather for them to work together ultimately to help us produce a unified understanding of intellectual phenomena.

Intelligent Agent Architecture

Intelligent agent architecture is a model of an intelligent information-processing system defining its major subsystems, their functional roles, and the flow of information and control among them.

Many complex systems are made up of specialized subsystems that interact in circumscribed ways. In the biological world, for example, organisms have modular subsystems, such as the circulatory and digestive systems, presumably because nature can improve subsystems more easily when interactions among them are limited (see, for example, Simon 1969). These considerations apply as well to artificial systems: vehicles have fuel, electrical, and suspension subsystems; computers have central-processing, mass-storage, and input-output subsystems; and so on. When variants of a system share a common organization into subsystems, it is often useful to characterize abstractly the elements shared by all variants. For example, a family of integrated circuits might vary in clock speed or specialized data operations, while sharing a basic instruction set and memory model. In the engineering disciplines, the term *architecture* has come to refer to generic models of shared structure. Architectures serve as templates, allowing designers to develop, refine, test, and maintain complex systems in a disciplined way.

The benefits of architectures apply to the design of intelligent agents as well. An intelligent agent is a device that interacts with its environment in flexible, goal-directed ways, recognizing important states of the environment and acting to achieve desired results. Clearly, when designing a particular agent, many domain-specific features of the environment must be reflected in the detailed design of the agent. Still, the general form of the subsystems underlying intelligent interaction with the environment may carry over from domain to domain. Intelligent agent architectures attempt to capture these general forms and to enforce basic system properties such as soundness of reasoning, efficiency of response, or interruptibility. Many architectures have been proposed that emphasize one or another of these properties, and these architectures can be usefully grouped into three broad categories: the deliberative, the reactive, or the distributed.

The deliberative approach, inspired in part by FOLK PSYCHOLOGY, models agents as symbolic reasoning systems. In this approach, an agent is decomposed into data subsystems that store symbolic, propositional representations, often corresponding to commonsense beliefs, desires, and intentions, and processing subsystems responsible for perception, reasoning, planning, and execution. Some variants of this approach (Genesereth 1983; Russell 1991) emphasize formal methods and resemble approaches from formal philosophy of mind and action, especially with regard to soundness of logical reasoning, KNOWLEDGE REPRESENTATION, and RATIONAL DECISION MAKING. Others (Newell 1990) emphasize memory mechanisms, general PROBLEM SOLVING, and search. Deliberative architectures go beyond folk psychology and formal philosophy by giving concrete computational interpretations to abstract processes of representation and reasoning. Ironically, the literal-minded interpretation of mental objects has also been a source of difficulty in building practical agents: symbolic reasoning typically involves substantial search and is of high COMPUTATIONAL COMPLEXITY, and capturing extensive commonsense knowledge in machine-usable form has proved difficult as well. These problems represent significant challenges to the deliberative approach and have stimulated researchers to investigate other paradigms that might address or sidestep them.

The reactive approach to intelligent-agent design, for example, begins with the intuition that although symbolic reasoning may be a good model for certain cognitive processes, it does not characterize well the information processing involved in routine behavior such as driving, cooking, taking a walk, or manipulating everyday objects. These abilities, simple for humans, remain distant goals for robotics and seem to impose hard real-time requirements on an agent. Although these requirements are not in principle inconsistent with deliberative architectures (Georgeff and Lansky 1987), neither are they guaranteed, and in practice they have not been easily satisfied. Proponents of the reactive approach, therefore, have argued for architectures that insure real-time behavior as part of their fundamental design. Drawing on the mathematical and engineering tradition of feedback control, advocates of reactive architectures model agent and environment as coupled dynamic systems, the inputs of each being the outputs of the other. The agent contains behavioral modules that are self-contained feedback-control systems, each responsible for detecting states of the environment based on sensory data and generating

appropriate output. The key is for state-estimation and output calculations to be performed fast enough to keep up with the sampling rates of the system. There is an extensive literature on how to build such behaviors (control systems) when a mathematical description of the environment is available and is of the proper form; reactive architectures advance these traditional control methods by describing how complex behaviors might be built out of simpler ones (Brooks 1986), either by switching among a fixed set of qualitatively different behaviors based on sensed conditions (see Miller, Galanter, and Pribram 1960 for precursors), by the hierarchical arrangement of behaviors (Albus 1992), or by some more intricate principle of composition. Techniques have also been proposed (Kaelbling 1988) that use off-line symbolic reasoning to derive reactive behavior modules with guaranteed real-time on-line performance.

A third architectural paradigm, explored by researchers in distributed artificial intelligence, is motivated by the following observation. A local subsystem integrating sensory data or generating potential actions may have incomplete, uncertain, or erroneous information about what is happening in the environment or what should be done. But if there are many such local nodes, the information may in fact be present, in the aggregate, to assess a situation correctly or select an appropriate global action policy. The distributed approach attempts to exploit this observation by decomposing an intelligent agent into a network of cooperating, communicating subagents, each with the ability to process inputs, produce appropriate outputs, and store intermediate states. The intelligence of the system as a whole arises from the interactions of all the system's subagents. This approach gains plausibility from the success of groups of natural intelligent agents, for example, communities of humans, who decompose problems and then reassemble the solutions, and from the parallel, distributed nature of neural computation in biological organisms. Although it may be stretching the agent metaphor to view an individual neuron as an intelligent agent, the idea that a collection of units might solve one subproblem while other collections solve others has been an attractive and persistent theme in agent design.

Intelligent-agent research is a dynamic activity and is much influenced by new trends in cognitive science and computing; developments can be anticipated across a broad front. Theoretical work continues on the formal semantics of MENTAL REPRESENTATION, models of behavior composition, and distributed problem solving. Practical advances can be expected in programming tools for building agents, as well as in applications (spurred largely by developments in computer and communications technology) involving intelligent agents in robotics and software.

Intentional Stance

The *intentional stance* is the strategy of interpreting the behavior of an entity (person, animal, artifact, or the like) by treating it as if it were a rational agent that governed its "choice" of "action" by a "consideration" of its "beliefs" and "desires." The distinctive features of the intentional stance can best be seen by contrasting it with two more basic stances or strategies of prediction, the physical stance and the design stance. The physical stance is simply the standard laborious method of the physical sciences, in which we use whatever we know about the laws of physics and the physical constitution of the things in question to devise our prediction. When I predict that a stone released from my hand will fall to the ground, I am using the physical stance. For things that are neither alive nor artifacts, the physical stance is the only available strategy. Every physical thing, whether designed or alive or not, is subject to the laws of physics and hence behaves in ways that can be explained and predicted from the physical stance. If the thing I release from my hand is an alarm clock or a goldfish, I make the same prediction about its downward trajectory, on the same basis.

Alarm clocks, being designed objects (unlike the rock), are also amenable to a fancier style of prediction—prediction from the design stance. Suppose I categorize a novel object as an alarm clock: I can quickly reason that if I depress a few buttons just so, then some hours later the alarm clock will make a loud noise. I do not need to work out the specific physical laws that explain this marvelous regularity; I simply assume that it has a particular design—the design we call an alarm clock—and that it will function properly, as designed. Design-stance predictions are riskier than physical-stance predictions, because of the extra assumptions I have to take on board: that an entity is designed as I suppose it to be, and that it will operate according to that design—that is, it will not malfunction. Designed things are occasionally misdesigned, and sometimes they break. But this moderate price I pay in riskiness is more than compensated for by the tremendous ease of prediction.

An even riskier and swifter stance is the intentional stance, a subspecies of the design stance, in which the designed thing is an agent of sorts. An alarm clock is so simple that this fanciful anthropomorphism is, strictly

speaking, unnecessary for our understanding of why it does what it does, but adoption of the intentional stance is more useful—indeed, well-nigh obligatory—when the artifact in question is much more complicated than an alarm clock. Consider chess-playing computers, which all succumb neatly to the same simple strategy of interpretation: just think of them as rational agents that want to win, and that know the rules and principles of chess and the positions of the pieces on the board. Instantly your problem of predicting and interpreting their behavior is made vastly easier than it would be if you tried to use the physical or the design stance. At any moment in the chess game, simply look at the chessboard and draw up a list of all the legal moves available to the computer when it is its turn to play (there will usually be several dozen candidates). Now rank the legal moves from best (wisest, most rational) to worst (stupidest, most self-defeating), and make your prediction: the computer will make the best move. You may well not be sure what the best move is (the computer may "appreciate" the situation better than you do!), but you can almost always eliminate all but four or five candidate moves, which still gives you tremendous predictive leverage.

The intentional stance works (when it does) whether or not the attributed goals are genuine or natural or "really appreciated" by the so-called agent, and this tolerance is crucial to understanding how genuine goal-seeking could be established in the first place. Does the macromolecule really want to replicate itself? The intentional stance explains what is going on, regardless of how we answer that question. Consider a simple organism—say a planarian or an amoeba—moving nonrandomly across the bottom of a laboratory dish, always heading to the nutrient-rich end of the dish, or away from the toxic end. This organism is seeking the good, or shunning the bad—its own good and bad, not those of some human artifact-user. Seeking one's own good is a fundamental feature of any rational agent, but are these simple organisms seeking or just "seeking"? We do not need to answer that question. The organism is a predictable intentional system in either case.

By exploiting this deep similarity between the simplest—one might as well say mindless—intentional systems and the most complex (ourselves), the intentional stance also provides a relatively neutral perspective from which to investigate the differences between our minds and simpler minds. For instance, it has permitted the design of a host of experiments shedding light on whether other species, or young children, are capable of adopting the intentional stance—and hence are higher-order intentional systems. Although imaginative hypotheses about "theory of mind modules" (Leslie 1991) and other internal mechanisms (e.g., Baron-Cohen 1995) to account for these competences have been advanced, the evidence for the higher-order competences themselves must be adduced and analyzed independently of these proposals, and this has been done by cognitive ethologists (Dennett 1983; Byrne and Whiten 1991) and developmental psychologists, among others, using the intentional stance to generate the attributions that in turn generate testable predictions of behavior.

Although the earliest definition of the intentional stance (Dennett 1971) suggested to many that it was merely an instrumentalist strategy, not a theory of real or genuine belief, this common misapprehension has been extensively discussed and rebutted in subsequent accounts (Dennett 1987, 1991, 1996).

Intentionality

The term *intentional* is used by philosophers, not as applying primarily to actions, but to mean "directed upon an object." More colloquially, for a thing to be intentional is for it to be *about something*. Paradigmatically, mental states and events are intentional in this technical sense (which originated with the scholastics and was reintroduced in modern times by FRANZ BRENTANO). For instance, beliefs and desires and regrets are about things, or have "intentional objects": I have beliefs about Boris Yeltsin, I want a beer and world peace, and I regret agreeing to write so many encyclopedia articles.

A mental state can have as intentional object an individual (John loves *Marsha*), a state of affairs (Marsha thinks that *it's going to be a long day*) or both at once (John wishes *Marsha were happier*). Perception is intentional: I see John, and that John is writing Marsha's name in his copy of *Verbal Behavior*. The computational states and representations posited by cognitive psychology and other cognitive sciences are intentional also, inasmuch as in the course of computation something gets computed and something gets represented. (An exception here may be states of NEURAL NETWORKS, which have computational values but arguably not representata.)

What is at once most distinctive and most philosophically troublesome about intentionality is its indifference to reality. An intentional object need not actually exist or obtain: the Greeks worshiped Zeus; a friend of mine believes that corks grow on trees; and even if I get the beer,

my desire for world peace is probably going to go unfulfilled.

Brentano argued both (A) that this reality-neutral feature of intentionality makes it the distinguishing mark of the mental, in that all and only mental things are intentional in that sense, and (B) that purely physical or material objects cannot have intentional properties—for how could any purely physical entity or state have the property of being "directed upon" or *about* a nonexistent state of affairs? (A) and (B) together imply the Cartesian dualist thesis that no mental thing is also physical. And each is controversial in its own right.

Thesis (A) is controversial because it is hardly obvious that every mental state has a possibly nonexistent intentional object; bodily sensations such as itches and tickles do not seem to, and free-floating anxiety is notorious in this regard. Also, there seem to be things other than mental states and events that "aim at" possibly nonexistent objects. Linguistic items such as the name "Santa Claus" are an obvious example; paintings and statues portray fictional characters; and one might ignorantly build a unicorn trap. More significantly, *behavior* as usually described is intentional also: I reach for the beer; John sends a letter to Marsha; Marsha throws the letter at the cat; Macbeth tries to clutch the dagger he sees. (Though some philosophers, such as Chisholm 1958 and Searle 1983, argue that the aboutness of such nonmental things as linguistic entities and behavior is second-rate because it invariably derives from the more fundamental intentionality of someone's mental state.)

Dualism and immaterialism about the mind are unpopular both in philosophy and in psychology—certainly cognitive psychologists do not suppose that the computational and representational states they posit are states of anything but the brain—so we have strong motives for rejecting thesis (B) and finding a way of explaining how a purely physical organism can have intentional states. (Though some behaviorists in psychology and eliminative materialists in philosophy have taken the bolder step of simply denying that people do in fact ever have intentional states; see BEHAVIORISM and ELIMINATIVE MATERIALISM.) The taxonomy of such explanations is now fairly rich. It divides first between theories that ascribe intentionality to presumed particular states of the brain and those that attribute intentional states only to the whole subject.

Many theorists, especially those influenced by cognitive science, do believe that not only the intentionality of cognitive computational states but also that of everyday intentional attitudes such as beliefs and desires (also called PROPOSITIONAL ATTITUDES) inhere in states of the brain. On this view, all intentionality is at bottom MENTAL REPRESENTATION, and propositional attitudes have Brentano's feature because the internal physical states and events that realize them represent actual or possible states of affairs. Some evidence for this is that intentional features are semantical features: Like undisputed cases of representation, beliefs are true or false; they entail or imply other beliefs; they are (it seems) composed of concepts and depend for their truth on a match between their internal structures and the way the world is; and so it is natural to regard their aboutness as a matter of mental referring or designation. Sellars (1963) and Fodor (1975, 1981) have argued that intentional states are just physical states that have semantical properties, and the existent-or-nonexistent states of affairs that are their objects are just representational contents.

The main difficulty for this representationalist account is that of saying exactly *how* a physical item's representational content is determined; in virtue of what does a neurophysiological state represent precisely *that the Republican candidate will win*? An answer to that general question is what Fodor has called a "psychosemantics"; the question itself has also been called the "symbol grounding problem." Several attempts have been made on it (Devitt 1981; Millikan 1984; Block 1986; Dretske 1988; Fodor 1987, 1990).

One serious complication is that, surprisingly, ordinary propositional attitude contents do not seem to be determined by the states of their subjects' nervous systems, not even by the total state of their subjects' entire bodies. Putnam's (1975) TWIN EARTH and indexical examples are widely taken to show that, surprising as it may seem, two human beings could be molecule-for-molecule alike and still differ in their beliefs and desires, depending on various factors in their spatial and historical environments. (For dissent, however, see Searle 1983.) Thus we can distinguish between "narrow" properties, those that are determined by a subject's intrinsic physical composition, and "wide" properties, those that are not so determined, and representational contents are wide. So it seems an adequate psychosemantics cannot limit its resources to narrow properties such as internal functional or computational roles; it must specify some scientifically accessible relations between brain and environment. (Though some theorists continue to maintain that a narrow notion of content—see NARROW CONTENT—and accordingly a narrow psychosemantics are needed and will suffice for cognitive science; see Winograd 1972; Johnson-Laird 1977; and Fodor 1987. A few maintain the same for the everyday propositional attitudes; see Loar 1988; Devitt 1990.)

A second and perhaps more serious obstacle to the representational view of thinking is that the objects of thought need not be in the environment at all. They may be abstract; one can think about a number, or about an abstruse theological property, and as always they may be entirely unreal. (The same things are true of representations posited by cognitive psychology.) An adequate psychosemantics must deal just as thoroughly with Arthur's illiterate belief that the number of the Fates was six, and with a visual system's hallucinatory detection of an edge that isn't really there, as much as with a real person's seeing and wanting to eat a muffin that is right in front of her.

In view of the foregoing troubles and for other reasons as well, other philosophers have declined to ascribe intentionality to particular states of subjects, and they insist that ascriptions of commonsense intentional attitudes, at least, are not about inner states at all, much less about internal causes of behavior. Some such theories maintain just that the attitudes are states, presumably physical states, of a whole person (Strawson 1959; McDowell 1994; Baker 1995; Lewis 1995). Others are overtly instrumentalist: Philosophers influenced by W.V. Quine (1960) or by continental hermeneuticists maintain that what a subject believes or desires is entirely a matter of how that person is interpreted

or translated into someone else's preferred idiom for one purpose or another, there being no antecedent or inner fact of the matter. A distinctive version of this view is that of Donald Davidson (1970) and D. C. Dennett (1978, 1987), who hold that intentional ascriptions express nonfactual, normative calculations that help to predict behavior but not in the same way as the positing of inner mechanisms does—in particular, not causally (see INTENTIONAL STANCE). Such views are usually defended epistemologically, by reference to the sorts of evidence we use in ascribing propositional attitudes.

Perhaps suspiciously, the instrumentalist views are not usually extrapolated to the aboutness of perceptual states or of representations posited by cognitive scientists; they are restricted to commonsense beliefs and desires. They do shed the burden of psychosemantics, that is, of explaining how a particular brain state can have a particular content, but they do no better than did the representationalist views in explaining how thoughts can be about abstracta or about nonexistents.

Intersubjectivity

Intersubjectivity is the process in which mental activity—including conscious awareness, motives and intentions, cognitions, and emotions—is transferred between minds. ANIMAL COMMUNICATION and cooperative social life require intersubjective signaling (Marler, Evans, and Hauser 1992). Individuals must perceive and selectively respond to the motives, interests, and emotions behind perceived movement in bodies of other animals, especially in conspecifics. Such communication has attained a new level of complexity in human communities, with their consciousness of collectively discovered cultural meanings.

Human intersubjectivity manifests itself as an immediate sympathetic awareness of feelings and conscious, purposeful intelligence in others. It is transmitted by body movements

(especially of face, vocal tract, and hands) that are adapted to give instantaneous visual, auditory, or tactile information about purposes, interests, and emotions and symbolic ideas active in subjects' minds. On it depends cultural learning, and the creation of a "social reality," of conventional beliefs, languages, rituals, and technologies. Education of children is rooted in preverbal, mimetic intersubjectivity. Human linguistic dialogue also rests on intersubjective awareness, as do the phenomena of "self-awareness" in society. A psychology of intersubjectivity concerns itself with analysis of this innate capacity for intimate and efficient intermental coupling, and attempts to assess what must be learned, through imitation or instruction, to advance intelligent cooperation.

Research on communication with infants and young children proves the existence in the developing human brain of emotional and cognitive regulators for companionship in thought and purposeful action (Aitken and Trevarthen 1997). The theory of innate intersubjectivity (Trevarthen 1998), like the theory of the virtual other (Braten 1988), invites new concepts of language and thinking, as well as of music and all temporal arts, and it requires deep examination of cognitive processing models of CONSCIOUSNESS.

Infants demonstrate that they perceive persons as essentially different "objects" from anything nonliving and nonhuman (Legerstee 1992; Trevarthen 1998). They are acutely sensitive to time patterns in human movement (manifestations of TIME IN THE MIND), and can react in synchrony, or with complementary "attunement" of motives and feelings (Stern 1985, 1993; Trevarthen, Kokkinaki, and Fiamenghi 1998). Dynamic forms of vocal, facial, and gestural emotional expression are recognized and employed in interactions with other persons from birth, before intentional use of objects is effective. Scientific research into the earliest orientations, preferences, and intentional actions of newborns when they encounter evidence of a person, and their capacities for IMITATION, prove that the newborn human is ready for, and needs, mutually regulated intersubjective transactions (Kugiumutzakis 1998). Infants do not acquire intersubjective powers in "pseudo dialogues" by being treated "as if" they wish to express intentions, thoughts, and feelings (Kaye 1982), but they do find satisfying communication only with partners who accept that they have such powers, because such acceptance releases intuitive patterns of "parenting" behavior that infants can be aware of, and with which they can enter into dialogue (Papoušek and Papoušek 1987). Infants' emotional well-being depends on a mutual regulation of consciousness with affectionate companions (Tronick and Weinberg 1997). Events in the infant-adult "dynamic system" (Fogel and Thelen 1987) are constrained by intrinsic human psychological motives on both sides (Aitken and Trevarthen 1997). These intrinsic constraints are psychogenic adaptations for cultural learning.

Human knowledge begins in exchange and combination of purposes between the young child and more experienced companions—in "joint attention" (Tomasello 1988). A "primary intersubjectivity" is active, in "protoconversational" play, soon after birth (Bateson 1975; Trevarthen 1979), and this develops by the end of the first year into "secondary intersubjectivity"—sympathetic intention toward shared

environmental AFFORDANCES and objects of purposeful action (Trevarthen and Hubley 1978). Before they possess any verbalizable THEORY OF MIND, children share purposes and their consequences through direct other-awareness of persons' interests and moods (Reddy et al. 1997). Acquired beliefs and concepts of a young child are redescriptions of narrativelike patterns of intention and consciousness that can be shared, without verbal or rational analysis, in a familiar "common sense" world. Narrative expression by rhythmic posturing and gesturing with prosodic or melodic vocalisation, or "mimesis," may have been a step in the prelinguistic evolution of hominid communication and cognition (Donald 1991). Pretense and socially demonstrated METACOGNITION is natural in infant play, and imitation of pretend actions and attitudes is essential in the development of imaginative representational play in toddlers of modern *Homo sapiens*.

Language and other symbolic conventions enrich intersubjectivity, generating and storing limitless common meaning and strategies of thought, but they do not constitute the basis for interpersonal awareness. Rather, as Wittgenstein perceived, the reverse is the case—all language develops from experience negotiated, with emotion, in intersubjectivity, whatever innate predispositions there may be to acquire language qua language (see PRAGMATICS). The acquisition of syntax is derived from expressive sequences that are perceived as emotional narratives in game rituals (Bruner 1983). Word meaning is acquired by imitation in narrative exchanges modulated by dynamic affects and expressions of interest, intention, and feeling deployed by the child and companions in a familiar, common world (Locke 1993; see WORD MEANING, ACQUISITION OF).

Intersubjective sympathy is shown when persons synchronize or alternate their motor impulses, demonstrating "resonance" of motives that have matching temporospatial dimensions (rhythms and morphology or "embodiment") in all individuals, and that, consequently, can be perceived by one to forecast the other's acts and their perceptual consequences (Trevarthen 1998). Psychophysical and physiological research proves that cognitive processes of perceptual information uptake, thoughts, and memories are organized by intrinsically generated "motor images" or "dynamic forms" (Jeannerod 1994). The same motor forms are demonstrated in communication. The discovery of "mirror neurons" in the ventral premotor cortex of monkeys, which discharge both when the monkey grasps or manipulates something and when the human experimenter makes similar manipulations, indicates how "self" and "other," or observer and actor, can be matched, and it helps explain how the essential intersubjective neural mechanisms of communication by language may have evolved (Rizzolatti and Arbib 1998). Conscious monitoring of intersubjective motives is asymmetric; in normal circumstances we are more aware of others' feelings and intentions than of our own inner states. However, we do not have to be in the presence of others to have them in mind. As Adam Smith explained, the moral sense, built around representations of an innate sympathy, takes the form of an "other-awareness" or "conscience." In his words, "When I endeavour to examine my own conduct, I divide myself, as it were, into two persons. The first is the

spectator . . . the second is the agent, the person whom I properly call myself, and of whose conduct, under the character of the spectator, I was endeavouring to form an opinion." (Smith 1759: 113, 6).

The aptitude of human minds for imitation does not mean, as social learning theory asserts, that a SELF-KNOWLEDGE is possible only as a result of learning how others see us, and how to talk about oneself. Impulses of purpose and interest, with the emotions that evaluate their prospects and urgency, have, as motives, similar status for the self as for others, and independently of culture. This consequence of immediate, innate intersubjective sympathy is overlooked by empiricists, including theorists of ECOLOGICAL PSYCHOLOGY, in their accounts of how perceptual information is taken up by behaving subjects, individually. There is a historical reason for the idea of the separate self.

The Western philosophical tradition (exemplified by RENÉ DESCARTES and IMMANUEL KANT) generally assumes that human minds are inherently separate in their purposes and experiences, seeking rational clarity, autonomous skills, and self-betterment. Subjects take in information for consciousness of reality or truth, become aware of other people as objects that have particular properties and affordances. They construct an awareness of the SELF in society, but remain single subjectivities. Interpersonal life and collective understanding result from individuals communicating thoughts in language, the grammar of which is derived from innate rational processes. The rational individual has both self-serving emotions and instinctive "biological" reactions to others, which must be regulated by conventional rules of socially acceptable behavior. With good management of education and social government, individuals learn how to negotiate with social partners and converge in awareness of transcendental universals in their individual consciousness and purposes, to their mutual benefit. We will call this view of intelligent and civilized cooperation as an artificial acquisition the "extrinsic intersubjectivity" or "subjective first" position. Psychology and cognitive science analyze awareness, thinking, learning, and skill in action from this position, which must find immediate intersubjectivity difficult to explain.

A different conception of human consciousness, exhibiting affinity with some philosophies of religious experience, perceives interpersonal awareness, cooperative action in society, and cultural learning as manifestations of innate motives for sympathy in purposes, interests, and feelings— that is, that a human mind is equipped with needs for dialogic, intermental engagement with other similar minds (Jopling 1993). Notions of moral obligation are conceived as fundamental to the growth of consciousness of meaning in every human being. Language is neither just a learned skill, nor the product of an instinct for generating grammatical structures to model subjective agency and to categorize awareness of objects. It emerges as an extension of the natural growth of a sympathy in purposes and experiences that is already clearly demonstrated in the mimetic narratives of an infant's play in reciprocal attention with an affectionate companion. We will call this view of how human cooperative awareness arises the "intrinsic intersubjectivity" or "intersubjective first" position.

Psychoanalysis, though interested in rational representations of self and others by introjection and projection, or transference and countertransference, seeks intersubjective explanations for psychopathology, and for the relation of disorders in child development to the acquisition of an emotionally communicated self-awareness (Stern 1985). Theories of childhood AUTISM, a challenging but highly instructive pathology, necessarily confront hypotheses concerning how engagement with mind states is normally possible between individuals from infancy (Hobson 1993).

As the political offspring of the subjective first position, individualism sees a society as animated by stressful encounters between competitors who survive and prosper by Machiavellian deceit. Positive relationships or attachments merely serve to build alliances that increase chances of success for their members in competition with the rest of the group. Like the misnamed "social Darwinism," SOCIOBIOLOGY is founded on the tacit belief that there is no natural ALTRUISM, no capacity to link purposes for collective goals that are valued because they are products of intuitive sympathy and cooperative awareness. Closer study of animal behaviors shows contrary evidence (De Waal 1996). The evidence that infants learn by emotional referencing to evaluate experiences through attunement with motives of familiar companions, for whom they have, and from whom they receive, affectionate regard, proves that it is the sense of individuality in society that is the derived state of mind, developed in contrast to more fundamental intersubjective needs and obligations.

Introspection

Introspection is a process by which people come to be attentively conscious of mental states they are currently in. This focused CONSCIOUSNESS of one's concurrent mental states is distinct from the relatively casual, fleeting, diffuse way we are ordinarily conscious of many of our mental states. "Introspection" is occasionally applied to both ways of being conscious of one's mental states (e.g., Armstrong 1968/1993), but is most often used, as in what follows, for the attentive way only.

Introspection involves both the mental states introspected and some mental representation of those very states (as suggested by the etymology, from the Latin *spicere* "look" and *intra* "within"; looking involves mental representations of what is seen). Because it involves higher-order mental representations of introspected states, introspection is a kind of conscious METAREPRESENTATION or METACOGNITION.

WILHELM WUNDT (1911/1912) held that introspection provides an experimental method for psychology, and relied on it in setting up, in 1879 in Leipzig, the first experimental psychology laboratory. Some challenged this introspectionist method, following Auguste Comte's (1830–42) denial that a single mind can be both the agent and object of introspection. This, Comte had held, would divide attention between the act and object of introspecting, which he thought impossible. These concerns led WILLIAM JAMES (1890) and others to propound instead a method of immediate retrospection.

Introspectionist psychology foundered mainly not for these reasons, but because results from different introspectionist laboratories frequently conflicted. Still, experimental procedures in psychology continue to rely on subjects' access to their current mental states, though the theoretical warrant for this reliance is seldom discussed.

The phenomenological movement in philosophy, pioneered by Wundt's contemporary Edmund Husserl (1913/1980), held that introspection, by "bracketing" consciousness from its object, enables us to describe and analyze consciousness, and thereby solve many traditional philosophical problems. This methodology encountered difficulties similar to those that faced introspectionist psychology.

Some have questioned whether higher-order mental representations of concurrent mental states ever actually occur and hence whether introspection, properly so-called, exists. According to Gilbert Ryle (1949) and William Lyons (1986), what we loosely describe as attending to current perceptions is really just perceiving in an attentive manner. But perceiving attentively itself sometimes involves attending to the perceiving, as when one is explicitly aware of visually concentrating on something. Moreover, when we report what mental states we are in, those reports express higher-order mental representations of the states we report; Ryle's denial that remarks such as "I am in pain" are literally about one's mental states is groundless.

It is often held that introspection involves some "inner sense" by which we perceive our own mental states. The seemingly spontaneous and unmediated character of perceiving generally would then explain why introspection itself seems spontaneous and immediate. This model could, in addition, appeal to mechanisms of perceptual attention to explain how we come to focus attentively on our concurrent mental states.

But introspection cannot be a form of perceiving. Perception invariably involves sensory qualities, and no qualities ever occur in introspection other than those of the sensations and perceptions we introspect; the introspecting itself produces no additional qualities. Moreover, speech acts generally express not perceptions, but thoughts and other intentional states (see INTENTIONALITY). So introspective reports express intentional states about the mental states we introspect, and introspective representations of concurrent mental states involve assertive intentional states, or thoughts. Introspection is deliberate and attentive because these higher-order intentional states are themselves attentive and deliberate. And our introspecting seems spontaneous and unmediated presumably because we remain unaware of any mental processes that might lead to these higher-order intentional states. Introspection consists in conscious, attentively focused, higher-order thoughts about our concurrent mental states.

Despite Comte's claim that attention cannot be divided, people can with a little effort attend to more than one thing. And attentive consciousness of concurrent mental states could in any case occur whenever the target mental state was not itself an attentive state.

A related concern is that attending to concurrent mental states may distort their character. But it is unclear why that should happen, inasmuch as attention does not generally alter the properties of its object. Introspection itself cannot show that distortion occurs, because even if it seems to, that appearance might be due not to the distorting effect of introspection, but to introspection's making us aware of more of a state's properties or of a different range of properties. Similarly for the idea that introspective attention might actually bring the introspected state into existence (Hill 1991: chap. 5). That may well happen, but it may instead be that, when that seems to happen, introspection simply makes one newly aware of a state that already existed.

Work by John H. Flavell (1993) has raised doubt about whether children five and younger have introspective access to their mental states. Four- and five-year-olds describe themselves and others as thinking, feeling, and experiencing. But they also describe people while awake as going for

significant periods without thinking or feeling anything whatever. Doubtless these children themselves have, when awake, normal streams of consciousness. But they seem not to think of themselves in that way and, hence, not to introspect their streams of consciousness. Flavell also reports that these children determine what people attend to and think about solely on the basis of behavioral cues and environmental stimulation. So perhaps their inability to introspect results from their simply not conceiving of thoughts and experiences as states that are sometimes conscious (see THEORY OF MIND).

Some have held that introspective access to one's mental states cannot be erroneous or, at least, that it overrides all other evidence (see SELF-KNOWLEDGE). RENÉ DESCARTES (1641/1984) famously noted that one cannot, when thinking, doubt that one is thinking. But this hardly shows that when one is thinking one always knows one is, much less that one is invariably right about which thoughts one has. In a similar spirit, Sydney Shoemaker (1996) has urged that when one has a belief one always knows one does, because a rational person's believing something itself involves cognitive dispositions that constitute that person's knowing about the belief. But the relevant rationality often fails to accompany our beliefs and other first-order mental states.

Indeed, psychological research reveals many such lapses of rationality. In addition to the misrepresentations of one's own mental states discovered by SIGMUND FREUD, other work (e.g., Nisbett and Wilson 1977) shows that introspective judgments frequently result from confabulation. People literally invent mental states to explain their own behavior in ways that are expected or acceptable. Daniel Dennett (1991) in effect seeks to generalize this finding by arguing that all introspective reports can be treated as reports of useful fictions.

Introspection not only misrepresents our mental states, but it also fails to reveal many concurrent states, both in ordinary and exotic situations (see BLINDSIGHT and IMPLICIT VS. EXPLICIT MEMORY). And it is likely that introspection seldom if ever reveals all the mental properties of target states. Many, moreover, would endorse KARL LASHLEY's (1958) dictum that introspection never makes mental processes accessible, only their results. At best, introspection is one tool among many for learning about the mind.

Jakobson, Roman

Roman Jakobson (1896–1982), one of the foremost students of linguistics, literature, and culture of the twentieth century, was born and educated in Moscow. In 1920 he moved to Czechoslovakia, where he remained until the Nazi occupation in 1939. During 1939–1941 Jakobson was in Scandinavia, and in 1941 he emigrated to the United States, where he served on the faculties of Columbia University (1946–1949), Harvard (1949–1966), and MIT (1958–1982).

The eight published volumes of Jakobson's *Selected Writings* reflect the impressive breadth and variety of his contributions. These include, in addition to linguistics proper, discussions of the foundations of literary theory; research into formal devices of literature, including pioneering inquiries into the principles governing meter in poetry; analyses of poetic texts in many languages; philological investigations into literary monuments; studies of Slavic folklore and comparative mythology; inquiries into the cultural history of the Slavs; and some of the finest literary criticism of modern Russian poetry. A bibliography of Jakobson's writing is Jakobson (1990).

Jakobson's chief contribution to linguistics concerns the nature of the speech sounds (phonemes). It has been accepted for well over a century that the phonemes that make up the words in all languages differ fundamentally from other, acoustically similar sounds that humans produce with the lips, tongue and larynx, for example yawns, burps, or coughs. (See, e.g., chap. 5 of Sievers 1901, the standard phonetics text of the time.) It was also understood that the sounds of a given language are not a random collection, but are made up of various intersecting groups of sounds; for example, [p t k] or [p b f v m] or [m n]. What was not understood was the basis on which speech and nonspeech sounds are differentiated, and how, short of listing, phonemes can be assigned to groups. It was Jakobson who proposed an answer to these fundamental questions.

In a 1928 paper written by Jakobson and co-signed by the Russian linguists N. S. Trubetzkoy (1890–1938) and S. Karcevskij (1884–1955), Jakobson proposed that the phonemes of all languages are complexes of a small number of DISTINCTIVE FEATURES such as nasal, labial, voicing, fricative, and so on. Although many features were used by phoneticians, they were viewed as somewhat accidental attributes of sounds. By contrast, for Jakobson the features are the raw material of which the phonemes—and only phonemes—are made. The fact that only phonemes, but no other sounds, are feature complexes differentiates phonemes from the rest, and this fact also explains the grouping of phonemes into intersecting sets, each defined by one or more shared features; for example, [m n] are nasal, [p b f v m] are labial, and [p t k] are voiceless. This conception of phonemes as feature bundles is fundamental to subsequent developments in PHONOLOGY.

In exploring the consequences of this proposal, Jakobson was joined by Trubetzkoy, whose important *Grundzüge der Phonologie* (1939) summarizes many results of these early investigations. Jakobson's own contributions to feature theory are reflected in such papers as Jakobson (1929), where the evolution of the phoneme system of modern Russian is reviewed in light of the feature concept; Jakobson (1939), where it is shown—contra Trubetzkoy (1939)—that such apparently multivalued features as "place of articulation" can be reanalyzed in terms of binary features, and that this makes it possible to analyze both vowels and consonants with the same set of features; Jakobson (1941), where facts of phoneme acquisition by children, phoneme loss in aphasia, phoneme distribution in different languages, and other phonological phenomena are reviewed in feature terms; and Jakobson, Fant, and Halle (1952), where the acoustic correlates of individual features were first described and many consequences of these new facts discussed. Jakobson also made enduring contributions to the phonological study of

individual languages, for instance Russian (Jakobson 1948), Slovak (Jakobson 1931), Arabic (Jakobson 1957*a*), and Gilyak (Jakobson 1957*b*).

In addition to phonology, Jakobson's major contributions to linguistics were in the area of MORPHOLOGY, the study of the form of words and their minimal syntactic constituents, the morphemes. Among the new ideas in these studies (collected in Jakobson 1984) is Jakobson's attempt to extend the feature analysis to morphemes, which, like its phonological counterpart, has been adopted in subsequent work.

James, William

William James (1842–1910) was born in New York City into a cultivated, liberal, financially comfortable and deeply religious middle-class family. It was also a very literary family. His father wrote theological works, his brother Henry became famous as a novelist, and his sister Alice acquired a literary reputation on the posthumous publication of her diaries. As his parents took to traveling extensively in Europe, William James was educated at home and in various parts of Europe by a succession of private tutors and through brief attendance at whatever school was at hand. After an unsuccessful attempt to become a painter in Newport, Rhode Island, James began to study comparative anatomy at the Lawrence Scientific School of Harvard University. After a few years, James moved to the Harvard Medical School, graduating in medicine in 1869.

After teaching anatomy and physiology at Harvard for two years, James began teaching physiological psychology in 1875. In 1879 James gave his first lectures in philosophy at Harvard. As he himself put it, these lectures of his own were the first lectures in philosophy that he had ever heard. In 1884 James helped found the American Society for Psychical Research and, in the following year, was appointed professor of philosophy at Harvard. In 1890, after some twelve years of labor on the project, James published his magnum opus, the two volumes of *The Principles of Psychology.* In that same year, James established the psychological laboratory at Dane Hall in Harvard, one of the first such laboratories to be set up in America. In 1892 James wrote a textbook of psychology for students derived from *The Principles,* entitled *Textbook of Psychology: Briefer Course.*

The next twenty years saw a rapid succession of books: *The Will to Believe, and Other Essays in Popular Philosophy* (1897), *Human Immortality: Two Supposed Objections to the Doctrine* (1898), *Talks to Teachers on Psychology: and to Students on Some of Life's Ideals* (1899), *The Varieties of Religious Experience* (1902—his Gifford lectures at Edinburgh), *Pragmatism* (1907—lectures delivered at the Lowell Institute in Boston and at Columbia University), *A Pluralistic Universe* (1909—his Hibbert lectures at Oxford) and *The Meaning of Truth: A Sequel to Pragmatism* (1909). These unusually accessible books of philosophy and psychology achieved a wide readership and acclaim. After a long period of illness, James died at his summer home in Chocorua, New Hampshire, in 1910.

At his death James left behind an uncompleted work that was published as *Some Problems of Philosophy: A Beginning of an Introduction to Philosophy* (1911). This work was followed by a number of other posthumous volumes, mainly collections of his essays and reviews: *Memories and Studies* (1911), *Essays in Radical Empiricism* (1912), *Selected Papers in Philosophy* (1917) and *Collected Essays and Reviews* (1920). A collection of his letters was published in 1920, and a reconstruction of his 1896 Lowell lectures on "exceptional mental states" was issued in 1982.

James's best known contributions can most readily be understood when seen against the background of the temperament of his thought. One central strand of this temperament was his desire always to emphasize the practical, particular, and concrete over the theoretical, abstract and metaphysical. Thus his doctrine of *pragmatism,* which he shared with Charles Sanders Peirce and John Dewey, was a plea that an abstract concept of modern philosophy, MEANING, was best understood in terms of the practical effects of the words or the concepts embodying it. The *meaning* of a word or concept was only discernible in the practical effects of its employment, and its *meaningfulness* was a function of its success (or failure) in practice.

Most famously, or in some quarters, notoriously, this account of meaning was clearly illustrated by James's account of *truth.* For James there was no "final, complete fact of the matter," no truth with a capital T. Truth was simply a word that we applied to a "work-in-progress belief," that is, a belief which we held and have continued to hold because it enables us to make our way in the world in the long run. A true belief, then, is one that is useful and one

that has survived, in Darwinian fashion, the pressures of its environment. Such "truths" are always revisable. As James himself put it, "The true is the name of whatever proves itself to be good in the way of belief, and good, too, for definite, assignable reasons" (*Pragmatism*).

James has sometimes been referred to as the first American phenomenologist, though he himself preferred to call this aspect of his thinking *radical empiricism.* Both these labels have some cash value, because another strand of James's temperament was his evangelical holism in regard to all experiences. By experience, James meant any subject's current stream of consciousness. Such a stream was always experienced as a seamless flux. It alone was what was real for any subject. Any concepts, categories, or distinctions that we might refer to in regard to CONSCIOUSNESS, indeed even to speak of consciousness in the traditional way as inner, subjective, and mental, were, strictly speaking, artificial conceptual matrices that we have placed over the flow of experience for particular pragmatic purposes. Although James's fascination with consciousness has led many to refer to him as a Cartesian or as an introspectionist like WILHELM WUNDT, it is more fruitful to see him in relation to Heraclitus and Henri Bergson.

James's evangelical holism regarding the nature of experience should be coupled with what might be called an evangelical pluralism about its scope. For James believed that all experiences, whether mystical, psychical, or "normal," were of equal value. They were properly to be differentiated only in terms of the purposes for which these experiences had been deployed. So James's lectures on *The Varieties of Religious Experience,* his championing of psychical research, and his interest in "exceptional mental states" associated with cases of multiple personality and other mental illnesses, were in harmony with his radical empiricism.

James connected his radical empiricism with mainstream psychology and physiology by taking as the central task of *The Principles of Psychology* "the empirical correlation of the various sorts of thought or feeling [as known in consciousness] with definite conditions of the brain." In the *Principles* James also connected his radical empiricism with his unyielding advocacy of the freedom of the will by analyzing this freedom as involving the momentary endorsement of a particular thought in our stream of consciousness such that this thought would thereby become the cause of some appropriate behavior.

In the *Principles,* as well as in some other texts, James also made important contributions to the psychology of MEMORY, self-identity, habit, instinct, the subliminal and religious experiences. For example, his distinction between *primary* and *secondary* memory was the precursor of the modern distinction between short-term and long-term memory, and his work on ATTENTION has influenced recent work on the human capacity for dividing attention between two or more tasks. However, the most influential part of the *Principles* has been the theory of emotion that James developed in parallel with the Danish physiologist Carl Lange. As James himself put it, *"bodily changes follow directly the perception of the exciting fact, . . . [so that] our feeling of the same changes as they occur IS the emotion."* That is, an emotional state *is* the feeling in our stream of consciousness of the

behavior and physiological effects that we usually associate with a particular emotion. "Common sense says, we lose our fortune, are sorry and weep. . . . The hypothesis here to be defended says. . . that we feel sorry because we cry."

Judgment Heuristics

People sometimes need to know quantities that they can neither look up nor calculate. Those quantities might include the probability of rain, the size of a crowd, the future price of a stock, or the time needed to complete an assignment. One coping strategy is to use a *heuristic*, or rule of thumb, to produce an approximate answer. That answer might be used directly, as the best estimate of the desired quantity, or adjusted for suspected biases. Insofar as heuristics are, by definition, imperfect rules, it is essential to know how much confidence to place in them.

Heuristics are common practice in many domains. For example, skilled tradespeople have rules for bidding contracts, arbitrageurs have ones for making deals, and operations researchers have ones for predicting the behavior of complex processes. These rules may be more or less explicit; they may be computed on paper or in the head. The errors that they produce are the associated "bias."

Heuristics attained prominence in cognitive psychology through a series of seminal articles by Amos TVERSKY and Daniel Kahneman (1974), then at the Hebrew University of Jerusalem. They observed that judgments under conditions of uncertainty often call for heuristic solutions. The precise answers are unknown or inaccessible. People lack the training needed to compute appropriate estimates. Even those with training may not have the intuitions needed to apply their textbook learning outside of textbook situations.

The first of these articles (Tversky and Kahneman 1971) proposed that people expect future observations of uncertain processes to be much like past ones, even when they have few past observations to rely on. Such people might be said to apply a "law of small numbers," which captures some properties of the statistical "law of large numbers" but is insufficiently sensitive to sample size. The heuristic of expecting past observations to predict future ones is useful but leads to predictable problems, unless one happens to have a large sample. Tversky and Kahneman demonstrated these problems, with quantitative psychologists as subjects. For example, their scientist subjects overestimated the probability that

small samples would affirm research hypotheses, leading them to propose study designs with surprisingly low statistical power. Of course, well-trained scientists can calculate the correct value for power analyses. However, to do so, they must realize that their heuristic judgment is faulty. Systematic reviews have found a high rate of published studies with low statistical power, suggesting that practicing scientists often lack this intuition (Cohen 1962).

Kahneman and Tversky (1972) subsequently subsumed this tendency under the more general *representativeness* heuristic. Users of this rule assess the likelihood of an event by how well it captures the salient properties of the process producing it. Although sometimes useful, this heuristic will produce biases whenever features that determine likelihood are insufficiently salient (or when irrelevant features capture people's attention). As a result, predicting the behavior of people relying on representativeness requires both a substantive understanding of how they judge salience and a normative understanding of what features really matter. Bias arises when the two are misaligned, or when people apply appropriate rules ineffectively.

Sample size is one normatively relevant feature that tends to be neglected. A second is the population frequency of a behavior, when making predictions for a specific individual. People feel that the observed properties of the individual (sometimes called "individuating" or "case-specific" information) need to be represented in future events, even when those observations are not that robust (e.g., small sample, unreliable source).

Bias can also arise when normatively relevant features are recognized but misunderstood. Thus, people know that random processes should show variability, but expect too much of it. One familiar expression is the "gambler's fallacy," leading people to expect, say, a "head" coin flip after four tails, but not after four alternations of head-tail. An engaging example is the unwarranted perception that basketball players have a "hot hand," caused by not realizing how often such (unrandom-looking) streaks arise by chance (Gilovich, Vallone, and Tversky 1985). In a sense, representativeness is a metaheuristic, a very general rule from which more specific ones are derived for particular situations. As a result, researchers need to predict how a heuristic will be used in order to generate testable predictions for people's judgments. Where those predictions fail, it may be that the heuristic was not used at all or that it was not used in that particular way.

Two other (meta)heuristics are *availability* and *anchoring and adjustment*. Reliance on availability means judging an event as likely to the extent that one can remember examples or imagine it happening. It can lead one astray when instances of an event are disproportionately (un)available in MEMORY. Reliance on anchoring and adjustment means estimating a quantity by thinking of why it might be larger or smaller than some initial value. Typically, people adjust too little, leaving them unduly "anchored" in that initial value, however arbitrarily it has been selected. Obviously, there are many ways in which examples can be produced, anchors selected, and adjustments made. The better these processes are understood, the sharper the predictions that can be made for heuristic-based judgments.

These seminal papers have produced a large research literature (Kahneman, Slovic, and Tversky 1982). Their influence can be traced to several converging factors (Dawes 1997; Jungermann 1983), including: (1) The initial demonstrations have proven quite robust, facilitating replications in new domains and the exploration of boundary conditions (e.g., Plous 1993). (2) The effects can be described in piquant ways, which present readers and investigators in a flattering light (able to catch others making mistakes). (3) The perspective fits the cognitive revolution's subtext of tracing human failures to unintended side effects of generally adaptive processes. (4) The heuristics operationalize Simon's (1957) notions of BOUNDED RATIONALITY in ways subject to experimental manipulation.

The heuristics-and-biases metaphor also provides an organizing theme for the broader literature on failures of human DECISION MAKING. For example, many studies have found people to be insensitive to the extent of their own knowledge (Keren 1991; Yates 1990). When this trend emerges as overconfidence, one contributor is the tendency to look for reasons supporting favored beliefs (Koriat, Lichtenstein, and Fischhoff 1980). Although that search is a sensible part of hypothesis testing, it can produce bias when done without a complementary sensitivity to disconfirming evidence (Fischhoff and Beyth-Marom 1983). Other studies have examined hindsight bias, the tendency to exaggerate the predictability of past events (or reported facts; Fischhoff 1975). One apparent source of that bias is automatically making sense of new information as it arrives. Such rapid updating should facilitate learning—at the price of obscuring how much has been learned. Underestimating what one had to learn may mean underestimating what one still has to learn, thereby promoting overconfidence.

Scientists working within this tradition have, naturally, worried about the generality of these behavioral patterns. One central concern has been whether laboratory results extend to high-stakes decisions, especially ones with experts working on familiar tasks. Unfortunately, it is not that easy to provide significant positive stakes (or threaten significant losses) or to create appropriate tasks for experts. Those studies that have been conducted suggest that stakes alone do not eliminate bias nor lead people, even experts, to abandon faulty judgments (Camerer 1995).

In addition to experimental evidence, there are anecdotal reports and systematic observations of real-world expert performance showing biases that can be attributed to using heuristics (Gilovich 1991; Mowen 1993). For example, overconfidence has been observed in the confidence assessments of particle physicists, demographers, and economists (Henrion and Fischhoff 1986). A noteworthy exception is weather forecasters, whose assessments of the probability of precipitation are remarkably accurate (e.g., it rains 70 percent of the times that they forecast a 70 percent chance of rain; Murphy and Winkler 1992). These experts make many judgments under conditions conducive to LEARNING: prompt, unambiguous feedback that rewards them for accuracy (rather than, say, for bravado or hedging). Thus, these judgments may be a learnable cognitive skill. That process may involve using conventional heuristics more effectively or acquiring better ones.

Given the applied interests of decision-making researchers, other explorations of the boundary conditions on suboptimal performance have focused on practical procedures for reducing bias. Given the variety of biases and potential interventions, no simple summary can be comprehensive (Kahneman, Slovic, and Tversky 1982; von Winterfeldt and Edwards 1986). One general trend is that merely warning about bias is not very useful. Nor is teaching statistics, unless direct contact can be made with people's intuitions. Making such contact requires an understanding of natural thought processes and plausible alternative ones. As a result, the practical goal of debiasing has fostered interest in basic cognitive processes, in areas such as reasoning, memory, METACOGNITION, and PSYCHOPHYSICS (Nisbett 1993; Svenson 1996; Tversky and Koehler 1994). For example, reliance on availability depends on how people encode and retrieve experiences; any quantitative judgment may draw on general strategies for extracting hints at the right answer from the details of experimental (or real-world) settings (Poulton 1995).

Justification

Philosophers distinguish between *justified* and *unjustified* beliefs. The former are beliefs a cognizer is entitled to hold by virtue of his or her evidence or cognitive operations. The latter are beliefs he or she is unwarranted in holding, for example, beliefs based on sheer fantasy, popular superstition, or sloppy thinking. Some justified beliefs are based on scientific findings, but scientific beliefs do not exhaust the class of justified beliefs. Ordinary perceptual and memorial beliefs, such as "There is a telephone before me" and "Nixon resigned from the Presidency," are also normally justified.

A belief's justification is usually assumed to be something that makes it probable that the belief is true. But justi-

fied beliefs are not guaranteed to be true. Even sound scientific evidence can support a hypothesis that is actually false. Almost all contemporary epistemologists accept this form of fallibilism.

There are three principal approaches to the theory of justification: *foundationalism, coherentism,* and *reliabilism.* The historical inspiration for foundationalism was RENÉ DESCARTES (1637), who launched the project of erecting his system of beliefs on solid, indeed indubitable, foundations. Most contemporary foundationalists reject Descartes's insistence on indubitable or infallible foundations, because they doubt that there are enough infallible propositions (if any) to support the rest of our beliefs. On their view, the core of foundationalism is the notion that justification has a vertical structure. Some beliefs are directly or immediately justified independently of inference from other beliefs, for example, by virtue of current perceptual experience. These beliefs are called *basic* beliefs, and they comprise the foundations of a person's justificational structure. Nonbasic justified beliefs derive their justification via reasoning from basic beliefs. It has been widely rumored that foundationalism is dead, perhaps because few people still believe in infallible foundations. But most epistemologists regard weak versions of foundationalism—those that acknowledge fallibility—as still viable.

Coherentism rejects the entire idea of basic beliefs, and the image of vertical support that begins at the foundational level. Instead, beliefs coexist on the same level and provide mutual support for one another. Each member of a belief system can be justified by meshing, or cohering, with the remaining members of that system. Beliefs get to be justified not by their relationship with a small number of basic beliefs, but by their fit with the cognizer's total corpus of beliefs.

Reliabilism, a theory of more recent vintage, holds (in its simplest form) that a belief is justified if it is produced by a sequence of reliable psychological processes (Goldman 1979). Reliable processes are ones that usually output true beliefs, or at least output true beliefs when taking true beliefs as inputs. Perceptual processes are reliable if they typically output accurate beliefs about the environment, and reasoning processes are (conditionally) reliable if they output beliefs in true conclusions when applied to beliefs in true premises. Some types of belief-forming processes are unreliable, and they are responsible for unjustified beliefs. This might include beliefs formed by certain kinds of biases or illegitimate inferential methods.

Because reliabilism's account of justification explicitly invokes psychological processes, its connection to cognitive science is fairly straightforward. To determine exactly which of our beliefs are justified or unjustified, we should determine which of the belief-forming practices that generate them are reliable or unreliable, and that is a task for cognitive science (Goldman 1986). There is no special branch of cognitive science that addresses this topic, but it is sprinkled across a range of cognitive scientific projects.

Although most perceptual beliefs are presumably justified, some applications of our visual object-recognition system are fairly unreliable. Biederman's (1987) account of visual object recognition posits a process of matching visually detected components of a stimulus with the component types associated with object categories, such as "cup," "elephant," or "airplane." Object recognition is sometimes produced by partial matching, however, as when an occluded or degraded stimulus reveals only a few of its contours. When partial matching is unreliable, beliefs so formed are unjustified. An example of unreliable reasoning is the overuse of confirming information and the neglect of disconfirming information in drawing covariational conclusions: "I am convinced you can cure cancer with positive thinking because I know somebody who whipped the Big C after practicing mental imagery." People focus on instances that confirm their hypothesis without attending to evidence that might disconfirm it (Crocker 1982; Gilovich 1991). The search for evidence can also be biased by desire or preference. If we prefer to believe that a political assassination was a conspiracy, this may slant our evidence collection. In one study, subjects were led to believe that either introversion or extroversion was related to academic success. Those who were led to believe that introversion was predictive of success (a preferred outcome) came to think of themselves as more introverted than those who were led to believe that extroversion was associated with success (Kunda and Sanitioso 1989).

Proponents of foundationalism and coherentism often reject the relevance of experimental science to the theory of justification (e.g., Chisholm 1989). But even these types of theories might benefit from psychological research. What makes a memory belief about a past event justified or unjustified, according to foundationalism? It is the conscious memory traces present at the time of belief. Exactly what kinds of memory traces are available, however, and what kinds of clues do they contain about the veridicality of an apparent memory? This question can be illuminated by psychology. Johnson and Raye (1981) suggest that memory traces can be rich or poor along a number of dimensions, such as their sensory attributes, the number of spatial and temporal contextual attributes, and so forth. Johnson and Raye suggest that certain of these dimensions are evidence that the trace originated from external sources (obtained through perception) and other of these dimensions are evidence of an internal origin (imagination or thought). A characterization of these dimensions could help epistemologists specify when a memory belief about an allegedly external past event is justified and when it is unjustified (Goldman forthcoming).

Epistemological theories of justification sometimes ignore computational considerations, which are essential from a cognitivist perspective. Coherentism, for example, usually requires of a justified belief that it be logically consistent with the totality of one's current beliefs. But is this logical relationship computationally feasible? Cherniak (1986) argues that even the apparently simple task of checking for truth-functional consistency would overwhelm the computational resources available to human beings. One way to check for truth-functional consistency is to use the familiar truth-table method. But even a supermachine that could check a line in a truth-table in the time it takes a light ray to traverse the diameter of a proton would require 20 billion years to check a belief system containing only 138 logically indepen-

dent propositions. Thus, the coherence theory implicitly requires a humanly impossible feat, thereby rendering justification humanly unattainable (Kornblith 1989). Attention to computational feasibility, obviously, should be an important constraint on theories of justification.

Kant, Immanuel

Immanuel Kant (1724–1804) is perhaps the single most influential figure in the pre-twentieth-century history of cognitive research. He was a devoutly religious man from a very humble background: his father was a saddlemaker. Though one-quarter Scottish (it is said that Kant is a Germanization of Candt), he lived his whole life in Königsberg (now Kaliningrad), just below Lithuania. By his death he was virtually the official philosopher of the German-speaking world.

Until middle age, he was a prominent rationalist in the tradition of Leibniz and Wolff. Then DAVID HUME, as he put it, "awoke me from my dogmatic slumbers." The critical philosophy ensued. One of its fundamental questions was, what must we be like to have the experiences we have? The view of the mind that Kant developed to answer this question framed virtually all cognitive research until very recently.

Philosophy of mind and knowledge were by no means the only areas in which Kant made seminal contributions. He founded physical geometry. (Fieldwork must not have been too important—he is said never to have traveled more than thirty-five miles from Königsberg in his whole life!) His work on political philosophy grounds modern liberal democratic theory. And his deontology put ethics on a new footing, one that remains influential to this day.

It is his view of the mind, however, that influenced cognitive research. Four things in particular shaped subsequent thought:

1. MENTAL REPRESENTATION requires both CONCEPTS and SENSATIONS (percepts). As Kant put it, "concepts without intuitions are empty, intuitions without concepts are blind." To represent something, we require both acts of judgment and material from the senses to judge. Put another way, to discriminate, we need information; but we also need the ability to discriminate. This doctrine is now orthodoxy in cognitive science.
2. The method of transcendental argument. Kant's central methodological innovation, transcendental arguments are inferences from phenomena of a certain kind to what must be the case for those phenomena to exist. Applied to mental representations, such arguments are about what must be true of the thing that has those representations. Because this move allows us to infer the unobservable psychological antecedents of observed behavior, it is now central to most experimental cognitive science.
3. The mind as a system of functions. Kant was the first theorist to think of the mind as a system of functions, conceptual functions transforming ("taking") percepts into representations, at any rate of the modern era (Sellars 1968). (Aristotle may have had the same idea much earlier.) FUNCTIONALISM is by far the most influential philosophy of mind of cognitive science. Even the recent antisententialism of ELIMINATIVE MATERIALISM and CONNECTIONISM still see the mind as a system of functions.

   Indeed, Kant's notorious "noumenalism" about the mind might be simply an early expression of FUNCTIONALISM. Noumenalism is the idea that we cannot know what the mind is like, not even something as basic as whether it is simple or complex. Part of Kant's argument is that we cannot infer how the mind is built from how it functions: function does not determine form. (The other part is an equally contemporary-sounding rejection of INTROSPECTION. Both arguments occur in his most important treatment of the mind, the chapter attacking rationalism's paralogisms of pure reason in the *Critique of Pure Reason*.)

4. Faculties: Kant developed a theory of mental faculties that strongly anticipates Fodor's (1983) well-known modularity ac-count (see MODULARITY OF MIND).

Kant also developed important ideas about the mind that have not played much of a role in subsequent cognitive research, though perhaps they should have. Two of them concern mental unity.

5. Synthesis: Kant urged that to represent the world, we must perform two kinds of synthesis. First we must synthesize colors, edges, textures, and the like into representations of single objects. Then we must tie the various represented objects together into a single representation of a world. The first kind of synthesis is now studied under the name "binding" (e.g., Treisman and Gelade 1980). The second receives little attention, though it would appear to be equally central to cognition.

6. Unity of CONSCIOUSNESS: The unity of consciousness is our ability to be aware of a great many things at the same time, or better, as parts of a single global representation.

Finally, Kant articulated some striking ideas about:

7. Consciousness and the SELF. The awareness that we have of ourselves is one form of unified consciousness; we are aware of ourselves as the "single common subject" of our representations. But Kant had insights into it that go well beyond that. Ideas he articulated about the peculiar barrenness of one form of consciousness of self and about the referential apparatus that we use to attain it did not reappear until Castañeda (1966) and Shoemaker (1968).

In sum, Kant articulated the view of the mind behind most of cognitive science (see Brook 1994 for further discussion).

Knowledge Acquisition

Knowledge acquisition is a phase in the building of knowledge-based or expert systems. Knowledge-based systems are a kind of computer program that apply technical knowledge, or expertise, to PROBLEM SOLVING. Knowledge acquisition involves identifying the relevant technical knowledge, recording it, and getting it into computable form so it can be applied by the problem-solving engine of the expert system. Knowledge acquisition is the most expensive part of building and maintaining expert systems.

The area of expertise represented in the expert system is called the "domain." For example, a system that diagnoses malfunctioning VCRs and suggests remedies has VCR repair as its domain. An expert VCR repairman would be a "domain expert" for the system. The domain knowledge a developer, or "knowledge engineer," might acquire includes the types of problems VCRs exhibit, the symptoms a domain expert would look for to figure out the underlying cause of the problem, and the types of repairs that could cure the problem.

One of the big challenges of knowledge acquisition is finding a source of EXPERTISE that can be harvested. Written manuals are typically incomplete and sometimes even misleading. Manuals may contain technical details not actually applied in solving the problem. At the same time, manuals often leave out crucial "tricks" that experts have discovered in the field. The best, most experienced domain experts are generally in high demand and do not have much time for system building. Furthermore, experts may perform very well but have difficulty describing what cues they are responding to and what factors contribute to decisions they make. Very often multiple experts equally skilled in the same field disagree on how to do their job.

Another challenge addressed by approaches to knowledge acquisition is the maintenance of the knowledge. Especially in technical fields dealing with fast-changing product lines, domain knowledge may be extensive and dynamic. A VCR repair system may need to know technical details of the construction of every brand and make of VCR as well as likely failures. New knowledge will need to be added as new VCRs come on the market and technical innovations are incorporated into the products.

Most approaches to knowledge acquisition make the task manageable by identifying the problem-solving method that will be applied by the knowledge-based system. The problem-solving method then identifies what kinds of knowledge the developer should go after and organizes the knowledge so that it is easy to access for maintenance. (For more detail on using structure in knowledge acquisition and building expert

systems, see Clancey 1983, 1985; Swartout 1983; Chandrasekaran 1983; Gruber and Cohen 1987; McDermott 1988; Steels 1990; Wielinga, Schreiber, and Breuker 1992.)

For example, in our VCR repair domain, we may decide that, based on symptoms the user describes, the system will classify VCR problems into categories that represent the most probable cause of the problem. The system will then choose a repair based on that suspected problem. What is "probable" will just be based on our domain experts' experience of what's worked in the past. If we use this problem-solving method, then the knowledge we need to acquire includes symptom-to-probable-cause associations and probable-cause-to-repair recommendations.

Alternatively, we may decide the system will diagnose the VCR by simulating failures of components on a schematic model until the simulated system shows readings that match the readings on the sick VCR. The system will then suggest replacing the failed components. If we use this problem-solving method, then the knowledge we need to acquire includes an internal model of a VCR identifying components, their dynamic behavior both when healthy and when sick, and their effect on the simulation readings.

A method-based approach to knowledge acquisition extends traditional software engineering for building expert systems (see, for example, Scott, Clayton, and Gibson 1991). During requirements analysis, while developers are figuring out what the system needs to do, they are also figuring out how it is going to do it. Developers interview domain experts and check additional knowledge sources and manuals to see how the expert goes about problem-solving and what types of knowledge are available for application in a method. This information helps them select a method for the system. Establishing a method focuses further specifications and knowledge gathering; the method serves to organize the acquired knowledge into the roles the knowledge plays in the method. (See also Schreiber et al. 1994 for extensive organizational schemes.)

To assist in the knowledge acquisition process, researchers have developed automated tools (Davis 1982; Boose 1984; Musen et al. 1987; Gaines 1987; Marcus 1988). The earliest tools assumed a single problem-solving method and had a user interface dedicated to extracting the knowledge needed by that method. For example, a knowledge-acquisition tool for diagnostic tasks might query a user for symptoms, causes, and the strengths of association between symptoms and causes. Queries would be phrased in a general way so that they could be answered as easily with symptoms of malfunctioning VCRs as with symptoms of sick humans. Such tools might employ specialized interviewing techniques to help get at distinctions experts find difficult to verbalize. They might also analyze the knowledge for completeness and consistency, looking, for example, for symptoms that have no causes, causes without symptoms, or circular reasoning.

Once the domain knowledge is built up, such an interviewing tool is typically used with a "shell" for this kind of diagnosis. A shell is an empty problem-solving engine that knows, for example, what to do with symptoms, causes, and symptom-cause association weights to select a probable cause. Domain knowledge gathered by the interviewing tool is added to the problem-solving shell to produce a functioning expert system.

A further development has been the creation of layered tools that handle multiple problem-solving methods (Musen 1989; Eriksson et al. 1995; Klinker et al. 1990; Runkel and Birmingham 1993). These layered tools help the system-builder select a problem-solving method and then, based on that method, query for domain terms and knowledge, conduct completeness and consistency analyses, and integrate with an appropriate problem-solving shell.

The techniques described so far have mainly focused on interviewing a domain expert in order to encode their knowledge into the system. Knowledge acquisition for expert systems has also benefited from the related field of MACHINE LEARNING (Michalski and Chilausky 1980; Quinlan 1986; Bareiss, Porter, and Murray 1989; Preston, Edwards, and Compton 1994). Machine learning focuses on getting computer programs to learn autonomously from examples or from feedback to their own behavior. Machine learning techniques have been used most effectively to train expert systems that need to make distinctions such as the distinction between symptoms caused by immune-deficiency diseases versus cancers. The knowledge of the domain is acquired through the machine's experience with training cases rather than by directly encoding instructions from an interview. In domains where the cases and training are available, the knowledge acquisition effort can be quite efficient and effective.

Finally, knowledge acquisition challenges have inspired efforts to get the most mileage out of the knowledge that is so expensive to acquire (Lenat and Guha 1990; Gruber 1991). Many of the method-based acquisition tools represent knowledge in a way that is specific to how it is used by the method. A use-specific representation simplifies the job of getting the knowledge into computable form to match the problem-solving shell. However, knowledge that was acquired to design car electrical systems might also be useful in diagnosing their failures. A use-neutral representation makes it easier to reuse the same knowledge with multiple problem-solving methods provided a mechanism to transform or integrate the knowledge with particular problem-solvers. Large knowledge-base efforts focus on storing knowledge in a use-neutral way and making it available to many knowledge-based systems.

Knowledge-Based Systems

Knowledge-based systems (KBS) is a subfield of artificial intelligence concerned with creating programs that embody the reasoning expertise of human experts. In simplest terms, the overall intent is a form of intellectual cloning: find persons with a reasoning skill that is important and rare (e.g., an expert medical diagnostician, chess player, chemist), talk to them to determine what specialized knowledge they have and how they reason, then embody that knowledge and reasoning in a program.

The undertaking is distinguished from AI in general in several ways. First, there is no claim of breadth or generality; these systems are narrowly focused on specific domains of knowledge and cannot venture beyond them. Second, the systems are often motivated by a combination of science and application on real-world tasks; success is defined at least in part by accomplishing a useful level of performance on that task.

Third, and most significant, the systems are knowledge based in a technical sense: they base their performance on the accumulation of a substantial body of task-specific knowledge. AI has examined other notions of how intelligence might arise. GPS (Ernst 1969), for example, was inspired by the observation that people can make some progress on almost any problem we give them, and it depended for its power on a small set of very general problem-solving methods. It was in that sense methods based.

Knowledge-based systems, by contrast, work because of what they know and in this respect are similar to human experts. If we ask why experts are good at what they know, the answer will contain a variety of factors, but to some significant degree it is that they simply know more. They do not think faster, nor in fundamentally different ways (though practice effects may produce shortcuts); their expertise arises because they have substantially more knowledge about the task.

Human EXPERTISE is also apparently sharply domain-specific. Becoming a chess grandmaster does not also make one an expert physician; the skill of the master chemist does not extend to automobile repair. So it is with these programs.

The systems are at times referred to as *expert systems* and the terms are informally used interchangeably. "Expert system" is however better thought of as referring to the level of aspiration for the system. If it can perform as well as an expert, then it can play that role; this has been done, but is relatively rare. More commonly the systems perform as intelligent assistants, making recommendations for a human to

review. Speaking of them as expert systems thus sets too narrow a perspective and restricts the utility of the technology.

Although knowledge-based systems have been built with a variety of representation technologies, two common architectural characteristics are the distinction between inference engine and knowledge base, and the use of declarative style representations. The knowledge base is the system's repository of task-specific information; the inference engine is a (typically simple) interpreter whose job is to retrieve relevant knowledge from the knowledge base and apply it to the problem at hand. A declarative representation is one that aims to express knowledge in a form relatively independent of the way in which it is going to be used; predicate calculus is perhaps the premier example.

The separation of inference engine and knowledge base, along with the declarative character of the knowledge, facilitates the construction and maintenance of the knowledge base. Developing a knowledge-based system becomes a task of debugging knowledge rather than code; the question is, what should the program know, rather than what should it do.

Three systems are frequently cited as foundational in this area: SIN (Moses 1967) and its descendant MACSYMA (Moses 1971), DENDRAL (Feigenbaum et al. 1971), and MYCIN (Davis 1977). SIN's task domain was symbolic integration. Although its representation was more procedural than would later become the norm, the program was one of the first embodiments of the hypothesis that problem solving power could be based on knowledge. It stands in stark contrast to SAINT (Slagle 1963), the first of the symbolic integration programs, which was intended by its author to work by tree search, that is, methodically exploring the space of possible problem transformations. SIN, on the other hand, claimed that its goal was the *avoidance* of search, and that search was to be avoided by knowing what to do. It sought to bring to bear all of the cleverness that good integrators used, and attempted to do so using its most powerful techniques first. Only if these failed would it eventually fall back on search.

DENDRAL's task was analytic chemistry: determining the structure of a chemical compound from a variety of physical data about the compound, particularly its mass spectrum (the way in which the compound fragments when subjected to ionic bombardment). DENDRAL worked by generate and test, generating possible structures and testing them (in simulation) to see whether they would produce the mass spectrum observed. The combinatorics of the problem quickly become unmanageable: even relatively modest sized compounds have tens of millions of isomers (different ways in which the same set of atoms can be assembled). Hence in order to work at all, DENDRAL's generator had to be informed. By working with the expert chemists, DENDRAL's authors were able to determine what clues chemists found in the spectra that permitted them to focus their search on particular subclasses of molecules. Hence DENDRAL's key knowledge was about the "fingerprints" that different classes of molecules would leave in a mass spectrum; without this it would have floundered among the millions of possible structures.

MYCIN's task was diagnosis and therapy selection for a variety of infectious diseases. It was the first system to have all of the hallmarks that came to be associated with knowledge-based systems and as such came to be regarded as a prototypical example. Its knowledge was expressed as a set of some 450 relatively independent if/then rules; its inference engine used a simple backward-chaining control structure; and it was capable of explaining its recommendations (by showing the user a recap of the rules that had been used).

The late 1970s and early 1980s saw the construction of a wide variety of knowledge-based systems for tasks as diverse as diagnosis, configuration, design, and tutoring. The decade of the 1980s also saw an enormous growth in industrial interest in the technology. One of the most successful and widely known industrial systems was XCON (for expert configurer), a program used by Digital Equipment Corporation (DEC) to handle the wide variation in the ways a DEC VAX computer could be configured. The system's task was to ensure that an order had all the required components and no superfluous ones. This was a knowledge-intensive task: factors to be considered included the physical layout of components in the computer cabinet, the electrical requirements of each component, the need to establish interrupt priorities on the bus, and others. Tests of XCON demonstrated that its error rate on the task was below 3 percent, which compared quite favorably to human error rates in the range of 15 percent (Barker and O'Connor 1989). Digital has claimed that over the decade of the 1980s XCON and a variety of other knowledge-based systems saved it over one billion dollars. Other commercial knowledge-based systems of pragmatic consequence were constructed by American Express, Manufacturer's Hanover, duPont, Schlumberger, and others.

The mid-1980s also saw the development of BAYESIAN NETWORKS (Pearl 1986), a form of KNOWLEDGE REPRESENTATION grounded in probability theory, that has recently seen wide use in developing a number of successful expert systems (see, e.g., Heckerman, Wellman, and Mamdani 1995).

Work in knowledge-based systems is rooted in observations about the nature of human intelligence, viz., the observation that human expertise of the sort involved in explicit reasoning is typically domain specific and dependent on a large store of task specific knowledge. Use of simple if/then rules—production rules—is drawn directly from the early work of Newell and Simon (1972) that used production rules to model human PROBLEM SOLVING.

The conception of knowledge-based systems as attempts to clone human reasoning also means that these systems often produce detailed models of someone's mental conception of a problem and the knowledge needed to solve it. Where other AI technologies (e.g., predicate calculus) are more focused on finding a way to achieve intelligence without necessarily modeling human reasoning patterns, knowledge-based systems seek explicitly to capture what people know and how they use it. One consequence is that the effort of constructing a system often produces as a side effect a more complete and explicit model of the expert's conception of the task than had previously been available. The system's knowledge base thus has independent value, apart from the program, as an expression of one expert's mental model of the task and the relevant knowledge.

MYCIN and other programs also provided one of the early and clear illustrations of Newell's concept of the knowledge level (Newell 1982), that is, the level of abstraction of a system (whether human or machine) at which one can talk coherently about what it knows, quite apart from the details of how the knowledge is represented and used.

These systems also offered some of the earliest evidence that knowledge could obviate the need for search, with DENDRAL in particular offering a compelling case study of the power of domain specific knowledge to avoid search in a space that can quickly grow to hundreds of millions of choices.

Knowledge Representation

Knowledge representation (KR) refers to the general topic of how information can be appropriately encoded and utilized in computational models of cognition. It is a broad, rather catholic field with links to logic, computer science, cognitive and perceptual psychology, linguistics, and other parts of cognitive science. Some KR work aims for psychological or linguistic plausibility, but much is motivated more by engineering concerns, a tension that runs through the entire field of AI. KR work typically ignores purely philosophical issues, but related areas in philosophy include analyses of mental representation, deductive reasoning and the "language of thought," philosophy of language, and philosophical logic.

Typically, work in knowledge representation focuses either on the representational formalism or on the information to be encoded in it, sometimes called *knowledge engineering.* Although many AI systems use ad-hoc representations tailored to a particular application, such as digital maps for robot navigation or graphlike story scripts for language comprehension, much KR work is motivated by the perceived need for a uniform representation, and the intuition that because human intelligence can rapidly draw appropriate conclusions, KR should seek conceptual frameworks in which these conclusions have short derivations. The philosophical integrity or elegance of this assumed framework is less important than its practical effectiveness; for example, Jerry Hobbs (1985) urges a principle of *ontological promiscuity* in KR.

The central topic in knowledge engineering is to identify an appropriate conceptual vocabulary; a related collection of formalized concepts is often called an *ontology.* For example, temporal or dynamic knowledge is often represented by describing actions as functions on states of the world, using axioms to give sufficient conditions for the success of the action, and then using logical reasoning to prove constructively that a state exists that satisfies a goal. The name of the final state then provides a "plan" of the actions necessary to achieve the goal, such as: *drink(move(mouth,pickup(cup,start-state))).* Though useful, this ontology has several stubborn difficulties, notably the FRAME PROBLEM, that is, how compactly to state what remains *unchanged* by an action. (For example, picking up something from a table obviously leaves the table in the same place and doesn't change the color of anything, but

because the state has changed this needs to be made explicit; and some actions do have such side effects, so the possibility cannot be ruled out on logical grounds.) Many solutions to the frame problem have been proposed, but none are fully satisfactory. Other approaches divide the world into objects with spatial and temporal boundaries (Hayes 1985), or use transformations on state descriptions to model actions more directly. Several areas of knowledge engineering have received detailed attention, notably intuitive physical knowledge, often called *qualitative physics* (Davis 1990; Weld and de Kleer 1990).

KR formalisms need a precisely defined SYNTAX, a useful SEMANTICS, and a computationally tractable inference procedure. A wide variety have been studied. Typical features include a notation for describing concept hierarchies and mechanisms to maintain property inheritance; an ability to check for, and correct, propositional inconsistency in the light of new information ("truth-maintenance"; see Forbus and de Kleer 1993); and ways of expressing a "closed world" assumption, that is, that a representation contains all facts of a certain kind (so if one is omitted it can be assumed to be false).

Many notations are inspired by sentential logics, some by semantic networks, others, often called "frame-based," resemble object-oriented programming languages. Most of these can be regarded as syntactic variations on subsets of first-order relational logic, sometimes extended to allow Bayesian probabilistic inference, fuzzy reasoning, and other ways to express partial or uncertain information or degrees of confidence. Many also use some form of default or *non-monotonic* reasoning, allowing temporary assumptions to be cancelled by later or more detailed information. For example, if told that something is an elephant one can infer that it is a mammal, but this inference would be withdrawn given the further information that it is a toy elephant. More recently there has been considerable interest in diagrammatic representations that are supposed to represent by being directly similar to the subject being represented (Glasgow, Narayan, and Chandrasekharan 1995). These are sometimes claimed to be plausible models of mental IMAGERY, but Levesque and Brachman (1985) point out that a set of ground propositions together with a closed-world assumption has many of the functional properties of a mental image.

A central issue for KR formalisms is the tradeoff between expressive power and deductive complexity. At one extreme, propositional logic restricted to Horn clauses (disjunctions of atomic propositions with at most one negation) admits a very efficient decision procedure but cannot express any generalizations; at another, full second-order logic is capable of expressing most of mathematics but has no complete inference procedure. Most KR formalisms adopt various compromises. Network and frame-based formalisms often gain deductive efficiency by sacrificing the ability to express arbitrary disjunctions. Description logics (Borgida et al. 1989) guarantee polynomial-time decision algorithms by using operators on concept descriptions instead of quantifiers.

Commercial applications use knowledge representation as an extension of database technology, where the "knowl-

edge" is seen as a reservoir of useful information rather than as supporting a model of cognitive activity. Here action planning is often unnecessary, and the ontology fixed by the particular application—for example, medical diagnosis or case law—but issues of scale become important. The contents of such systems can often be thought of either as sentential knowledge or as program code; one school of thought in KR regards this distinction as essentially meaningless in any case. More recently, increased available memory size has made it feasible to use "compute-intensive" representations that simply list all the particular facts rather than stating general rules. These allow the use of statistical techniques such as Markov simulation, but seem to abandon any claim to psychological plausibility.

Commercial use of knowledge bases and a proliferation of Krep systems with various ad-hoc syntactic restrictions has created a need for "standard" or "interchange" formalisms to allow intertranslation. These include the Knowledge Interchange Format, a blend of first-order set theory and LISP (Genesereth et al. 1992) and conceptual graphs, a graphical notation inspired by C. S. Peirce (Sowa 1997). There is also considerable interest in compiling standard ontologies for commonly used concepts such as temporal relations or industrial process control (see the "ontology page" http://mnemosyne.itc.it:1024/ontology.html for the current state of research in this area).

Although there has been a great deal of work on KR, much intuitive human knowledge still resists useful formalization. Even such apparently straightforward areas as temporal and spatial knowledge are still subjects of active research, and the knowledge involved in comprehending simple stories or understanding simple physical situations is still yet to be adequately formalized. Many ideas have been developed in NL research, such as "scripts" or idealized story-frameworks and the use of a limited number of conceptual primitive categories, but none have achieved unqualified success.

Early work in AI and cognitive science assumed that suitably represented information must be central in a proper account of cognition, but more recently this assumption has been questioned, notably by "connectionist" and "situated" theories. Connectionism seeks to connect cognitive behavior directly to neurally inspired mechanisms, whereas situated theories focus on how behavior emerges from interaction with the environment (Brooks 1991). Both were initially seen as in direct opposition to knowledge-representation ideas, but reconciliations are emerging. In particular, phase-encoding seems to enable connectionist networks to perform quite sophisticated logical reasoning. The single most important lesson to emerge from these controversies is probably that the representation of knowledge cannot be completely isolated from its hypothesized functions in cognition.

Language Acquisition

Language acquisition refers to the process of attaining a specific variant of human language, such as English, Navajo, American Sign Language, or Korean. The fundamental puzzle in understanding this process has to do with the open-ended nature of what is learned: children appropriately use words acquired in one context to make reference in the next, and they construct novel sentences to make known their changing thoughts and desires. In light of the creative nature of this achievement, it is striking that close-to-adult proficiency is attained by the age of 4–5 years despite large differences in children's mentalities and motivations, the circumstances of their rearing, and the particular language to which they are exposed. Indeed, some linguists have argued that the theoretical goal of their discipline is to explain how children come to have knowledge of language through only limited and impoverished experience of it in the speech of adults (i.e., "Plato's problem"; Chomsky 1986). For closely related reasons, philosophers, evolutionary biologists, and psychologists have long used language acquisition as a testbed for exploring and contrasting theories of learning, development, and representation. Neither the natural communication systems of infrahumans nor the outcomes for apes specially tutored in aspects of spoken or signed systems approach in content or formal complexity the achievements of the most ordinary 3-year-old human (see also PRIMATE LANGUAGE). Because children are the only things (living or nonliving) that are capable of this learning, computer scientists concerned with simulating the process study language acquisition for much the same reason that Leonardo Da Vinci, who was interested in building a flying machine, chose to study birds.

Language acquisition begins at birth, if not earlier. Children only a few days old can discriminate their own language from another, presumably through sensitivity to language-specific properties of prosody and phonetic patterning. In the first several months of life, they discriminate among all known phonetic contrasts used in natural languages, but this ability diminishes over time such that by about 12 months, children distinguish only among the contrasts made in the language they are exposed to. Between about the seventh and tenth month, infants begin reduplicative babbling, producing sounds such as "baba" and "gaga" (see also PHONOLOGY, ACQUISITION OF). At this age, deaf children too begin to babble—with their hands—producing repetitive sequences of sign-language formatives that resemble the syllabic units of vocal babbling. In general, the acquisition sequence does not seem to differ for spoken and signed languages, suggesting that the language-learning capacity is geared to abstract linguistic structure, not simply to speech (see SIGN LANGUAGES).

Comprehension of a few words has been demonstrated as early as 9 months, and first spoken words typically appear between 12 and 14 months. The most common early words are names for individuals (*Mama*), objects (*car*), and substances (*water*); these nominal terms appear early in language development for children in all known cultures. Other common components of the earliest vocabulary are animal names, social terms such as *bye-bye* and—of course—*no*. Verbs and adjectives as well as members of the functional categories (such as *the, -ed, is,* and *with*) are rare in the early vocabulary compared to their frequency in the input corpus. At this initial stage, new words appear in speech at the rate of about two or three a week and are produced in isolation (that is, in "one word sentences"). The rate of vocabulary growth increases and so does the character of the vocabulary, with verbs and adjectives being added and functional morphemes beginning to appear. This change in growth rate and lexical class typology coincides with the onset of syntax (for further discussion and references, see WORD MEANING, ACQUISITION OF and SYNTAX, ACQUISITION OF).

The most obvious sign of early syntactic knowledge is canonical phrasal order: Children's speech mirrors the canonical sequence of phrases (be it Subject-Verb-Object, Verb-Subject-Object, etc.) of the exposure language as soon as they begin to combine words at all (Pinker 1984). English-speaking children's first word combinations were originally called "telegraphic" by investigators (Brown and Bellugi 1964) because they are short and because they lack most function words and morphemes, giving the speech the

minimalist flavor of telegrams and classified ads. But more recent investigation shows this characterization to be inadequate, in part because this pattern of early speech is not universal. In languages where closed-class morphemes are stressed and syllabic, they appear before age 2 (Slobin 1985).

Another problem with calling children's language "telegraphic" is that this characterization underestimates the extent of child knowledge. There is significant evidence that infants' knowledge of syntax, including the forms and semantic roles played by functional elements, is radically in advance of their productive speech. One source of evidence is preferential looking behavior in tasks where a heard sentence matches only one of two visually displayed scenes. Such methods have shown, for example, that appreciation of word order and its semantic implications are in place well before the appearance of two-word speech. For example, infants will look primarily to the appropriate action video in response to hearing *Big Bird tickles Cookie Monster* versus *Cookie Monster tickles Big Bird* (Hirsh-Pasek and Golinkoff 1996) and show a rudimentary understanding of the semantic implications of functional elements (Snedeker 1996). Another compelling source of evidence for underlying syntactic knowledge is that analyses of the relative positioning of subjects, negative words, and verbs, and their interaction with verb morphology, makes clear that children have significant implicit knowledge of functional projections; for example, they properly place negative words with respect to finite versus infinitive forms of the verb. That is, the French toddler regularly says "mange pas" but "pas manger" (Deprez and Pierce 1993).

By the age of 3 years or before, the "telegraphic" stage of speech ends and children's utterances increase in length and complexity. For instance, at age 3 and 4 we hear such constructions as inverted yes/no questions (*Is there some food over there?*), relative clauses (*the cookie that I ate*), and control structures (*I asked him to go*). Production errors at this stage are largely confined to morphological regularizations (e.g., *goed* for *went*) and syntactic overextensions (*She giggled the baby* for *She made the baby giggle*; see Bowerman 1982), though even these errors are rare (Marcus et al. 1992).

One important commitment that all acquisition theories make is to the sort of input that is posited to be required by the learner. After all, the richer and more informative the information received, the less preprogrammed capacity and inductive machinery the child must supply "from within." Adults tend to communicate with their offspring using slow, high-pitched speech with exaggerated intonation contours, a relatively simple and restricted vocabulary, and short sentences. Although whimsically dubbed "Motherese" (Newport, Gleitman, and Gleitman 1977), this style of speech is characteristic of both males and females, and even of older children when talking to younger ones. DARWIN, who was interested in language learning and kept diaries of his children's progress, called this style of speech "the sweet music of the species." Infants resonate to it, strongly preferring Motherese to the adult-to-adult style of speech (Fernald and Kuhl 1987). Although it is possible that these apparent adult simplifications might facilitate aspects of learning, there is plenty of evidence that the abused and neglected children of the world, regardless of their other difficulties, adequately acquire the language of their communities.

Because speech to children is almost perfectly grammatical and meaningful, it seems to offer a pretty straightforward model for acquisition. Yet in principle such a "good sample" of, say, English, is a limited source of information for of necessity it doesn't explicitly expose the full range of structure and content of the language. Notice, as an example, that although an adjective can appear in two structural positions in certain otherwise identical English sentences (e.g., *Paint the red barn* and *Paint the barn red*), this is not always so: Woe to the learner who generalizes from *See the red barn* to *See the barn red*. It has been proposed, therefore, that "negative evidence"—information about which sentences are ill-formed in some way—might be crucial for deducing the true nature of the input language. Such information might be available in parents' characteristic reactions to the child's ill-formed early speech, thus providing statistical evidence as to right and wrong ways to speak the language. However, a series of studies beginning with Brown and Hanlon (1970) have demonstrated that there is little reliable correlation between the grammaticality of children's utterances and the sorts of responses to these that their parents give, even for children raised in middle-class American environments. Moreover, children learn language in cultures in which nobody speaks to infants until the infants themselves begin to talk (Lieven 1994).

As mentioned above, neonates can detect and store at least some linguistic elements and their patterning from minimal distributional information (Saffran, Aslin, and Newport 1997). Recent computational simulations suggest that certain lexical category, selectional, and syntactic properties of the language can be gleaned from such patterns in text (e.g., Cartwright and Brent 1997). Most theories of language development, following Chomsky (1965) and Macnamara (1972), assume that children also have access to some nonlinguistic encoding of the context. That is, they are more likely to hear *hippopotamus* in the presence of hippos than of aardvarks, and *The cat is on the mat* is, other things being equal, a more likely sentence in the presence of cats and mats than in their absence. The effects of such contextual support are obvious for learning the meanings of words, but they are likely to be critical as well for the acquisition of syntax (Bloom 1994; Pinker 1984).

Whatever the detailed cause-and-effect relations between input properties and learning functions, it seems a truism that the variant of human language attained by young children is that modeled by the adult community of language users. Yet even in this regard, there are significant exceptions. For example, isolated deaf children not exposed to signed languages spontaneously generate gestural systems that share many formal and substantive features with the received languages (e.g., Feldman, Golden-Meadow, and Gleitman 1978; see also SIGN LANGUAGES). Similarly, children whose linguistic exposure is to "pidgin" languages (simple contact systems with little grammatical structure) elaborate and regularize these in the course of learning them (Bickerton 1981; Newport 1990; see CREOLES). Much of language change can be explained as part of this process of

regularization and elaboration of received systems by children. In a very real sense, then, children do not merely learn language; they create it.

The acquisition properties just described sketch the known facts about this process as it unfolds in young children, under all the myriad personal, cultural, and linguistic circumstances into which they are born. Acquisition is astonishingly "robust" to environmental circumstance. This finding is at the heart of theorizing that assigns the child's acquisition in large part to internal, biological, predispositions that can correct for adventitious properties of the environment. One more stunning indication of the merit of such a view is that young children simultaneously exposed to two—or even three—languages in infancy and early childhood acquire them all as rapidly and systematically as the child in monolingual circumstances acquires one language. That is, if the child in a bilingual home sleeps as much as her monolingual cousin, she necessarily hears a smaller sample of each of the languages; yet attainment of each is at age-level under conditions where both languages are in regular use in the child's immediate environment.

If it is true that biologically "prepared" factors in young children significantly support and constrain the learning process, then learning might look different when those biological factors vary. And indeed it does. The most obvious first case to inspect is that of learners who come into a language-learning situation at a later brain-maturational state. In contrast to the almost universal attainment of a high level of language knowledge by humans exposed to a model in infancy or early childhood stand the sharply different results for such late learners. In the usual case, these are second-language learners, and the level of their final attainment is inferior to infant learners as a direct negative function of maturational status at first exposure. However, the same generalizations apply to acquisition of a primary language late in life (Newport 1990). Apparently, these increasing decrements in language-acquisition skills over maturational time apply both to learning idiosyncratic details of the exposure language and to language universals, properties common across the languages of the world. Such "critical period" or "sensitive period" effects, though undeniable on the obtained evidence, cannot by themselves reveal just what is being lost or diminished in the late learner: This could be some aspects of learning specific to language itself, general capacities for structured cognitive learning, or some combination of the two (for discussion of the complex interweave of nature and nurture in accounting for critical period effects, see Marler 1991).

A large and informative literature considers tragedies of nature, populations of learners with conceptually or linguistically relevant deficits. The effect of these studies, taken as a whole, is to demonstrate, first, that linguistic and general-cognitive capacities are often dissociated in pathology. For example, in Williams syndrome (Bellugi et al. 1988), language-learning abilities are virtually unscathed but these children's IQs are severely below normal; in SLI (Specific Language Impairment; van der Lely 1997), children with normal and even superior IQs exhibit defects in the timing and content of language acquisition. The second overall finding from these unusual populations is that language deficiencies are not across-the-board but may affect only a single aspect. For example, both in SLI (Rice and Wexler 1996) and in Down's syndrome (Fowler 1990), word learning and some aspects of syntax (e.g., word order) are adequate, but there is a specific deficit for functional projections (i.e., knowledge of the interaction of verb morphology and syntactic structure).

To many theorists the bottom-line message from joint investigation of normal and unusual learning is this: Language acquisition is little affected by the ambiance in which learners find themselves, so long as they have intact young human brains; whereas any change in mentality (even: growing up!) massively, and negatively, impacts the learning process.

Beyond questions of nature-nurture in the acquisition process are more specific questions about acquisition functions for language at various levels in the linguistic hierarchy, including PHONOLOGY, SYNTAX, SEMANTICS, and word learning. At this moment in the progress of the field, interpretation of such results is limited to the extent that a number of viable theories of language design—that is, of the targets of acquisition—contend in the linguistic literature. Moreover, theoretical pressure to account for the emerging facts about language learning often motivates revision of the linguistic theory. One way to think about how language and its learning are jointly explored, then, is to contrast two different questions that investigators ask, depending on their orientations: "What is a child, such that it can learn language?" versus "What is language, such that every child can learn it?"

Particularly informative in adjudicating these issues are studies that contrast learning and language effects crosslinguistically (a classic collection of such articles appears in Slobin 1985). Another useful direction has been to consider acquisition across various levels of the linguistic hierarchy, to examine the extent of their interaction. For example, phonological and semantic knowledge underlie aspects of how children understand the syntax of a sentence; syntactic and morphological cues support the acquisition of word meaning; and so on. Recent technological developments are beginning to enable acquisition work in directions unforeseen and infeasible up until the last few years. One important example concerns child on-line language processing, an area that has remained largely closed to investigation (for an exception, see McKee 1996) until the advent of eyetracking equipment that can monitor the child's linguistic representations as these are constructed, in milliseconds, dependent on the reference world (Trueswell, Sekerina, and Hill 1998). Another is neuropsychological investigation employing techniques such as POSITRON EMISSION TOMOGRAPHY and functional MAGNETIC RESONANCE IMAGING (fMRI) recording of neural activity during linguistic processing. Finally, the increasing use of computer models and simulations allows explicit and detailed theories to be tested on large bodies of computerized linguistic data.

In light of the growing armamentarium of investigative technique and increasingly sophisticated linguistic analysis, understanding of language acquisition can be expected to increase rapidly in the coming decade. All current theoretical positions, no matter how different in other ways,

acknowledge that language acquisition is the result of an interaction between aspects of the human mind and aspects of the environment: children learn language but rocks and dogs do not; children in France learn French and children in Mawu learn Mawukakan. Substantive debates in the present literature largely center on the nature of the learning mechanism. One issue is whether language is learned through a specialized organ or module or is the product of more general learning capacities. A further issue, logically distinct from the question of specialization, is whether the mechanisms of language acquisition and representation exploit symbolic rules, associations, or some combination of the two.

In conclusion, we should stress that language acquisition is a diverse process. It is extremely likely, for instance, that the right explanation for how children learn to form *wh*-questions will involve different cognitive mechanisms from those required for learning proper names or learning to take turns in conversation. We suspect, in fact, that there is no single story to be told about how children acquire language. Rather, the formatives, the learning machinery, and the combinatorial schemata at each level of the final system can be expected to vary. At the same time, knowledge of one aspect of the system can be expected to piggyback on the next in a complex incremental learning scheme, some of whose dimensions and procedures cannot now even be guessed at.

Language and Cognition

See INTRODUCTION: LINGUISTICS AND LANGUAGE; LANGUAGE AND THOUGHT; LANGUAGE OF THOUGHT

Language and Communication

Language and communication are often defined as the human ability to refer abstractly and with intent to influence the thinking and actions of other individuals. Language is thought of as the uniquely human part of a broader system of communication that shares features with other ANIMAL COMMUNICATION systems. In the twentieth century, language research has focused largely on those aspects of vocal communication (or their homologs in SIGN LANGUAGES) that are organized as categorial oppositions (de Saussure (1916/1959); for example, categories of sound, grammar, and meaning. The domain of language research has been largely speech. In 1960, the linguist Charles Hockett advocated restricting the term "[human] language" to just those dimensions of communication that are vocal, syntactic, arbitrary in relation to their referents, abstractly referential (that is, meaning is determinable independently of the immediate context of utterance), and learned. The host of other patterned dimensions of communicative acts—social, kinesic and affective-volitional: vocal and nonvocal—has often been labeled "paralanguage" and regarded as outside the proper domain of linguistic inquiry.

The dominant paradigm in linguistics since the 1950s (Piatelli-Palmarini 1980) has as its foundation some notion of language as a disembodied symbol manipulation device. This Cartesian rationalist approach (Dreyfus 1992) has informed much research in experimental PSYCHOLINGUISTICS. The approach meshes with a general theory of mind in cognitive science whose influence has spread with the increasing use of computer technology. Based on the metaphor of the mind as a computer, higher human mental functions (language among them) are modeled on analogy with the operating principles of formal information processing (IP) systems, including, "decomposition of complexity into simpler units; routines and subroutines that automatically and recursively operate on atomic units" (Gigerenzer and Goldstein 1996). In modular IP models, subroutines are

"unintelligent" and encapsulated; that is, each functions in relative isolation from other modules in the system. Gigerenzer and Goldstein cite Levelt's (1989) influential model of LANGUAGE PRODUCTION as representative of this general approach. As well, a great deal of basic research on SPEECH PERCEPTION, SENTENCE PROCESSING, and LANGUAGE ACQUISITION has been concerned with the nature of psycholinguistic functions when variables of meaning and context enter the experimental format only in a controlled manner, via symbol and syntax. One goal has been to understand how arbitrary symbol and syntax, thought of as the "purely linguistic" dimensions of human communicative acts, function as pointers to extralinguistic meaning and context. Olson (1994) implicates the technology of writing as another source for this way of thinking about language, saying, "we introspect our language in terms of the categories laid down by our script." In this view, spoken linguistic units are containers to carry abstract reference and these units have an existence independent from the context that gives rise to them. (That linguistic units can be made to function in this way *in vitro* is an issue crucially distinct from what their nature and functions may be in the organic whole of face-to-face communication.)

Research cued by formal linguistics links to the combined senses of what language is (speech and syntax) and what its "main function" is (abstract reference). Lieberman's (1991) research on the evolution of the human vocal tract, for instance, pinpoints when in evolutionary time humans became capable of producing the modern range of spoken phonetic categorial distinctions, identifying this with the onset of human language as a whole. Research on PRIMATE LANGUAGE often imports frameworks and units of analysis from linguistic analyses of human language. For example, reports of chimpanzee and gorilla attempts to use artificial and signed languages give totals of the words in the animals' vocabularies and comment on the extent to which the animals are able to negotiate task demands absent information from context on the basis of symbol manipulation alone. Cheney and Seyfarth's (1990) finding that vervet monkeys have distinct calls to alert conspecifics to the presence of different types of predators gives rise to discussions about the role of something like "words" in these animals' natural communication system.

The dominant paradigm puts a chasm between animal communication and human language, one that has been notably difficult for theories of the EVOLUTION OF LANGUAGE to bridge. Saltationist evolutionary accounts assume a significant structure-producing genetic mutation that makes human-language syntax possible. Some researchers hypothesize that humans are uniquely capable of developing a THEORY OF MIND necessary for intentional communication; some that a particular mimetic ability is the key. Other accounts emphasize the continuity between human cognitive, social, and communicative abilities and those of our primate relatives (see the collected papers in Hurford, Studdert-Kennedy, and Knight 1998). The crucial evolutionary join, however, remains underspecified.

Alternative research strategies in linguistics, sociolinguistics, anthropology, and psychology have assembled evidence of much interpenetration and interdependence of the many dimensions of human communicative acts that have been theorized to be functionally independent. Sociolinguistics (for example, Labov 1980) has shown that individuals' attempts to position themselves relative to different groups or social strata can have effects even to the level of language phonology. The psycholinguist Locke (1994) has noted that, "linguists have neglected the role of language as a medium for social interaction and emotional expression." He distinguishes "talk" (loosely: social speech) in human communication from a more restricted sense of speech and claims that the language acquisition process targets talk first, assembling an essential social-interactional framework within which speech is then acquired. The anthropologist Kendon (1994) assigns equal status to gesture and speech as communicative resources. Cognitive and functional linguistic theory (Lakoff 1987) attempts to ground language in embodied experience and rejects the analytic separation of grammar from meaning. In later years, Hockett himself (1987), in writing about "how language means," acknowledged the difficulty of drawing a sharp boundary in situated language use between language and "paralanguage"; between the arbitrary and the iconic. He exhorted linguists to learn about language by studying the communicative package as a whole, "*in vivo*," and to avoid focusing too exclusively on, thereby making too much of, the abstract referring and symbol manipulation properties of language.

The linguist Dwight Bolinger (Bolinger and Sears 1975) pursued linguistic research with a very different focus, stating, "language is speech embedded in gesture." This statement puts paralanguage ("gesture," both vocal and kinesic) before abstract, syntactic speech in studies of human language. The "gesture" with which Bolinger was primarily concerned is prosody, the patterns of stress and intonation in speech. He also reported, however, observations of the facial and bodily gestures that occur together with speech and noted their relation to prosody. He was interested, for example, in how a prosodic contour determines the meaning of an utterance as much as do the combined meanings of the words in the sentence; also in how gesture expresses affect or can reveal a speaker's perspective on her own utterance at the moment of speaking.

McNeill and Duncan (1999) largely reject the language/paralanguage distinction. These authors theorize that gesture, broadly construed to include prosodic and rhythmic phenomena (cf. Tuite 1993), iconic gestures, nonrepresentational movements of the hands and body, semiotic valuation of gesture space, as well as analog (as opposed to discrete) patterning on other communicative dimensions, is intrinsic to language. On this view, language is an organized form of on-line, interactive, embodied, and contextualized human cognition. By hypothesis, the initial organizing impulse of a communicative production is a unit of thinking patterned simultaneously according to two distinct representational systems: one categorial, compositional, and analytic; the other imagistic, synthetic, and holistic. Patterning in either system may emerge in speech or gesture production, though it has often been convenient to think of speech as the embodiment of the categorial, and gesture as the embodiment of the noncategorial. According to McNeill and Duncan, reductionist accounts that isolate categorial speech from image,

prosody, and gesture in separate processing modules (Levelt 1989; Krauss, Chen, and Gottesman 1999) will fail to account for the way language production and comprehension evolve on-line in real-time communication. Speech and gesture together provide an enhanced window on cognition during communication. Much is externalized, a fact that minimizes the burden on interlocutors' theories of mind.

Gigerenzer and Goldstein (1996) identify the information encapsulation feature of modularist IP models such as Levelt's as the Achilles' heel of these models. Pushed by cross-disciplinary study of language *in vivo*, there is growing consensus that models must deal with the massive interpenetration of what have traditionally been analyzed as functionally distinct levels of linguistic analysis. Such consensus points to a paradigm shift underway, one that encompasses Saussure's paradigm-shifting formulation but moves beyond it. It locates human language in the human body and postulates as its theoretic atom the conversational dyad, rather than a monad with a message to transmit or receive (Goodwin 1986; Schegloff 1984). The shift was foreshadowed by Lev Semenovich VYGOTSKY (1934/1986), who analyzed communicative events as developing simultaneously on an "inter-" as well as an "intra-psychic plane." At the vangard are socio- and psycholinguistic gesture research, research on sign languages liberated from earlier constraints to minimize iconic dimensions of patterning (Armstrong, Stokoe, and Wilcox 1995), cognitive and functional linguistic research, as well as philosophical (Heidegger: see Dreyfus 1991) and anthropological (Levinson, forthcoming) re-search that highlights the situated, culturally embedded character of language use.

Language and Culture

Languages differ in fundamental ways: their phoneme inventories vary from 11 to 141 (Maddieson 1984), they may have elaborate or no morphology, may or may not use word order or constituent structure or case to signify syntactic relations, may or may not have word roots of fixed grammatical word class, may make use of quite different semantic parameters, and so on (see TYPOLOGY). There are an estimated 7000 or more distinct languages in the world, each a cultural tradition of (generally) thousands of years in the making, and there are at least 20 (how many is controversial) language families across which relationships cannot be demonstrated. Each is adapted to a unique cultural and social environment, with striking differences in usage patterns (Bauman and Sherzer 1974). This cultural adaptation constitutes the cultural capital of language, and language differences are perhaps the most perduring of all aspects of culture. On the other hand, language is a biological capacity, instantiated in the anatomy of our vocal tract and the corresponding acuity of our hearing and in dedicated areas of the brain (see LANGUAGE, NEURAL BASIS OF). In fact, language provides the best evidence for the thesis of coevolution, whereby cultural replication and genetic replication became intertwined, each providing the context for the evolution of the other (see EVOLUTION OF LANGUAGE; also Durham 1991). CULTURAL VARIATION also requires that the biological capacity for language be malleable (see NEURAL PLASTICITY)—for example, able to learn and parse speech of quite different sound and structural type (see PSYCHOLINGUISTICS)—although this malleability is progressively lost during maturation of the individual.

Most models of human cognition abstract away from variation, whether cultural or individual. But in the case of language, the capacity to handle the cultural variation is a central property of cognitive ability. Consider for example that language ability is modality independent; according to cultural tradition it can be not only spoken or signed (see SIGN LANGUAGES) but also represented visually by reference to sounds, meanings, or both (according to the writing system) or signed with the hands as in auxilliary hand-sign systems. In this modality independence it is very unlike any other sensory input or motor output system.

Current linguistic theory proceeds by positing universal hypotheses across all languages, and workers in other branches of cognitive science may therefore be led to think that large numbers of universals of language have been established. In actual fact these have proved very hard to formulate, and nearly all successful generalizations are either very abstract (and correspondingly difficult to test) or of the form "if a language is of a certain type T, then it tends to have property P" (see Greenberg 1978), usually with exceptions rapidly discovered. Most databases for extrapolation cover less than 10% of the world's languages; the great majority of languages have never been described, let alone carefully analyzed.

Through language, and to a lesser extent other semiotic systems, individuals have access to the large accumulation of cultural ideas, practices, and technology that instantiate a distinct cultural tradition. The question then arises as to what extent these ideas and practices are actually embodied in the language in lexical and grammatical distinctions. Humboldt, and later SAPIR and Whorf, are associated with the theory that a language encapsulates a cultural perspective and actually creates conceptual categories (see CONCEPTS; LINGUISTIC RELATIVITY HYPOTHESIS; Gumperz and Levinson 1996). In some respects this seems clearly true (consider notions like "tort" or "manslaughter" that reflect and constitute part of the English legal tradition, not an aspect of culture-independent reality); in other respects it seems to be false ("black" appears to be a universal concept, reflecting aspects of PSYCHOPHYSICS). Yet many cognitive scientists assume that basic semantic parameters are universal, culture-specific notions like "tort" being constructed from such universal semantic primitives (an influential exception is Fodor, who claims that all such notions are universal unanalyzed wholes in the LANGUAGE OF THOUGHT). Current work on semantics, however, makes it clear than even apparently fundamental notions may vary crosslinguistically, and children learning language do not invariably appear to make the same initial assumptions about meaning (Slobin 1985). Take for example spatial notions: readers are likely to think of the things on the desk before them in terms of things "in front" of themselves, "to the left," or "to the right." But some languages do not lexicalize these notions at all. Instead one must refer to things as, for example, "to the north," "to the east" or "to the west," and so forth, as appropriate. Consequently, speakers of these languages must keep their bearings, and they can be shown to conceive of spatial arrangements differently in nonverbal memory and inference (Levinson 1996).

There are many aspects of the cultural patterning of language that may be fundamental to its role in cognition. One is special elaborations of linguistic ability—for instance, highly skilled performance as in simultaneous translation or rapid sports commentary that can be delivered at twice the speed of the fastest conversation. Perhaps the majority of the world's population are multingual, and multilingualism is a capacity largely beyond current psycholinguistic understanding. Another is the elaboration of technologies of language, of which writing is the most fundamental (Goody 1977) and NATURAL LANGUAGE PROCESSING the most advanced. Natural languages are learned in and through

social interaction and constitute probably the most complex cognitive task that humans routinely undertake (and quite plausibly the major pressure for brain evolution in our species; see Byrne and Whiten 1988; COOPERATION AND COMPETITION). Many aspects of natural language can only be understood in relation to this interactional context, including INDEXICALS AND DEMONSTRATIVES, speech acts, and conveyed politeness (Brown and Levinson 1987).

Cognitive scientists are not interested in all aspects of language (most aspects of their history for example, but see LANGUAGE VARIATION AND CHANGE). Four aspects though are of particular importance. One is how language is learned (see LEARNING). A second is how language is processed (viewing the mind or the brain as an information-processing device), both in comprehension (Tyler 1992) and production (Levelt 1989). A third is how language interfaces with other cognitive abilities and how semantic representations are related to other conceptual representations (Nuyts and Pederson 1997). A fourth concerns how linguistic ability is instantiated in neurophysiology.

In all four aspects, the complex interplay between culture and biology in language is crucial to our understanding of the phenomena. In LANGUAGE ACQUISITION, the cultural variability makes learning a fundamental puzzle; even if there are significant universals, the child must still pair sounds and meanings, where the analysis of neither is given by first principles. For language processing, again language variation is highly problematic: it is hard to see how the same mechanisms can be involved in radically different languages. For example, languages with verbs in medial or final position in the sentence allow one to start speech production before the sentence is fully worked out; but languages with verbs in initial position, fully marked for agreement with subject and object, would seem to require a different production strategy. Similarly, parsing strategies for comprehension would seem necessarily divergent in languages with fixed word order or no fixed word order, with rich morphology or none. Thirdly, fundamental variation in semantic parameters makes the interface between language and general cognition look much more problematic than is commonly assumed. Not all concepts are directly expressible in a language. Further, the semantic distinctions obligatorily required by the grammar are not necessarily of the kind that would universally be noted and memorized for future possible linguistic expression (e.g., was the referent visible at event time, was the participant to be described of greater or lesser rank than the speaker and the addressee, was the referent a singleton or not, etc.). This points to the likelihood that to speak a particular language, experience must be coded in the appropriate categories, and it also raises questions about the universality of the language of thought. Finally, with regards to brain and language, there is evidence from selective brain damage (see APHASIA) that linguistic abilities are localized partly in accordance with the structure of a particular language (Bates and Wulfreck 1989).

Language and Gender

Exploring the interaction of language and gender raises many fundamental questions of cognitive science. What are the connections of LANGUAGE AND THOUGHT, of LANGUAGE AND CULTURE, of language and action? What role do LANGUAGE ACQUISITION and language processing play in forging these connections? Even research on language and gender that does not address such questions explicitly can usually be seen as implicitly relevant to them. Relatively few language and gender researchers have cast their work in primarily cognitive terms, more often emphasizing social or economic or political phenomena, but of course such phenomena can themselves be fruitfully approached from the perspective of cognitive science—for example, in work on SOCIAL COGNITION.

Two basic families of questions have dominated language and gender research. First, does gender influence language and, if so, how? That is, how might gender identities and relations of interlocutors be connected to the form and content of what they say? There is considerable sociolinguistic research on how women and men use language in different situations (see, e.g., Coates 1992; Coates and Cameron 1988; Eckert 1990); there is some developmental research that looks at gender issues and a very little neurolinguistic work on sex differences in brain activity during

language processing (along with sociolinguistic work, Philips, Steele, and Tanz 1987 include contributions addressing both language development and neurolinguistics). There is also a very little work on phonetic issues (e.g., Hanson 1996; Henton 1992). With the exception of some of the best sociolinguistic work (e.g., Brown 1990; Goodwin 1991; and a number of the articles in Coates 1998), most research on how gender affects language conflates gender with sex, focusing on overall sex differences while ignoring the intertwining of gender with other aspects of social identity and social relations (see Eckert and McConnell-Ginet 1992, 1996; Ochs 1992) and also ignoring other aspects of intrasex variation as well as complexities in sexual classification. Some work has addressed ways in which gender arrangements may affect the development of linguistic conventions (e.g., McConnell-Ginet 1989 discusses how changes in lexical meaning might be driven by certain features of gender arrangements, including, for example, practices that give greater voice in public contexts to men than to women). And much sociolinguistic work has addressed the question of how gender affects changes in patterns of pronunciation and other aspects of language use that ultimately can change language structure (e.g., Milroy et al. 1995).

Second, does language influence gender and, if so, how? That is, how might linguistic resources and conventions affect the shape of a culture's gender arrangements? There have been a number of psycholinguistic studies on such topics as masculine generics (see, e.g., Sniezek and Jazwinski 1986) and studies in PRAGMATICS and related fields on topics like METAPHOR and linguistic discrimination (see, e.g., papers in Vetterling-Braggin 1981). There is also considerable work on these topics from anthropologists and cultural theorists, who look at a culture's favored figures of speech (e.g., using the terminology of delectable edibles to talk about women) and other linguistic clues to cultural assumptions in order to map the gender terrain. There is some evidence that gender (and other) stereotypes help drive inferencing even in those who don't accept them, suggesting that linguistically triggered stereotyping may be consequential both in acculturating children and in helping to maintain the gender status quo. What should be seen as the direction of influence is certainly not clear, however, and many studies of gender biases evident in linguistic resources are positing the influence of gender arrangements on language as much as the other way around (McConnell-Ginet 1989 and others suggest that influences typically go in both directions). Some of the same sociolinguistic studies that explore how women and men speak also look at the social and political effects of different speech styles and interactional dynamics. Lakoff (1975) made popular the idea that women's language use is part of what contributes to men's dominance over them. Although Lakoff herself and others would frame matters somewhat differently now, looking also at men's language use and at attitudes toward different speech styles, there continues to be considerable research suggesting that ways of speaking often play a role in maintaining male dominance (see, e.g., Henley and Kramarae 1991). Much of this research, however, also emphasizes the advantages that can accrue to women who have developed certain kinds of interactionally useful speech skills that

many men lack (Tannen 1994 makes this kind of point, as does Holmes 1995).

As the discussion of these questions suggests, the distinction between these two families of questions is not as clearcut as it might at first seem. To talk in this way is to suppose that gender and language are somehow quite separate phenomena and that our goal is to articulate their connections. While useful for certain purposes, this supposition can mislead us. In particular, it does not come to grips with the rooting of both language use and gender in situated social practices, which involve the jointly orchestrated actions of groups of cognitive agents. Gal (1991) and Eckert and McConnell-Ginet (1992) have argued that the real interaction of gender and language, their coevolution, can be best illumined by examining both language and gender as they are manifest in social practice.

Both language and gender are of course also partly biological phenomena. In the view of most linguists and many other cognitive scientists, the possibilities for human language systems are very much constrained by the biologically given language capacity. There are, however, not only parameters along which language systems can vary; there are also many different ways that communities can (and do) use language in their activities. And gender is linked to sexual difference. Biological sex itself, however, is far less dichotomous than many assume (English speakers show little tolerance for gradations between "female" and "male," insisting on classifying intersexed people in one or the other category; see Bing and Bergvall 1996), and there is considerable intrasex variation on many dimensions (including cognitive functioning as well as physical and behavioral attributes), even among those whose classification seems biologically quite unproblematic. There is an extraordinary amount of sociocultural work done to elaborate femaleness and maleness, to construct gender identities (not limited to two in all cultures) and also gender relations. Most of this work is at the same time also shaping other aspects of social identities and relations (e.g., ethnicity, race, class). Because language use is an integral component of most social practices, language is necessarily a major instrument of the sociocultural construction of gender. Thus an emerging research goal is exploration of the linguistic practices through which sex and gender are elaborated in a wide range of different communities (see, e.g., Hall and Bucholtz 1996). Although rather little of this research has a cognitive orientation and some interesting work is not really empirical or scientific, it raises many important questions for cognitive scientists to address.

Language and Modularity

See MODULARITY AND LANGUAGE

Language and Thought

Perhaps because we typically think in words, language and thought seem completely intertwined. Indeed, scholars in various fields—psychology, linguistics, anthropology—as well as laypeople have entertained these questions: Is thought possible without language? Does the structure of our language shape our thinking? Does our perception/cognition shape the structure of language? Are our abilities to learn and use language part of our general intelligence?

Is thought possible without language? Research on babies and children who have not yet acquired any language suggests that little babies muse over rather important things. For instance, 3- to 4-month-old babies seem to think that each object occupies its own space and so one solid object cannot go through another solid object. Five-month-old babies can do simple arithmetic. If they see a hand carrying two objects to the back of a screen and reappearing empty-handed, they seem to expect two more objects behind the screen than before this addition event. When developmental psychologists such as Renee Baillargeon and Karen Wynn concocted "magic shows" that violated fundamental principles of physics or numbers by clever subterfuge, preverbal babies showed surprise by staring at the scenes longer than they would at physically plausible scenes. Other evidence for thought without language came from profoundly deaf children who had not been exposed to any sign language. Susan Goldin-Meadow, a psychologist, found several such children growing up in loving families. They invented their own signs and gestures to communicate their thoughts and needs (e.g., talking about shoveling snow, requesting someone to open a jar).

Still other evidence for thinking without language has to do with mental images. Scientists and writers as well as visual artists have claimed that some of their most creative work was inspired by their mental images. One of the best known examples, perhaps, is James Watson and Francis Crick's discovery of the double helix structure of DNA. Albert Einstein was another self-described visual thinker. It seems, then, brilliant as well as mundane thought is eminently possible without language.

Does language shape or even dictate thought? The linguistic anthropologist Edward SAPIR argued, "No two languages are ever sufficiently similar to be considered as representing the same social reality." His student, Benjamin Lee Whorf, asserted, "The world is presented in a kaleidoscopic flux of impressions which has to be organized . . . largely by the linguistic systems in our minds." The Sapir-Whorf hypothesis has two tenets: LINGUISTIC RELATIVITY HYPOTHESIS (i.e., structural differences between languages will generally be paralleled by nonlinguistic cognitive differences) and linguistic determinism (i.e., the structure of a language strongly influences or fully determines the way its native speakers perceive and reason about the world).

John Lucy, an anthropologist, has written about language differences associated with perceptual differences. For example, speakers of languages with different basic color vocabularies might sort nonprimary colors (e.g., turquoise, chartreuse) in slightly different ways. But such subtle effects were hardly what Sapir and Whorf had in mind when they wrote about how language might be related to, or might even shape, its speakers' worldview (e.g., time, causality, ontological categories).

One notable exception is the psychologist Alfred Bloom's intriguing claim that the lack of a distinct counterfactual marker in the Chinese language might make it difficult for Chinese speakers to think counterfactually—that is, to think hypothetically about what is not true (e.g., If Plato had been able to read Chinese, he could have . . .). Upon close scrutiny, however, Chinese speakers' purported difficulty in understanding Bloom's counterfactual stories disappeared when researchers such as Terry Au and Lisa Liu rewrote those stories in idiomatic Chinese with proper counterfactual markers. With 20/20 hindsight, perhaps we should have realized that Bloom's initial finding had to be too fascinating to be true. Note that when we feel lucky and realize that things could have turned out badly but didn't, or when we regret having done something and wish that we had acted differently, we have to think counterfactually. How can something so fundamental and pervasive in human thinking be difficult in any human language?

Despite early disappointing efforts to uncover evidence for language shaping thought, a "Whorfian Renaissance" seems to be in the making. For instance, the anthropologist Stephen Levinson has reported interesting variations in spatial language across cultures (see LANGUAGE AND CULTURE). However, how each language carves up space seems to be principled—influenced by the direction of gravity (e.g., up, down), human perception (e.g., near, far, front, back) and so forth—rather than random or arbitrary. Moreover, there is as yet no evidence for fundamental differences in spatial cognition associated with linguistic variations. For example, unlike some Papuan languages, English has no simple word meaning "that far away up there." Are English speakers less capable than Papuan speakers to construe such a location? Probably not. While the jury is still out for the Sapir-Whorf hypothesis, it is probably safe to say that important aspects of our worldview are unlikely to be at the mercy of arbitrary aspects of our language.

How about the other way around? By virtue of being human, we tend to perceive, organize, and reason about the world in certain ways. Do languages build upon our perceptual categories and conceptual organization? Consider color perception. Four-month-old babies prefer looking at primary colors (red, blue, green, yellow) to colors near the boundaries of primary colors; toddlers can identify primary colors better than nonprimary ones. Interestingly, anthropologists Brent Berlin and Paul Kay found that, if a language has fewer than five basic color words, it would include red, blue, green, and yellow (in addition to black and white). Nonprimary colors such as brown, pink, orange, and purple are encoded only in languages that have encoded the four primary colors (see COLOR CATEGORIZATION). Perceptual salience, then, seems to shape the encoding of color words rather than the other way around.

Our cognition also seems to shape our language. For instance, when asked in their native language "Paul amazes Mary. Why?" and "Paul admires Mary. Why?", the psychologist Roger Brown found that both Chinese and English speakers tended to talk about something amazing about Paul and something admirable about Mary. Note that in English, "amazing" and "admirable"—rather than "amazable" and "admiring"—are entrenched adjectives for describing people's disposition. These cognitive causal schemas, then, might be a universal and may have influenced the derivation of dispositional adjectives in English, rather than the other way around.

One more central issue in the study of language and thought: Are our abilities to learn and use language part of our general intelligence? Or, are they subserved by a special "language faculty"? Recent findings on language-specific impairments (i.e., language delay or disorder experienced by children who are not hearing or cognitively impaired) and Williams syndrome (i.e., extreme mental retardation with almost intact language abilities) suggest that cognition and language can be decoupled (see LANGUAGE IMPAIRMENT, DEVELOPMENTAL). In short, although language and thought might be quite modular (see also MODULARITY OF MIND), there is some evidence for our cognition and perception shaping the evolution of our language. Evidence for influence in the opposite direction, however, seems more elusive.

Language Impairment, Developmental

It has been estimated that approximately thirteen percent of all children have some form of language impairment (Beitchman et al. 1986a). The most common known causes of developmental language impairments are hearing loss (including intermittent hearing loss resulting from chronic otitis media), general MENTAL RETARDATION, neurological disorders such as lesions or epilepsy affecting the auditory processing or language areas of the brain, and motor defects affecting the oral musculature. Many other developmental disorders, such as pervasive developmental disability (including AUTISM), attention deficit disorder, central auditory processing disorder, and Down's syndrome, may include delay in language development. In addition to these known causes of developmental language impairment, a recent epidemiological study of monolingual English-speaking kindergarten children in the United States found that approximately 8 percent of boys and 6 percent of girls have a significant developmental language impairment of unknown origin, referred to as specific language impairment (SLI; Tomblin et al. 1997). This epidemiological study also showed that the clinical identification of language impairments remains low. Only 29 percent of the parents of children identified as having SLI had previously been informed that their child had a speech or language problem.

The differential diagnosis of developmental language impairments is based on behavioral evaluations that include audiological, neurological, psychological, and speech and language testing. Developmental language disorders are divided into two basic categories, expressive language disorder and mixed receptive-expressive language disorder, a disorder encompassing both language comprehension and production deficits (DSM-IV. 1994). Comprehension or production problems may occur within one or more of the components of language, including PHONOLOGY, MORPHOLOGY, SEMANTICS, or SYNTAX. Problems with PRAGMATICS, that is, conversational skills, also occur frequently. A high proportion of children with developmental language disorders also have concomitant speech articulation defects, that is, they have difficulty clearly and correctly producing one or more of the speech sounds of their language. However, speech articulation defects and developmental language impairments can occur independently of each other.

Developmental language impairment has been shown to be a risk factor for other childhood disorders. For example, epidemiological studies showed that children referred to child guidance clinics for a variety of social and emotional conditions were found to have a higher-than-expected incidence of developmental language disorders (Beitchman et al. 1986b). Conversely, children diagnosed with developmental language disorders also have been found, upon examination, to have a preponderance of behavioral and emotional disorders (Cantwell, Baker, and Mattison 1979). Longitudinal research studies that have followed children with early developmental language impairments prospectively from the preschool though elementary school years have demonstrated a striking link between early developmental language impairments and subsequent learning disabilities, especially DYSLEXIA, a developmental reading disability (Aram et al. 1984; Bishop and Adams 1990; Rissman, Curtiss, and Tallal 1990; Catts 1993). Research that has compared children classified as SLI with those classified as dyslexic has shown that both groups are characterized by a variety of oral language deficits, specifically phonological analysis deficits (Liberman et al. 1974; Wagner and Torgeson 1987; Shankweiler et al. 1995). Whether the phonological deficit derives from speech-specific mechanisms, or from more basic acoustic processing deficits, has been the focus of considerable research and theoretical debate.

Phonological processing deficits are generally accompanied by central auditory processing disorders, particularly in the areas of AUDITORY ATTENTION and serial memory. These processing problems may result from a more basic impairment in the rate of neural information processing, specifically a severe backward masking deficit (Tallal, Miller, and Fitch 1993a; Tallal et al. 1993b; Wright et al.

1997). Tallal and colleagues have shown that children with phonologically based speech, language, and READING disorders need significantly more neural processing time (hundreds of milliseconds instead of tens of milliseconds) between brief, rapidly successive acoustic cues in order to process them correctly. This slowed processing rate has a particularly detrimental effect on phonological processing. Many acoustic changes occurring within syllables and words, necessary to distinguish the individual phonological elements (speech sounds), occur within the tens-of-milliseconds time window. Research has demonstrated that perception of those speech syllables that incorporate rapidly successive acoustic cues is most problematic for these children (see Tallal et al. 1993a for review).

These findings linking slow auditory processing rate and phonological processing deficits to developmental language and reading disorders have recently led to the development of novel remediation strategies for the treatment of developmental language-learning impairments. In a treatment-controlled study, using speech that was acoustically computer modified to extend and amplify the rapidly successive components, it was shown that intensive, individually adaptive daily training with computer-based exercises resulted in highly significant gains in auditory processing rate, speech discrimination, and language comprehension of syntax and grammar (Merzenich et al. 1996; Tallal et al. 1996).

There also have been considerable advances made in understanding the specific linguistic deficits of these children. Research has demonstrated particular difficulty with components of syntax and morphology (see Leonard 1998 for review). The results of longitudinal studies have shown, however, that children with developmental language impairments develop the linguistic structures of language along a similar linguistic trajectory to that observed in normal younger children. There is little evidence that these children make linguistic errors that are deviant or substantially different from younger children at the same stage of language development. Rather, children with language impairments take much longer to progress through the stages of normal language development (Curtiss, Katz, and Tallal 1992). A similar pattern of delay, rather than deviance, occurs across most populations of children with developmental language impairment. Looking cross-linguistically at children with developmental language impairments learning different languages in different countries, it also has been shown that whatever linguistic structures are unstressed or of weak phonetic substance in a particular language are the most difficult for children to learn and also the most delayed in children with language impairments (Leonard 1992). That the same order of development occurs across populations and language environments gives strong support that there is a potent metric of sheer difficulty (whether representational or perceptual) that is imposed on the learning of linguistic structures and contents.

There is growing evidence from family and twin studies that developmental language impairments may aggregate in families and may be genetically transmitted. Twin studies have shown a high concordance rate (heritability) for measures of phonological analysis (Bishop, North, and Donlan 1995). As a group, infants born into families with a positive history of developmental language impairment demonstrate longer processing times than matched infants born into families with a negative family history for SLI. When followed prospectively, the processing rate established at six months of age has been shown to predict the rate of language development, with the infants showing impaired processing rate subsequently being most likely to be delayed in language development (Benasich and Tallal 1996). It also has been found that adults with dyslexia, or who have a family history of language-learning impairments, show significant psychoacoustic deficits, particularly a slower auditory processing rate. These adults also show poorer phonological analysis abilities when compared with matched adults who are family history–negative for developmental language learning disorders (Tomblin, Freese, and Records 1992).

Recently, brain imaging technologies also have been used to examine the neurobiological basis of developmental language impairment. Electrophysiological studies support the results of behavioral studies showing specific deficits in acoustic analysis and phonological processing (Kraus et al. 1995). Results from MAGNETIC RESONANCE IMAGING (MRI) show that the pars triangularis (Broca's area) is significantly smaller in the left hemisphere of children with SLI and that these children are more likely to have rightward asymmetry of language structures. The opposite pattern is seen in children developing language normally (Jernigan et al. 1991; Gauger, Lombardino, and Leonard 1997).

Language, Innateness of

See INNATENESS OF LANGUAGE; LANGUAGE ACQUISITION; PARAMETER SETTING APPROACHES TO ACQUISITION, CREOLIZATION, AND DIACHRONY

Language, Neural Basis of

Investigations into the neural basis of language center around how the brain processes language. To do this, we must understand that language is a most complex function, one that encompasses numerous subprocesses, including the recognition and articulation of speech sounds, the comprehension and production of words and sentences, and the use of language in pragmatically appropriate ways. Underlying and interacting with these are also the functions of ATTENTION and MEMORY. All contribute in special ways to our ability to process language, and each may, in fact, be handled differently by the human brain. Classic neurolinguistic theories, developed over a hundred years ago, have suggested that certain brain areas play specific roles in the process of language. Since then, modern techniques are offering us new data on what these areas might actually do and how they might contribute to a network of brain areas that collectively participate in language processing.

Most of our information about how the brain processes language has been gleaned from studies of brain-injured

patients who have suffered strokes due to blockage of blood flow to the brain or from gunshot wounds to the head during wartime. In these cases, the language deficits resulting from these injuries have been compared to the areas of the brain which became lesioned.

In the past, such investigations had to rely on autopsy data obtained long after the behavioral data had been collected. These days, structural neuroimaging using computed tomography (CT) and MAGNETIC RESONANCE IMAGING (MRI) can help us view the location and extent of the brain lesion while behavioral data can be collected concurrently. Modern electrophysiology studies as well as functional neuroimaging with POSITRON EMISSION TOMOGRAPHY (PET) and functional magnetic resonance imaging (fMRI) are now being conducted with normal non–brain-injured subjects and are also beginning to assist in our understanding of the brain mechanisms involved in language.

Classic descriptions of the brain areas involved in language have largely implicated those in the left cerebral hemisphere known as Broca's area, Wernicke's area, and the connecting bundle of fibers between them, the arcuate fasciculus. These descriptions began in 1861 when Pierre Paul BROCA described his examination of a chronically ill patient with an unusual speech deficit that restricted his ability to communicate (Broca 1861). Whenever the patient attempted to speak, his utterance was reduced to the single recurring syllable "tan," though he could intone it in different ways to change its meaning. When the patient died a few days after the examination, Broca discovered a lesion involving the posterior inferior frontal gyrus (i.e., the back part of the lowest section within the frontal lobe). Though Broca never cut the brain to examine the extent of this lesion, he suggested that this specific region was responsible for the articulation of speech. The area later became known as Broca's area and the behavioral deficit as Broca's APHASIA.

In 1874, Carl Wernicke reported on two patients with a language disturbance that was very different from the one Broca described (Wernicke 1874). These patients had difficulty with what Wernicke described as the "auditory memory for words." In short, they had trouble understanding spoken language, even though their own speech was fluent and unencumbered. Wernicke examined the brain of one of these patients at autopsy and thought that the most significant area of damage in this patient was in the superior temporal gyrus (i.e., the top part of the temporal lobe). He concluded that this region was crucial to the purpose of language comprehension, and subsequently the disorder in language comprehension was referred to as Wernicke's aphasia. Wernicke also developed an elaborate model of language processing that was revived by the neurologist Norman GESCHWIND in the 1960s, and which has formed the basis of our current investigations (Geschwind 1965, 1972).

The Wernicke-Geschwind model holds that the comprehension and formulation of language is dependent on Wernicke's area, after which the information is transmitted over the arcuate fasciculus to Broca's area where it can be prepared for articulation. In general, data from patients with lesions in these areas support this model. Those patients with injuries that involve temporal lobe structures have easily articulated speech but do not always understand spoken or written language. Those with frontal lobe lesions generally have speech or articulation difficulty but tend to understand simple sentences fairly well.

Like most theories, this one has its problems. First, the correlation between lesions to Broca's area and language deficits is far from perfect. Lesions to Broca's area alone never result in a persisting Broca's aphasia. The language deficits that are seen in these patients during the first few weeks after the injury always resolve into a mild or nonexistent problem (Mohr 1976). Several patients have also been reported that suffer from a persisting Broca's aphasia with no involvement of Broca's area whatsoever (Dronkers et al. 1992). Furthermore, Broca's original patient, on whom a significant part of the model is based, had multiple events that led to his aphasia. Since Broca never cut the brain, he could not have seen that other brain areas were also affected by these injuries.

Similar discrepancies can be seen with regard to Wernicke's area. Lesions to this area alone do not result in a persisting language comprehension problem, nor do all chronic Wernicke's aphasia patients have lesions in Wernicke's area (Dronkers, Redfern, and Ludy 1995). In fact, the data that originally predicted the participation of Wernicke's area in language comprehension were based on Wernicke's two problematic cases. One of these was noted to have resolved the comprehension problem after seven weeks and was never even brought to autopsy, while the second was a demented patient with numerous other pathological changes besides just those in the superior temporal gyrus. Current findings are showing that lesions must encompass far more than just the inferior frontal gyrus or superior temporal gyrus to produce the respective chronic Broca's or Wernicke's aphasia.

Still, those who study language and the brain have clung to traditional theory for several good reasons. First, there have been no good substitute theories that can explain as much of the data as the classic theories have been able to do. Most aphasic patients do show the pattern of behaviors described by Broca, Wernicke, and Geschwind. Furthermore, physicians and speech pathologists have found it easy to diagnose and treat their aphasic patients within this framework. While the original cases may have been faulty, the theories that resulted have served to answer most of the questions that surround these patients.

Modern techniques and technologies may gradually be changing the classic model. Most of these contributions concern the roles of traditional language areas, the possibility that other brain areas might also be important, and the likelihood that language processing involves a network of brain areas that contribute in individual but interactive ways. Being so new, these conclusions have not yet made it into neuroscience or linguistics textbooks. Still, it is clear that the classic model, despite its important contributions to understanding language mechanisms in the brain, will see some revision in the next decade.

Take the elusive role of Broca's area as an example. Though Broca thought it was concerned only with the articulation of speech, it has since been associated with many functions. Work in the 1970s included the manipulation of grammatical rules as a function of Broca's area, since those patients with a "Broca's aphasia" and lesions encompassing

Broca's area had difficulty in using and comprehending grammatical information (Zurif, Caramazza, and Meyerson 1972). Recent functional imaging work with PET has suggested that it may play a role in short-term memory for linguistic information (Stromswold et al. 1996). Still other PET studies conclude that it is part of an articulatory loop (Paulesu, Frith, and Frackowiak 1993), while those that involve electrically stimulating the exposed brain during neurosurgery specify it as an end stage for motor speech (Ojemann 1994).

Lesion studies, coupled with high-resolution structural neuroimaging, continue to give us new information regarding other brain regions that might participate in speech and language. One new area that may participate in the articulation of speech is deep in the insula, the island of cortex that lies beneath the frontal, temporal, and parietal lobes. A recent study used computerized lesion reconstructions to find that a very specific area of the insula (high on its precentral gyrus) was lesioned in twenty-five stroke patients who all had a disorder in coordinating the movements for speech articulation (Dronkers 1996). Nineteen stroke patients without this particular disorder had lesions that spared the same area.

The insula is also lesioned in the majority of cases of Broca's aphasia (Vanier and Caplan 1990). This is not surprising, since Broca's aphasia patients have trouble in coordinating articulatory movements in addition to their other language deficits. Even Broca's original case had a large lesion that included the insula, as confirmed by a CT scan of the preserved brain done a hundred years later (Signoret et al. 1984). The fact that Broca's aphasia requires a large lesion that involves multiple brain areas supports the idea that many different regions must participate in the normal processing of language.

The functional imaging literature has given us new insight into areas of the brain that are actively engaged during a language task. Some of these areas would not have been detected from traditional lesions studies because the vascular supply to the brain is more susceptible to stroke in certain areas than others. For example, the supplementary motor area is consistently activated in functional imaging studies involving speech, but strokes to this area are relatively uncommon or do not come to the attention of those who study or treat language disorders. The same holds for posterior temporal areas that appear to be active in word form recognition. Also, functional imaging studies can signal the involvement of the right hemisphere in a given speech or language task, in addition to activation of traditional areas within the left hemisphere.

One area of the frontal lobe that has received a fair amount of attention in the functional imaging literature is the left inferior prefrontal cortex, the area of the brain in front of and below Broca's area. Peterson and colleagues found it to be activated in semantic retrieval tasks where subjects generated verbs associated with nouns presented to them (Peterson et al. 1988). Others have also found it involved in tasks requiring word retrieval or semantic encoding (e.g., Demb et al. 1995; Warburton et al. 1996). Still, it is not clear whether the role played by this area is one that is truly related to language or whether it is related to attention or executive functioning and merely plays an assistive role in language

processing. Patients with lesions to this area do show deficits on constrained verbal fluency tasks in which they must generate words that begin only with certain letters or belong only to certain semantic categories, yet these patients are not obviously aphasic. Thus, the true contribution of this area to language must still be determined.

The basal temporal area is another region that was not implicated in classic models. This region lies at the base of the temporal lobe and is not usually affected by stroke, though it can be the source of epileptic seizure activity. Some epileptic patients have had electrodes temporarily placed under the skull directly on the cortex to monitor seizure activity. These electrodes can also deliver small electrical charges to the cortex that interfere with normal functioning. When placed over the basal temporal area, stimulation disrupts patients' ability to name objects, implying that this area is somehow involved in word retrieval (Luders et al. 1986). In a different kind of study, an epileptic patient with a seizure focus in the basal temporal area had an aphasia associated with the duration of the seizures that resolved once the seizures were stopped (Kirshner et al. 1995). All these data are derived from a different source than are most of the data from stroke patients, but still provide strong evidence that this area may also be important for normal language processing.

There are several other areas that may also contribute to language in their own way. The cingulate gyrus has been implicated in word retrieval, possibly because of its role in maintaining attention to the task. The anterior superior temporal gyrus, just in front of primary auditory cortex, may also play a role in sentence comprehension because of its rich connections to hippocampal structures important in memory. The fact that there are so many new brain regions emerging in modern lesion and functional imaging studies of language suggests that the classic Wernicke-Geschwind model, though useful for so many years, is now seen as oversimplified. Areas all over the brain are recruited for language processing; some are involved in lexical retrieval, some in grammatical processing, some in the production of speech, some in attention and memory. These new findings are still too fresh for any overarching theories to have developed that might explain how these areas interact. Future imaging and electrophysiological studies will undoubtedly show us not only the areas involved in language but also the recruitment of these areas at any stage of the process, the manner in which they interact, the time course of these activities, and the change in activation and allocation of resources relative to task complexity. The study of the neural mechanisms of language is evolving rapidly in conjunction with advances in the technologies that allow us to study it.

Other avenues of interest that are being pursued include the intriguing possibility that the brain may choose where to store lexical information depending on the semantic category to which the word belongs (Damasio et al. 1996; Martin et al. 1996). Another is that the brain might store and process language in different ways depending on the modality of acquisition (auditory vs. visual) (Neville, Mills, and Lawson 1992). Others question whether the brain mechanisms involved in language may differ for men and women,

left-handers and right-handers, or monolinguals and bilinguals. These are all challenges for continued exploration whose findings are shaping contemporary models of language processing.

Language of Thought

The language of thought hypothesis is an idea, or family of ideas, about the way we represent our world, and hence an idea about how our behavior is to be explained. Humans are marvelously flexible organisms. The commuter surviving her daily trip to New York, the subsistence agriculturalist, the inhabitant of a chaotic African state all thread their different ways through the maze of their day. This ability to adapt to a complex and changing world is grounded in our mental capacities. We navigate our way through our social and physical world by constructing an inner representation, an inner map of that world, and we plot our course from that inner map and from our representation of where we want to get to. Our capacity for negotiating our complex and variable environment is based on a representation of the world as we take it to be, and a representation of the world as we would like it to be. In the language of FOLK PSYCHOLOGY— our everyday set of concepts for thinking about ourselves and others—these are an agent's beliefs and desires. Their interaction explains action. Thus Truman ordered the bombing of Japan because he wanted to end World War II as quickly as possible, and he believed that bombing offered his best chance of attaining that end.

We represent—think about—many features of our world. We have opinions on politics, football, food, the best way to bring up children, and much more. Our potential range of opinion is richer still. You may not have had views on the pleasures of eating opossum roadkills, but now that you are prompted, you quickly will. This richness of our cognitive range is important to the language of thought hypothesis. Its

defenders take our powers of MENTAL REPRESENTATION to be strikingly similar to our powers of *linguistic representation.* Neither language nor thought are stimulus bound: we can both speak and think of the elsewhere and the elsewhen. Both language and thought are counterfactual: we can both speak and think of how the world might be, not just how it is. We can misrepresent the world; we can both say and think that it is infested by gods, ghosts, and dragons. Moreover, thoughts and sentences can be indefinitely complex. Of course, if sentences are too long and complex, we cease to understand them. But this limit does not seem intrinsic to our system of linguistic representation but is instead a feature of our capacities to use it. Under favorable circumstances, our capacity to handle linguistic complexity extends upwards; in unfavorable circumstances, downwards. Moreover, the boundary between the intelligible and the unintelligible is fuzzy and not the result of hitting the system's walls. The same seems true of mental representation. These similarities are no surprise. Although there may be thoughts we cannot express, surely there are no utterances we cannot think.

The power of linguistic representation comes from the organization of language. Sentences are structures built out of basic units, words or morphemes. The meaning of the sentence—what it represents—depends on the meaning of those words together with its structure. So when we learn a language, we learn the words together with recipes for building sentences out of them. We thus acquire a representational system of great power and flexibility, for indefinitely many complex representations can be constructed out of its basic elements. Since mental representation exhibits these same properties, we might infer that it is organized in the same way. Thoughts consist of CONCEPTS assembled into more complex structures. A *minimal* language of thought hypothesis is the idea that our capacities to think depend on a representational system, in which complex representations are built from a stock of basic elements; the meaning of complex representations depend on their structure and the representational properties of those basic elements; and the basic elements reappear with the same meaning in many structures. This representational system is "Mentalese."

This minimal version of the language of thought hypothesis leaves many important questions open. (1) Just how "languagelike" is the language of thought? Linguists emphasize the complexity and abstractness of natural-language sentence structure. Our thoughts might be complex structures built out of simple elements without thought structures being as complex as those of natural language. Mentalese may have no equivalent of the elaborate MORPHOLOGY and PHONOLOGY of natural languages. Natural languages probably have features that reflect their history as spoken systems. If so, these are unlikely to be part of Mentalese. (2) The minimal hypothesis leaves open the nature of the basic units. Perhaps the stock of concepts is similar to the stock of simple words of a natural language. Just as there are words for tigers and trucks, there are concepts of them amongst the basic stock out of which thoughts are built. But the minimal version is also compatible with the idea that the basic units out of which complexes are built are

nothing like the semantic equivalent of words. Thus the concept "tiger" might itself be a complex semantic structure. (3) The minimal version leaves open the relationship between Mentalese and natural languages. Perhaps only learning a natural language powers the development of Mentalese. Perhaps learning a natural language enhances and transforms the more rudimentary language of thought with which one begins. Perhaps learning a natural language is just learning to produce linguistic representations that are equivalent to those that can already be formulated in Mentalese.

Jerry Fodor goes beyond the minimal language of thought hypothesis. Fodor argues for Mentalese not just from intentional psychology but from cognitive psychology. He argues that our best accounts, and often our only accounts, of cognitive abilities presuppose the existence of a rich, language-like internal code. So, for example, any account of rational action presupposes that rational agents have a rich enough representational system to represent a range of possible actions and possible outcomes. They must have the capacity not just to represent actual states of the world but possible ones as well. Most importantly, learning in general, and concept acquisition in particular, depends on hypothesis formation in the inner code. You cannot learn the concept "leopard" or the word *leopard* unless you already have an inner code in which you can formulate an appropriate hypothesis about leopards. So Fodor thinks of Mentalese as semantically rich, with a large, word-like stock of basic units. For example, he expects the concepts "truck," "elephant," and even "reactor" to be semantically simple. Moreover, this large stock of basic units is innate. Experience is causally relevant to an agent's conceptual repertoire. But we do not learn our basic concepts from experience. Concept acquisition is more like the development of secondary sexual characteristics than like learning the dress code at the local pub. So Mentalese is independent of any natural language we speak. The expressive power of natural language depends on the expressive power of Mentalese, not vice versa.

The language of thought hypothesis has been enormously controversial. One response focuses on the inference from intentional psychology to the language of thought. For example, Daniel Dennett has long argued that the relationship between an agent's intentional profile—the beliefs and desires she has—and her internal states is likely to be very indirect. In a favorite illustration, he asks us to consider a chess-playing computer. These play good chess, so we treat them as knowing a lot about the game, as knowing, for example, that the passed-rook pawn is dangerous. We are right to do so, even though there is no single causally salient inner state that corresponds to that belief. Dennett thinks that the relationship between our beliefs and our causally efficacious inner states is likely to be equally indirect. I think this argument is best seen as a response to Fodor's strong version of the language of thought hypothesis. The same is true of many other critical responses, for these often focus on Fodor's denial that learning increases the expressive capacity of our thoughts. The Churchlands, for example, have taken this to be a reduction of the language of thought hypothesis itself, but if anything, it is a

reduction only of Fodor's strong version of it. Connectionist models of cognition, on the other hand, do seem to be a threat to any version of a language of thought hypothesis, for in connectionist mental representation, meaning is not a function of the structure plus the meaning of the atomic units (see CONNECTIONISM, PHILOSOPHICAL ISSUES).

Language Processing

Language Production

Language production means talking, but not merely that. When people talk, it is usually because they have something to say. Psycholinguistic research on language production concerns itself with the cognitive processes that convert nonverbal communicative intentions into verbal actions. These processes must translate perceptions or thoughts into sounds, using the patterns and elements of a code that constitutes the grammar of a language. For theories of language production, the goal is to explain how the mind uses this code when converting messages into spontaneous speech in ongoing time. This requires an explanation of the action system that puts language knowledge to use.

The action system for language production has a COGNITIVE ARCHITECTURE along the lines shown in figure 1. Imagine a speaker who wishes to draw a listener's attention to a rabbit browsing in the garden. The process begins with a communicative intention, a *message,* that stands at the interface between thought and language. Little is known about the content or structure of messages, but they are assumed to include at least conceptual categorizations (in figure 1, tacit rabbit-knowledge) and the information needed for making distinctions such as tense, number, aspect, and speaker's perspective. Less certain is whether messages habitually include different kinds of information as a function of the language being spoken, along the lines proposed in the Sapir-Whorf hypothesis (see LINGUISTIC RELATIVITY HYPOTHESIS; Slobin 1996).

Of primary interest to contemporary theories of production are the processing components dubbed *grammatical* and *phonological* in figure 1 (following Levelt 1989). These are the processes immediately responsible for recruiting the linguistic information to create the utterances that convey messages. Grammatical encoding refers to the cognitive mechanisms for retrieving, ordering, and adjusting words for their grammatical environments, and phonological encoding refers to the mechanisms for retrieving, ordering, and adjusting sounds for their phonological environments.

The motivation for separating these components comes from several lines of evidence for a division between word-combining and sound-combining processes. Speech errors suggest that there are two basic sorts of elements that are manipulated by the processes of production, roughly corresponding to words and sounds (Dell 1995). So-called tip-of-the-tongue states (the familiar frustration of being unable to retrieve a word that one is certain one knows) can carry word-specific grammatical information, in the absence of sound information (Miozzo and Caramazza 1997; Vigliocco, Antonini, and Garrett 1997). Electrophysiological evidence also suggests that grammatical information about words is accessible about 40 ms before information about sounds (van Turennout, Hagoort, and Brown 1998). Finally, the arbitrariness of the linguistic mapping from meaning to sound creates a computational problem that can only be solved by a mediating mechanism (Dell et al. 1997). These and other observations argue that there are distinct grammatical and phonological encoding mechanisms.

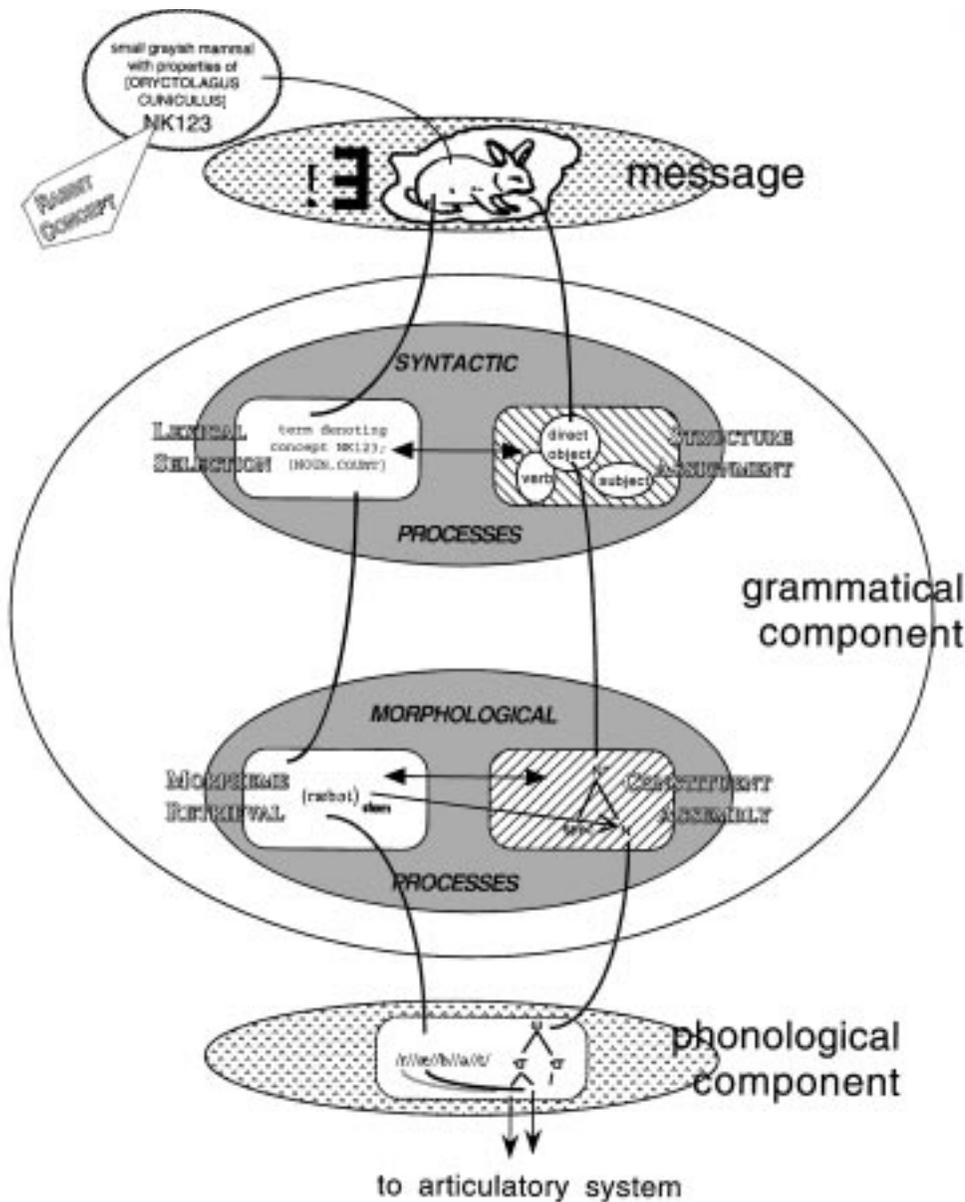
Grammatical encoding Adult speakers of English know between 30,000 and 80,000 words. The average for high-school graduates has been estimated at 45,000 words. These words can be arranged in any of an infinite number of ways that conform to the grammar of English. The ramifications of this can begin to be appreciated in the number of English sentences with 20 or fewer words, which is about 10^{30}. Using these resources, speakers must construct utterances to convey specific messages. They normally do so in under two seconds, although disruptions are common enough that average speakers spend about half of their speaking time in *not* speaking—hemming, hawing, and pausing between three and twelve times per minute (Goldman-Eisler 1968). These


Figure 1. A cognitive architecture for language production.

disfluencies reflect problems in retrieving a suitable set of words and arranging them into a suitable syntactic structure. What is suitable, of course, is not merely a matter of grammaticality (though it is also that) but of adequacy for conveying a particular message to particular listeners in particular places and times.

Lexical selection and retrieval are integral to grammatical processing because of the kinds of information that words carry about their structural and positional requirements. In everyday language use, words are rarely produced in isolation. Instead, they occupy places within strings of words, with their places determined in part by their grammatical categories (e.g., in most English declarative sentences, at least one noun will precede a verb) and their MORPHOLOGY determined in part by their positions with respect to other words (e.g., a present-tense English verb accompanying a

singular subject will be inflected differently than the same verb accompanying a plural subject: *A razor cuts,* whereas *Scissors cut*). Thus, speakers must recover information about grammatical class and morphology.

Lexical selection involves locating a lexical entry (technically, a *lemma*) that adequately conveys some portion of a message, ensuring that there exists a word in one's mental lexicon that will do the job. A rough analogy is looking for a word in a reverse dictionary, which is organized semantically rather than alphabetically. If the desired meaning is listed in the dictionary with a single word that expresses the sense, there is an appropriate word to be had in the language; if not, the search fails. The mental lexicon is presumably accessible in a comparable fashion, permitting speakers to determine whether they know a word that conveys the meaning they intend. Most English speakers, for

example, will find at least one lemma for their concept of a member of the family *Oryctolagus cuniculus.*

Locating a lemma yields basic information about how a word combines with other words. This corresponds to information about grammatical class (noun, verb, adjective, etc.) and other grammatical features that control a word's combinatorial privileges and requirements (e.g., nouns must be specified as mass or count, and if count, as singular or plural; verbs must be specified as intransitive or transitive, and if transitive, as simple or ditransitive, etc.; cf. LEXICON). The lemma for an instance of *Oryctolagus cuniculus,* for example, is a noun, count, and singular. These features in turn affect the determination of syntactic functions such as subject phrases, predicate phrases, and their arrangement (cf. SYNTAX).

Once a lemma is found, the word's morphology (technically, its *lexeme*) may have to be adjusted to its syntactic environment. In connected speech, this will encompass inflectional processes (e.g., making a verb singular or plural). Lexical retrieval processes yield an abstract specification of the morphological structure of the selected word. So, retrieving the lexeme for the count noun that denotes a member of the family *Oryctolagus cuniculus* should yield a word stem for *rabbit.*

The role of active morphological processes in language use is currently disputed in some quarters. The issue is whether regularly inflected words are stored and retrieved from memory in the same way as uninflected words (Seidenberg 1997) or require a separable set of specifically inflectional operations (Marslen-Wilson and Tyler 1997). Although this debate has been confined primarily to research on word recognition, logically comparable issues arise regarding language production. In production, however, it may be harder to account for the available data with passive retrieval mechanisms (see Bock, Nicol, and Cutting, forthcoming).

Phonological encoding Words can be comfortably articulated at a rate of four per second, calling on more muscle fibers than may be required for any other mechanical performance of the human body (Fink 1986). Yet errors in the production of speech sounds are rare, only occurring once in every 5,000 words or so (Deese 1984). Controlling the activity requires some specification of phonological segments (/r/, /æ/, /b/, etc.), syllabification, and metrical structure. The broad outlines of phonological encoding are sketched similarly in current theories (Dell et al. 1997; Levelt, Roelofs, and Meyer, forthcoming). Counter to the intuition that words are stored as wholes, sound segments are actually assembled into word forms during the encoding process. Consonantal and vocalic segments must be selected and assigned to positions within syllabic frames. Additionally, the syllables and sounds must be integrated into the stream of speech: In a sequence of words such as *rabbit in,* the /t/ in rabbit will be produced differently than it is in *rabbit by.* One implication is that a description of the sound segments in an isolated word is insufficient to explain the word's form in connected speech.

Where theories of word production diverge is in their view of the relationship between phonological encoding and the higher level processes of lexical selection and retrieval.

The *discrete-stage* view (Levelt, Roelofs, and Meyer, forthcoming) argues that each step of the retrieval process is completed before the next is begun (*discrete* processing), and without feedback to higher level processes from lower levels (strict *feedforward* processing). In contrast, *interactive* views (Dell et al. 1997) embrace the possibilities of partial information from one stage affecting the next (*cascaded* processing) and of information from lower levels affecting higher levels of processing (*feedback*).

What is at stake in this theoretical battle, in part, is the role that an explanation for speech errors should play in the account of normal speech. Speech errors are a traditional foundation for the study of language production (Dell 1986; Fromkin 1973; Garrett 1988), and the properties of errors have long been viewed as informative about the production of error-free speech. Consider the word exchange by a speaker who intended to say *minds of the speakers* and instead uttered "speakers of the minds." Or the sound exchange that yielded "accipital octivity" instead of *occipital activity.* Such errors point to the embodiment of rule-like constraints in the arrangement process. When words exchange, they exchange almost exclusively with other words from the same syntactic class (noun, verb, adjective, and so on). When sounds exchange, they exchange almost exclusively with other sounds from the same phonological class (consonant or vowel). The net effect is that erroneous utterances are almost always grammatical, albeit often nonsensical. In the spirit of exceptions proving the rule, this has been taken to mean that speech errors represent small, local, and most importantly, principled departures from normal retrieval or assembly operations.

Models of word production that incorporate discrete stages have been less successful in accounting for the distribution and the features of speech errors than interactive views, in part because of a difference in explanatory emphasis. Levelt, Roelofs, and Meyer, forthcoming) elaborate a discrete-stage approach that is designed primarily to account for experimental data about the time course of word production, and not for errors, for the simple reason that errors are departures from the norm. What the production system does best, and remarkably well under the circumstances, is retrieve words and sounds appropriate for speakers' communicative intentions. Within the approach endorsed by Levelt, Roelofs, and Meyer, errors are a product of aberrations from the basic operating principles of the production system and are correspondingly rare events. By this argument, errors demand a separate theory.

Despite these differences, the leading theories of language production are in agreement that knowledge about words comes in pieces and that the pieces are not recovered all at once. In normal speaking, the semantic, syntactic, and phonological properties of words are called upon in quick succession, not simultaneously. Thus, what normally feels like a simple, unitary act of finding-and-saying-a-word is actually a complicated but fast assembly of separate, interlocking features. More broadly, speaking cannot be likened to the recitation of lines, as E. B. Titchener once did in describing it as "reading from a memory manuscript" (1909). It involves active, ongoing construction of utterances from rudimentary linguistic parts.

Communicative processes All the processes of language production serve communication, but certain activities tailor messages and utterances to the needs of particular listeners at particular places and times. The tailoring requirements are legion. They range from such patent demands as choosing language (English? Spanish?) and gauging loudness (whisper? shout?) to the need to infer what the listener is likely to be thinking or capable of readily recollecting. These are aspects of PRAGMATICS (cf. PSYCHOLINGUISTICS). A common shortcoming of speakers is presuming too much, failing to anticipate the myriad misconstruals to which any given utterance or expression is vulnerable. The source of this presumptuousness is transparent: Speakers know what they intend. For them, there is no ambiguity in the message.

The direct apprehension of the message sets speakers apart from their listeners, for whom ambiguity is rife. In this crucial respect, language production has little in common with language comprehension. In other respects, however, successful communication demands that production and comprehension share certain competencies. They must somehow draw on the same linguistic knowledge, because we speak as well as understand our native languages.

The cognitive processing systems responsible for comprehension and production may nonetheless be distinct. Research on language disorders suggests a degree of independence between them, because people with disorders of production can display near-normal comprehension abilities, and vice versa (Caramazza 1997). At a minimum, the flow of information must differ, leading from meaning to sound in production and from sound to meaning in comprehension.

This simple truth about information flow camouflages the deep questions that are at stake in current debates about the isolability and independence of the several cognitive and linguistic components of production. The questions are a piece of the overarching debate about modularity, to do with whether language and its parts are in essence the same as other forms of cognition and more broadly, whether all types of knowledge are in essence the same in acquisition and use. Accordingly, answers to the important questions about language production bear on our understanding of fundamental relationships between LANGUAGE AND THOUGHT, between free will and free speech, and between natural and artificial intelligence.

Language Variation and Change

The speech of no two people is identical, so it follows that if one takes manuscripts from two eras, one will be able to

identify differences and so point to language "change." In this sense, languages are constantly changing in piecemeal, gradual, chaotic, and relatively minor fashion. However, historians also know that languages sometimes change abruptly, several things changing at the same time, and then settle into relative stasis, in a kind of "punctuated equilibrium."

So, all of the long vowels in English were raised (and the highest vowels diphthongized) in the famous Great Vowel Shift, which took place in late Middle English. Similarly, the language lost several uses of the verb *be* simultaneously in the nineteenth century (*I wish our opinions were the same, but in time they will; you will be to visit me in prison; their being going to be married*) and developed the first progressive passives: *everything is being done* (Warner 1995).

We may adopt a cognitive view of grammars, that they are mental entities that arise in the mind/brain of individual children. Hermann Paul (1880) was the first person to study change with roughly this view of grammars. Then it is natural to try to interpret cascades of changes in terms of changes in grammars, a new setting for some parameter, sometimes having a wide variety of surface effects and perhaps setting off a chain reaction. Such "catastrophic" changes are recognizable by the distinctive features discussed in Lightfoot 1991 (chap. 7). So grammatical approaches to language change have focussed on these large-scale changes, assuming that the clusters of properties tell us about the harmonies that follow from particular parameters. By examining the clusters of simultaneous changes and by taking them to be related by properties of Universal Grammar, we discover something about the scope and nature of parameters and about how they are set. Work on language change from this perspective is fused with work on language variation and acquisition. Change illuminates the principles and parameters of Universal Grammar in the same way that, when we view a forest at some distance, we may not see the deer until it moves.

This grammatical approach to diachrony explains changes at two levels. First, the set of parameters postulated as part of UG explains the unity of the changes, why superficially unrelated properties cluster in the way that they do.

Second, historical records, where they are rich, show not only when catastrophic change takes place but also what kinds of changes were taking place in the language prior to the parametric shift. This enables us to identify in what ways the trigger experiences of children who underwent the parametric shift differed from those of people with the older grammar. This, in turn, enables us to hypothesize what the crucial trigger experience is for setting a given parameter.

Recent work has treated this topic in terms of cue-based learning (Dresher and Kaye 1990; Dresher 1997; Lightfoot 1997): under this view, parameters have a designated cue; children scan their linguistic environment for the relevant cues and set parameters accordingly. The distribution of those cues may change in such a way that a parameter was set differently.

This model has nothing to say about why the distribution of the cues should change. That may be explained by claims about language contact or socially defined speech fashions, and it is a function of the use of grammars and not a func-

tion of theories of grammar, acquisition, or change—except under one set of circumstances, where the new distribution of cues results from an earlier parametric shift; in that circumstance, one has a "chain" of grammatical changes.

This approach to change is not tied to any particular grammatical model. Warner (1995) offers a persuasive analysis of parametric shift using a lexicalist HEAD-DRIVEN PHRASE STRUCTURE GRAMMAR model. Interesting diachronic analyses have been offered for a wide range of phenomena, invoking different grammatical claims; see the Further Readings for examples.

This approach to abrupt change, where children acquire different systems from those of their parents, is echoed in work on creolization (see CREOLES) under the view of Bickerton (1984), and the acquisition of signing systems by children exposed largely to unnatural input (Goldin-Meadow and Mylander 1990; Newport 1999; Supalla 1990; see SIGN LANGUAGES). Bickerton argues that situations in which "the normal transmission of well-formed language data from one generation to the next is most drastically disrupted" will tell us something about the innate component and how it determines acquisition (Bickerton 1999).

The vast majority of deaf children are exposed initially to fragmentary signed systems that have not been internalized well by their primary models. Goldin-Meadow and Mylander (1990) take these to be artificial systems, and they show how deaf children go beyond their models in such circumstances and "naturalize" the system, altering the code and inventing new forms that are more consistent with what one finds in natural languages. The acquisition of signed languages under these circumstances casts light on abrupt language change, creolization, and on cue-based learning (Lightfoot 1998).

There has been interesting work on the replacement of one grammar by another—that is, the spread of change through a community. So, Kroch and his associates (Kroch 1989; Kroch and Taylor 1997; Pintzuk 1990; Santorini 1992, 1993; Taylor 1990) have argued for coexisting grammars. That work postulates that speakers may operate with more than one grammar in a kind of "internalized diglossia" and it enriches grammatical analyses by seeking to describe the variability of individual texts and the spread of a grammatical change through a population.

Niyogi and Berwick (1995) have offered a population genetics computer model for describing the spread of new grammars. Certain changes progress in an S-curve and now Niyogi and Berwick provide a model of the emergent, global population behavior, which derives the S-curve. They postulate a learning theory and a population of child learners, a small number of whom fail to converge on preexisting grammars, and they produce a plausible model of population changes for the loss of null subjects in French.

Taking grammars to be elements of cognition has been productive for work on language change, but it is not as common an approach as one that takes grammars to be social entities. The distinction and its implications for historical linguistics are discussed by Lightfoot (1995). The approach described here is analogous to the study of evolutionary change in order to learn about general biological principles and about particular species.

Lashley, Karl Spencer (1890–1958)

Donald HEBB described Karl Lashley's career as "perhaps the most brilliant in the psychology of this century" (Hebb 1959: 142). Lashley's intellectual odyssey about brain and behavior extended from the earliest days of Watsonian BEHAVIORISM to astonishingly modern cognitive views.

Lashley attended the University of West Virginia, where he studied with John Black Johnston, a neurologist. When taking his first class from Johnston in zoology, Lashley "knew that I had found my life's work." Lashley plunged into the study of zoology, neuroanatomy, embryology, and

animal behavior, graduating in 1910. He received an M.S. in bacteriology at the University of Pittsburgh in 1911, where he studied experimental psychology with K. M. Dallenbach. Following this he enrolled for the Ph.D. in zoology at Johns Hopkins with H. S. Jennings, with a minor in psychology with Adolf Meyer and John B. Watson. Watson's developing theory of behaviorism, and Watson himself, had a profound influence on Lashley.

In a letter written much later to Ernest Hilgard at Stanford, Lashley described taking a seminar with Watson in 1914. Watson called attention in the seminar to the writings of Bechterev and Pavlov on conditioned reflexes, which they translated.

In the spring I served as an unpaid assistant and we constructed apparatus and did experiments, repeating a number of their experiments. Our whole program was then disrupted by the move to the lab in Meyer's Clinic. There were no adequate animal quarters there. Watson started work with infants as the next best material available. I tagged along for awhile but disliked the babies and found me a rat lab in another building.

We accumulated a considerable amount of experimental material on the conditioned reflex that was never published. Watson sought the basis of a systemic psychology and was not greatly concerned with the reaction itself.

The conditioned reflex thus came to form the basis of Watson's behaviorism. Lashley, on the other hand, had become interested in the physiology of the reaction and the attempt to trace conditioned reflex paths through the central nervous system.

During the period at Hopkins, Lashley worked with Shepherd Irvory Franz at St. Elizabeth's Hospital in Washington. Together, they developed a new approach to the study of brain mechanisms of learning and memory and published landmark papers on the effect of cortical lesions on learning in rats. From this time (1916) until 1929, Lashley systematically used the lesion method in an attempt to localize memory traces in the brain. Following Watson (and Pavlov), Lashley conceived of the brain as a massive reflex switchboard, with sequential chaining of input-output circuitries via the cerebral cortex as the basis of memory. This work culminated in his classic 1929 monograph *Brain Mechanisms of Intelligence.* He was also president of the American Psychological Association that year. His presidential address, and his 1929 monograph, destroyed the switchboard reflexology theory of brain function and learning as it existed at that time. In complex mazes, rats were impaired in LEARNING and MEMORY in proportion to the degree of cerebral cortex destroyed, independent of locus. He employed the terms "mass action" and "equipotentiality" more to describe his results than as a major theory. Lashley did not deny localization of function in the neocortex. Rather, he argued that the neural substrate for higher-order memorial functions—he often used the term "intelligence"—as in complex maze learning in rats, was widely distributed in the CEREBRAL CORTEX.

Lashley was perhaps the most formidable critical thinker of his time, successfully demolishing all major theories of brain behavior, from Pavlov to the Gestalt psychologists to his own views. "He remarked that he had destroyed all theories of behavior, including his own" (Hebb 1959: 149). Near the end of his career, looking over his lifetime of research on memory, Lashley (1950) concluded that

This series of experiments has yielded a good bit of information about what and where the memory trace is not. It has discovered nothing directly of the real nature of the memory trace. I sometimes feel, in reviewing the evidence of the localization of the memory trace, that the necessary conclusion is that learning is just not possible. It is difficult to conceive of a mechanism that can satisfy the conditions set for it. Nevertheless, in spite of such evidence against it, learning sometimes does occur. (477–478).

Lashley's positive contributions were extraordinary. Perhaps most striking was his brilliant analysis of the "problem of serial order in behavior" (Lashley 1951). Ranging from the properties of language to the performance of complex motor sequences, he showed that "associative chaining" cannot account for serial behavior. Rather, higher-order representations must exist in the brain in the form of patterns of action "where spatial and temporal order are. . .interchangeable." (Lashley 1951: 128).

Lashley made a number of other major contributions, including an insightful analysis of "instinctive" behaviors, analysis of sexual behaviors, characterization of the patterns of thalamocortical projections, functions of the visual cortex, a rethinking of cortical cytoarchitectonics (Beach et al. 1960).

In 1936 James B. Conant, then the new president of Harvard, appointed an ad hoc committee to find "the best psychologist in the world" (Beach 1961). Lashley, then at the University of Chicago, was chosen and hired in 1937. He became director of the Yerkes Laboratory of Primate Biology in Florida but maintained his chair at Harvard, traveling to Cambridge once each year to give his two-week graduate seminar. The roster of eminent psychologists and neuroscientists who worked with Lashley is without parallel.

According to his student Roger SPERRY (personal communication), Lashley was interested in the problem of CONSCIOUSNESS but refused to write about it, considering it something of an epiphenomenon. He did, however, speculate about the mind, in itself heretical for a behaviorist:

"Mind is a complex organization, held together by interaction processes and by time scales of memory, centered about the body image. It has no distinguishing features other than its organization . . . there is no logical or empirical reason for denying the possibility that the correlation (between mental and neural activities) may eventually show a complete identity of the two organizations" (Lashley 1958: 542).

In his biographical memoir of Lashley, Frank Beach (1961) offered the following tribute (163):

Eminent psychologist with no earned degree in psychology
Famous theorist who specialized in disproving theories, including his own
Inspiring teacher who described all teaching as useless.

Laws

See CAUSATION; PSYCHOLOGICAL LAWS

Learning

Although learning can be understood as a change in an organism's capacities or behavior brought about by experience, this rough definition encompasses many cases usually not considered examples of learning (e.g., an increase in muscular strength brought about through exercise). More important, it fails to reflect the many forms of learning, which may be distinguished, for example, according to what is learned, may be governed by different principles, and may involve different processes.

One form of learning is *associative learning,* in which the learner is exposed to pairs of events or stimuli and has the opportunity to learn these pairings—which event or stimulus goes with which (see CONDITIONING). The study of associative learning has led to the discovery of numerous learning principles applicable to species as diverse as flatworms and humans, and behaviors as different as salivation and the onset of fear. Investigators have also learned a great deal about the biological bases for this form of learning (see CONDITIONING AND THE BRAIN).

Another crucial form of learning involves the acquisition of knowledge about the spatial layout of the organism's surrounding—these COGNITIVE MAPS can include the locations of food sources or of dangers, the boundaries of one's territory, and so on. The acquisition of this spatial knowledge often involves *latent learning*: The organism derives some knowledge from its experiences, but with no immediately visible change in the organism's behavior. (The latent learning does become visible later on, however, when the organism finds occasion to use what it has earlier learned.) In many species, this learning about spatial layout can be extraordinarily sophisticated, allowing the organism to navigate across great distances, or to remember the locations of hundreds of food caches, or to navigate by dead reckoning,

with little or no reliance on sensory landmarks (see ANIMAL NAVIGATION and ANIMAL NAVIGATION, NEURAL NETWORKS).

Spatial learning may be considered a special case within a broader category of learning, in which an organism gains ("memorizes") information about its environment (see MEMORY). In humans, this information may be derived directly from firsthand experience, or indirectly, from what one reads or hears from others. This information may then be used later on for some memory-based report (e.g., a response to the question, "What happened yesterday?"), or as a basis for modifying future action. In any of these cases, one *encodes* the information into memory during the initial exposure, and then *retrieves* this stored information later on. The initial encoding may be *intentional* (if one is seeking to memorize the target information) or *incidental* (if the learning is a by-product of one's ordinary commerce with the world, with no intention of learning). Similarly, the subsequent use of the information may involve *explicit* memory (if one wittingly and deliberately seeks to use the stored information later on) or *implicit* memory (if the stored information has an unwitting and automatic influence on one's subsequent behavior; see IMPLICIT VS. EXPLICIT MEMORY).

Still another form of learning is *skill learning,* in which one learns how to perform some action or procedure, often without any ability to describe the acquired skill (also see MOTOR LEARNING). In this case, one is said to have acquired "procedural knowledge" (knowing how to carry out some procedure), as opposed to "declarative knowledge" (knowing that some proposition is correct). It should be emphasized, however, that skill learning is not limited to the acquisition of motor skills (such as learning how to serve a tennis ball or how to ride a bicycle). In addition, much of our mental activity can be understood in terms of skill acquisition—we acquire skills for reading, solving problems within a particular domain, recognizing particular patterns, and so on. Thus, for example, chess masters have acquired the skill of recognizing specific configurations of chess pieces, a skill that helps them both in remembering the arrangement of the game pieces and (probably more important) allows them to think about the game in terms of strategy-defined, goal-oriented patterns of pieces, rather than needing to focus on individual pieces (see EXPERTISE and PROBLEM SOLVING).

Skill learning can also lead to AUTOMATICITY for the particular skill or procedure. Once automatized, a skill can be run off as a single, integrated action, even though the skill was initially composed of numerous constituent actions. The skilled tennis player, for example, need not focus on wrist position, the arch of the back, and the position of the shoulders, but instead launches the single (complex) behavior, "backhand swing." This automatization promotes fluency among the constituents of a complex behavior, dramatically decreases the extent to which one must attend to the various elements of the behavior, and thus frees ATTENTION for other tasks. On the other hand, automatic behaviors are often inflexible and difficult to control, leading some to speak of them as "mental reflexes."

A further form of learning is INDUCTION, in which the learner is exposed to a series of stimuli or events and has the

opportunity to discover a general rule or pattern that summarizes these experiences. In some cases, induction is produced by the simple forgetting of an episode's details and the consequent blurring together in memory of that episode with other similar episodes. This blurring together is, for example, the source of our knowledge of, say, what a kitchen is likely to contain. Investigators refer to knowledge acquired in this fashion as "generic" or "schematic knowledge" (see EPISODIC VS. SEMANTIC MEMORY and SCHEMATA).

In other cases, induction results from a more deliberate judgment process in which one actively seeks to generalize from one's previous experiences, a process that seems to rely on a relatively small number of strategies or JUDGMENT HEURISTICS. For example, subjects in many studies seem to rely on the assumption that the categories they encounter are relatively homogeneous, and this encourages them to extrapolate freely from the sample of observations made so far, even if that sample is relatively small, and even (in some cases) if warnings are in place that the sample is not representative of the larger category (see CATEGORIZATION).

Some aspects of induction seem to be governed by highly specialized domain-specific skills. One clear example is provided by LANGUAGE ACQUISITION in the small child. The human infant appears to be well prepared to induce the regularities of language, so that language acquisition is relatively swift and successfully achieved by virtually all children, independent (within certain boundary conditions) of the child's individual abilities or circumstances. The same learning skills, however, seem irrelevant to the acquisition of information in other domains (also see COGNITIVE DEVELOPMENT and DOMAIN SPECIFICITY).

Finally, let us note still other forms of learning: Many species are capable of learning through IMITATION, in which an action is first observed and then copied. A number of species display *imprinting,* in which a young organism learns to recognize its parents or its conspecifics. Human learning often also involves DEDUCTIVE REASONING, in which one is able to discover (or generate) new knowledge, based on beliefs one already holds. In some cases of deduction, one's reasoning is guided by relatively abstract rules or principles. In others, one's reasoning is guided by a specific remembered experience; one then draws an analogy, based on that experience, and the analogy indicates how one should act, or what one should conclude, for the current problem (see CASE-BASED REASONING AND ANALOGY).

Thus the term *learning* plainly covers a diversity of phenomena. But having now emphasized this diversity, we should ask what these many forms of learning have in common. At a general level, some principles may apply across domains—for example, the importance of acknowledging task-specific learning skills, or the possibility of latent learning, not immediately manifest in behavioral change. At a much finer-grained level, it is likely that similar processes in the nervous system provide the substrate for diverse forms of learning, including, for example, the process of LONG-TERM POTENTIATION, in which the pattern of interaction among neurons is modified through experience. Similarly, it is plausible that connectionist models may provide powerful accounts of many of these forms of learning (see COGNITIVE MODELING, CONNECTIONIST). In between these extremes, however, we may be unable to formulate general "laws of learning," applicable to all learning types.

Learning Systems

The ability to formulate coherent and predictive theories of the environment is a salient characteristic of our species. We perform this feat at diverse stages of development and with respect to sundry features of our experience. For example, almost all infants construct grammatical theories of their caretakers' language; most children master the moral and aesthetic codes of their household and community; and selected adults discover scientific principles that govern fundamental aspects of the physical world. In each case, our theories are underdetermined by the data that trigger them in the sense that there exist alternative hypotheses (with different predictive consequences) that are equally compatible with the evidence in hand. In some cases, the underdetermination reaches dramatic proportions, revealed by comparing the fragmentary nature of available data to the scope and apparent accuracy of the theories they engender. Such appears to be the case in the physical sciences. For example, Dodelson, Gates, and Turner (1996) describe a theory of the origin of astrophysical structure, from stars to great walls of galaxies, presenting evidence that such structure arose from quantum mechanical fluctuations during the first 10^{-34} seconds in the life of the universe. If the theory is true, surely one of its most curious features is that it could be known by a human being. Similarly, radical underdetermination has also been suggested for the grammatical theories constructed by infants learning their first language (for elaboration of this view, see Chomsky 1988 and POVERTY OF THE STIMULUS ARGUMENTS; a critical rejoinder is provided by Pullum 1996; see also INDUCTION and LANGUAGE ACQUISITION).

The psychological processes mediating discovery no doubt vary with the specific problem to which they must apply. There may be little in common, for example, between the neural substrate of grammatical hypotheses and that underlying the conjectures of professional geologists. Such

matters are controversial, so it will be prudent to limit the remainder of our discussion to discovery of a patently scientific kind.

The psychological study of discovery has focused on how people choose tests of specific hypotheses, and how they modify hypotheses in the face of confirming or disconfirming data. Many of the experiments are inspired by "Mill's methods" of causal inquiry, referring to the nineteenth-century logician John Stuart Mill. The results suggest that both children and adults are apt to test hypotheses by seeking data that cannot be disconfirmatory, and to retain hypotheses whose predictions are observed to be falsified (see, for example, Kuhn 1996). In contrast to this bleak picture of intuitive science, other researchers believe that Mill's methods are too crude for the framing of pertinent questions about the psychology of empirical inquiry. A different assessment of lay intuition is thought to arise from a subtler account of normative science (see, for example, Koslowski 1996 and SCIENTIFIC THINKING AND ITS DEVELOPMENT).

More generally, investigation of the psychology of theory discovery can benefit from a convincing model of rational inquiry, if only to help define the task facing the reasoner. Two formal perspectives on discovery have been developed in recent years, both quite primitive but in different ways. One view focuses on the credibility that scientists attach to alternative theories, and on the evolution of these credibilities under the impact of data. Interpreting credibility as probability leads to the *Bayesian analysis* of inquiry, which has greatly illuminated diverse aspects of scientific practice (see BAYESIAN LEARNING). For example, it is widely acknowledged that a theory T is better confirmed by data D_s, which verify a surprising prediction, than by data D_o, which verify an obvious one. The Bayesian analysis of this fact starts by interpreting surprise probabilistically: $0 < P(D_s) < P(D_o) \leq 1$. Because both predictions are assumed to follow deductively from T, the probability calculus implies $P(D_s \mid T) = P(D_o \mid T) = 1$, and Bayes's theorem yields

$$P(T|D_s) = \frac{P(D_s|T) \times P(T)}{P(D_s)} = \frac{P(T)}{P(D_s)} > \frac{P(T)}{P(D_o)}$$

$$= \frac{P(D_o|T) \times P(T)}{P(D_o)} = P(T|D_o).$$

The greater support of T offered by D_s compared to D_o is thus explained in terms of the posterior probabilities $P(T \mid D_s)$ and $P(T \mid D_o)$. This example and many others are discussed in Earman (1992), Horwich (1982), Howson and Urbach (1993), and Rosenkrantz (1977).

A second perspective on inquiry is embodied in the "theory of scientific discovery" (see, for example, Kelly 1996; Martin and Osherson 1998; for a computational perspective, see Langley et al. 1987; COMPUTATIONAL LEARNING THEORY; and MACHINE LEARNING). Scientific success here consists not in gradually increasing one's confidence in the true theory, but rather in ultimately accepting it and holding on to it in the face of new data. This way of viewing inquiry is consonant with the philosophy of Karl Popper (1959), and was first studied from an algorithmic point of view in Put-

nam (1975), Solomonoff (1964), and Gold (1967). Analysis proceeds by distinguishing five components of empirical inquiry, namely: (1) potential realities or "worlds"; (2) a scientific problem; (3) a set of potential data streams or "environments" for each world, which provide information about the world; (4) scientists; and (5) a criterion of success that stipulates the conditions under which a scientist is credited with solving a given problem. Any precise formalization of the preceding items is called a "model" or "paradigm" of inquiry, and may be analyzed mathematically using the techniques developed within the general theory (the five components are adapted from Wexler and Culicover 1980). Particular attention is devoted to characterizing the kinds of problems that can be solved, distinguishing them from problems that resist solution by any scientist.

One of the simplest paradigms to be studied in depth has a numerical character, and may be described as follows (for fuller treatment see Jain et al. forthcoming). Let N be the set $\{0,1,2, \ldots\}$ of natural numbers.

1. A world is any infinite subset of N, for example: $N - \{0\}$ or $N - \{1\}$. The numbers making up a world are conceived as codes for individual facts that call for prediction and explanation.
2. A scientific problem is any collection of worlds, for example, the collection $\mathbf{P} = \{ N - \{x\} \mid x \in N \}$ of all subsets of N with just one number missing. A problem thus specifies a range of theoretically possible worlds, the "real" member of which must be recognized by the scientist.
3. An environment for a world is any listing of all of its members. For example, one environment for $N - \{3\}$ starts off: 0,1,2,4,5,6 . . . . We emphasize that an environment for a world S may list S in *any* order.
4. A scientist is any mapping from initial segments of environments into worlds. To illustrate, consider the scientist S that responds to each initial segment of its environment with the set $N - \{x\}$, where x is the least number not yet encountered. Then faced with the environment 0,1,2,4,5,6 . . . shown above, S would first conjecture $N - \{1\}$, then $N - \{2\}$, then $N - \{3\}$, then again $N - \{3\}$, and so on.
5. A scientist is said to "solve" a given problem just in case the following is true. No matter what world W is drawn from the problem, and no matter how the members of W are listed to form an environment e, the scientist's conjectures on e are wrong only finitely often. That is, starting at some point in e, the scientist begins to (correctly) hypothesize W, and never deviates thereafter.

It is not difficult to see that the scientist S solves the problem $\mathbf{P}$ described above. In contrast, it can be demonstrated that no scientist whatsoever solves the problem that results from adding the additional world N to $\mathbf{P}$. This new problem is *unsolvable*.

The foregoing model of inquiry can be progressively enriched to provide more faithful portraits of science. In one version, worlds are relational structures for a first-order language, scientists implement belief revision operators in the sense of Gärdenfors (1988), and success consists in fixing upon an adequate theory of the structure giving rise to the atomic facts of the environment (see Martin and Osherson 1998).

Lévi-Strauss, Claude

The most remarkable aspect of the French anthropologist Lévi-Strauss's (1908–) undertaking is his ambition to take seriously the very idea of anthropology. His aim has been to develop anthropology not just as an inventory of human cultures or of types of institutions (kinship, myths, rituals, arts, technologies, knowledge systems), but also as an investigation of the mental equipment common to all humans. This has not always been understood. It has been seen as an overambitious philosophical project when in fact it is better understood as a cognitivist project.

Lévi-Strauss develops this approach by taking up the concept of *structure* and by proposing a new use of this concept in anthropology. He abandons the notion of social structure (promoted by A. R. Radcliffe-Brown and G. P. Murdock) as the totality of directly observable relations in a society (a notion that still refers to the traditional understanding of "structure" as architectural frame or organic system). Lévi-Strauss's conception of structure as a *model* stems directly from linguistics (particularly from Troubetskoi and JAKOBSON) where structure refers to a recurring relation between terms (such as phonemes) considered as minimal units. The second source is mathematics where it refers to constant relations between elements regardless of what the set in question is. Lévi-Strauss admits that this kind of stable relations only appears in certain objects and under certain conditions. In other words, in the field of social sciences, a structural analysis is productive and legitimate only in such cases as phonology, kinship, taxonomies, "totemic" phenomena, rituals, mythical narratives, and certain artifacts. It is better avoided in domains where probabilistic factors prevail over the mechanical order.

From a cognitivist point of view, Lévi-Strauss's most interesting contribution is linked to his conviction that there is a continuity between forms of organization of external reality (matter, living organisms, social groups, artifacts) and the human mind. To understand a specific field of objects is to show how that field produces its own rationality, that is, how it is regulated by a spontaneous intelligible order. This is the epistemological presupposition behind Lévi-Strauss's analyses of kinship systems. This aim dominates the following inquiries he has conducted on the traditional forms of classification of objects in the natural world. He began his research by going back to an old controversial and seemingly insoluble problem, that of so-called totemism, and by showing that it was a nonissue, first because it was badly stated. In fact, totemism is not a one-to-one correspondence between the human and the natural world but a way of establishing and expressing a system of differences between humans (individuals and groups), with the help of a system of differences between things (animals, plants, or artifacts). What resembles each other are not humans and things but their differential relations.

Of course, this presupposes that the human mind has the capacity and a disposition to recognize differences and to classify things themselves. In fact, traditional forms of knowledge show that this spontaneous work of classification is very sophisticated. This means that it is not primarily guided by vital need (such as food or survival) but indeed by the desire to understand and interpret the world; in short, as Lévi-Strauss reminds us, things are not just "good for eating," but also "good for thinking." From this perspective it is therefore important not to underestimate the power of "untamed thinking" (literally: *la pensée sauvage*). There, the flourishing symbolic systems are based on the differential values themselves that have come out of the operations of classification of the observed world.

What is finally the difference between "untamed thinking" and "domesticated thinking," between traditional forms of knowledge and modern reason? According to Lévi-Strauss, it stems from the progressive branching out of

two types of society at the end of the neolithic period: some evolved toward the pursuit and preservation of a stable equilibrium between the human and the natural world, while others turned toward change by developing technologies for mastery over nature, which involved the explicit recognition and formalization of abstract representations, as was the case of the civilizations of writing, particularly those where alphabetical writing developed.

This exercise of traditional knowledge appears particularly in the production of mythical narratives. According to Lévi-Strauss, myths are a complex expression of forms of thought inherent in a culture or a group of cultures (which refers back to an empirical corpus); at the same time they reveal mental processes that are verifiable everywhere (this concerns operations that are part of the basic equipment of every human mind). In the interpretation of myths it is therefore impossible to maintain a purely functionalist approach (which seeks an explanation of narrative based on need alone), or a symbolist approach (which seeks for keys of universal interpretation), or a psychological approach (which seeks archetypes). To be sure, myths do refer back to an empirical environment (geographical, technical, social) and express it directly or not, but above all they construct representations where through the categorial use of sensory elements (such as diversity of species, places, forms, colors, materials, directions, sounds, temperatures) emerges a symbolic order of things and humans (cosmogony, sociogony) and where, above all, the logical faculties of the mind are at work—for example, opposition, symmetry, contradiction, disjunction, negation, inclusion, exclusion, complementarity. Hence the surprising character of certain myths that do not correspond to any etiology, that is, to any specific referential situation, but seem to arise and develop just for the sake of pure speculative play. Therefore a narrative cannot be interesting in itself. Some elements reappear from one myth to another (mythemes or segments); there are clusters of narratives related in various ways (symmetrical, oppositional, etc.); and finally there are whole cycles with groups of myths that are linked in networks and constitute complete systems of representation. Lévi-Strauss's most original and ambitious theoretical contribution has been to demonstrate that those networks consist of transformation groups (in the mathematical sense of the term).

The recourse to the structural model stemming from linguistics and mathematics allowed Lévi-Strauss to bring to the fore invariants hitherto only seen as simple empirical recurrences, if not residues of lost history—invariants that he attributes to the propensitites of the human mind. This is unquestionably pioneering work for a cognitivist approach to traditional societies and for the elaboration of a global theory of the human mind.

Lexical Functional Grammar

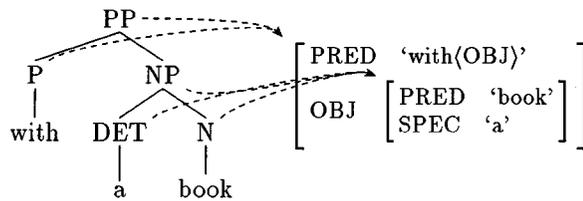
Lexical Functional Grammar (LFG) is a theory of the structure of natural language and how different aspects of linguistic structure are related. The name of the theory expresses two ways in which it differs from other theories of linguistic structure and organization. LFG is a lexical theory: relations between linguistic forms, such as the relation between an active and passive form of a verb, are generalizations about the structure of the lexicon, not transformational operations that derive one form on the basis of another one. And LFG is a functional theory: GRAMMATICAL RELATIONS such as subject and object are basic, primitive constructs, not defined in terms of phrase-structure configurations or of semantic notions such as agent or patient.


Figure 1. Simplified constituent structure and functional structure for the prepositional phrase *with a book*.

Two aspects of syntactic structure are copresent in the LFG analysis of a sentence or phrase. The concrete, perceptible relations of dominance, precedence, and phrasal grouping are represented by a phrase structure tree, the constituent structure or *c-structure*. More abstract functional syntactic information such as the relation of subjecthood or objecthood is represented by an attribute-value matrix, the functional structure or *f-structure*. Each node of the constituent structure is related to its corresponding functional structure by a functional correspondence Φ, illustrated in Figure 1 by dotted lines. This functional correspondence induces equivalence classes of structural positions that can be related to a particular grammatical function. There may be functional structures that are not related to any constituent structure node (that is, the Φ correspondence function is not onto); for example, in so-called pro-drop languages, a verb may appear with no overtly expressed arguments. In such a case, the verb's arguments are represented at functional structure but not at constituent structure.

Information about the constituent structure category of each word as well as its functional structure is contained in the LEXICON, and the constituent structure is annotated with information specifying how the functional structures of the daughter nodes are related to the functional structure of the mother node. The functional structure must also obey the well-formedness conditions of *completeness* and *coherence*: all grammatical functions required by a predicate must be present, and no other grammatical functions may be present. For example, a transitive verb requires the presence of a subject and an object (completeness) and no other grammatical functions (coherence). Thus, the universally applicable principles of completeness and coherence together with a language-specific lexicon and principles for phrase-structure annotation provide the criteria for determining the constituent-structure tree and the functional structure that corresponds to it for a sentence or phrase of a language.

LFG adheres to the lexical integrity principle, which states that morphological composition does not interact with syntactic composition: the minimal unit analyzed by the constituent structure is the word, and the internal morphological structure of the word is not accessible to syntactic processes (Bresnan and Mchombo 1995). However, it is possible for words and phrases to have similarly articulated functional structure: a verb with a morphologically incorporated pronominal object may have the same functional structure as a verb phrase with a verb and an independent pronoun. A number of apparent paradoxes are explained by distinguishing between syntactic phenomena at the two different syntactic levels.

Distinguishing the outer, crosslinguistically variable constituent structure from the functional structure, which encodes relations that hold at a more abstract level in every language, allows for the incorporation of a comparative assessment of grammatical structures as proposed in OPTIMALITY THEORY (Bresnan 1997; Choi 1996).

The formal generative properties of LFG grammars are fairly well described. Like context-free languages, LFG languages are closed under union, concatenation, and Kleene closure (Kelly Roach, unpublished work). The recognition problem (whether a given string is in the language generated by a given LFG grammar) was shown to be decidable by Kaplan and Bresnan (1982). The emptiness problem (whether a given LFG grammar generates a nonempty set of strings) was shown to be undecidable in further unpublished work by Roach. A synopsis of Roach's results is given by Dalrymple et al. (1995).

The efficient processing of LFG grammars, both from a psycholinguistic and a computational standpoint, is a central concern of the theory. It has been shown that LFG recognition is *NP*-complete (Berwick 1982): for some string (not necessarily a string in any natural language) and some LFG grammar, no known algorithm exists to determine in polynomial time whether that string is in the language generated by that grammar. Kaplan (1982) proposes that the *NP*-complete class is actually a psycholinguistically plausible one for a linguistic model: the exponentially many candidate analyses of a string can be heuristially winnowed, and subsequent verification of the correct analysis can be accomplished very quickly. Strategies can also be devised to optimize the distribution of processing work between the two syntactic structures (Maxwell and Kaplan 1993). In recent unpublished work, Ronald M. Kaplan and Rens Bod explore the Data-Oriented Parsing approach within the LFG framework; this approach assumes that LANGUAGE ACQUISITION proceeds by forming generalizations over fragments of constituent structures and functional structures of previously encountered utterances and by inducing the most likely structure of newly encountered utterances based on these generalizations.

Besides constituent structure and functional structure, LFG assumes other structures for other aspects of linguistic form. These structures are generally assumed to be related by functional correspondence to the constituent structure, the functional structure, and/or one another (Kaplan 1987). Argument structure encodes the THEMATIC ROLES of the arguments of predicates and plays an important role in LFG's linking theory, principles for how the thematic role of an argument affects its grammatical function and realization in the functional structure (Bresnan and Kanerva 1989; Alsina 1994). The meaning of a phrase or sentence is represented at semantic structure (Halvorsen 1983), related directly to functional structure and indirectly to other linguistic structures. The relation between semantic structures and their corresponding functional structures is exploited in recent deductive accounts of the SYNTAX-SEMANTICS INTERFACE; syntactic relations established at functional structure interact with lexically specified information about the meaning of individual words in a logical deduction of the meaning of larger phrases and sentences (Dalrymple, Lamping, and Saraswat 1993).

Further information about LFG, including a continually updated bibliography, is available at http://clwww.essex.ac.uk/LFG/.

Lexicon

The lexicon is a list of the morphemes in a language, containing information that characterizes the SYNTAX (hence distribution), MORPHOLOGY (hence PHONOLOGY), and meaning for every morpheme. Thus, for a word such as *forget*, the lexical entry states its meaning, that it is a verb and takes a nominal or clause complement (*I forgot the picnic, I forgot that the picnic was at 3:00*), and that its phonological representation is /fɔrgɛt/.

However, the study of the lexicon in linguistics and in cognitive science saw a major shift in perspective in the 1980s and early 1990s stemming from the realization that lexicons are much more than this: they are studded with principled phenomena, which any lexical theory must explicate (Wasow 1977 is a classic study). In particular, the lexicon is the domain of a set of linguistic operations or regularities that govern the formation of complex words from lexical components. A much-studied example is passivization (e.g., *arrest > arrested* as in *The thief was arrested by the police*). Why does the passive form of *arrest*, unlike the active, require that its "logical subject" (see GRAMMATICAL RELATIONS) *the police* appear in a prepositional phrase beginning with *by*, instead of in object position, or indeed subject position? Why does a verb like *suffocate* have both a causative and a change-of-state meaning (*The pillow suffocated Mary, Mary suffocated*), and why is the object of one verb the subject of the other? Work on the lexicon has aimed to uncover the principles underlying regular lexical phenomena and to examine their implications for learning and processing.

Most lexical research has centered on the words of obvious semantic importance in a sentence, primarily substantives such as nouns and verbs, treating words like determiners and complementizers (e.g., *that* in *I think that it is raining*) as peripheral to linguistic structure. Recent work argues, however, that these words determine properties of entire phrases, hence their lexical properties are now of considerable interest.

In sum, the theory of the lexicon must encompass two subtheories: one (the primary focus of this article) governing words that are "meaningful" in the obvious if pretheoretic sense, and the other governing words that are functional, or grammatical in character.

The Lexicon for Substantives

The lexicon determines the ability of nouns, verbs and adjectives to combine with arguments. For example *give* takes three arguments (*She gave the box to Peter*), *eat* takes two (*She ate the sandwich*) and *rise* takes one (*The balloon rose rapidly*). The representation that includes this information is often called an "argument structure" (Williams 1981; Grimshaw 1990; Levin and Rappaport Hovav 1995).

The most important source of evidence concerning the representation of argument structure is alternations in argument organization, such as active/passive and causative/change-of-state mentioned above. Others include the "dative alternation": *They gave a present to the teachers/They gave the teachers a present*; morphological causativization: *large > enlarge*; and nominalization: *legislate > legislator, legislation.*

Certain properties of arguments are important in explaining their behavior. Arguments can be usefully classified according to their semantic role as agent, theme, or goal (Jackendoff 1972; see THEMATIC ROLES). Williams (1981) argued that the "external argument" is singled out for special grammatical and lexical treatment. Thus the argument structure of *give* might be (1), where the first argument is marked as external, the others as internal.

(1) *give* (ext, int, int)

Further work on morphology and syntax suggests that some verbs have no external argument, including unaccusatives and perhaps some psychological predicates, and that this has important morphological and syntactic consequences (Burzio 1986; Belletti and Rizzi 1988; see also RELATIONAL GRAMMAR).

The existence of strong semantic regularities within the alternation system sheds light on the semantic representation of substantives, most prominently verbs. For example, the alternation of argument realization seen in the *suffocate* examples above, where the object of the transitive verb corresponds to the subject of the intransitive, is a completely regular phenomenon but is found only with causative verbs. *The pillow suffocated Mary* can be paraphrased roughly as "The pillow caused Mary to suffocate". Verbs that lack this interpretation do not show the alternation, thus *The thief robbed the bank* does not have a counterpart **The bank robbed.*

This constellation of facts, which is crosslinguistically remarkably stable, can be explained by lexical theory, if the verb meanings can be broken down or decomposed into smaller meaning components, one of which (represented here by CAUSE) is part of the meaning of causative verbs. A verb like *suffocate* has two semantic representations, often called "lexical conceptual structures," one with the CAUSE component and one without.

(2) *suffocate*
   a. (x CAUSE (y suffocate));
   b. (y suffocate)

Because the CAUSE component has its own argument, the causative version has one more argument than the noncausative: this holds mutatis mutandis for all causative verbs in all languages. Because the argument of CAUSE is higher in the argument structure than the other, it occupies the syntactic subject position when it is present; when it is absent, the other argument occupies this position in English, which requires that the subject position be filled in all sentences. Hence we find the alternation in argument realization with these verbs. Verbs like *rob* do not have an intransitive counterpart because their semantic analysis does not have the required properties.

A related line of reasoning allows us to explain why verbs like *apologize* occur only intransitively (**He apologized the impolite clerk*). Argument structures are subject to a very general constraint: only one argument of a given semantic

type is allowed in each one. Analysis shows that *apologize* and CAUSE have arguments of the same type, with the thematic role agent. Hence the two cannot be combined into a single argument structure, hence the causative cannot exist. Thus generalizations and gaps in the system can be explained, not merely described within this system of representation. Further quite remarkable evidence comes from the discovery by Talmy (1985) that there are crosslinguistic differences in what meaning components can be combined. He showed that French systematically lacks verbs like English *float*, which encode motion and manner in a single morpheme.

Despite the progress that has been made in understanding lexical alternations, they still pose some powerful challenges. On the one hand, many verbs participate in them and many languages show similar patterns. On the other hand, not *all* verbs participate in them, and some fail to show the alternation, apparently for no very good reason. For example, *donate* appears in only the first of the two configurations that *give* occurs in above, and similarly, *rise* does not occur in the causative (*The balloon rose into the sky*, **They rose the balloon into the sky*). Yet *rise* does not have an argument that is plausibly an agent, unlike *apologize*. Gaps such as these pose an important problem for learning: we can explain the existence of lexical generalizations only if learners generalize heavily, but then how can we explain the existence of exceptions? (See WORD MEANING, ACQUISITION OF; Pinker 1989, Gleitman and Landau 1994.)

A very appealing answer holds that there are no entirely arbitrary exceptions once the generalizations themselves are properly understood. This is probably a fair way to characterize the general direction of the field, but it is not an easy commitment to make good on. One idea is that the meaning of the verb in one configuration is systematically different from the meaning of the verb in others, as the result of a lexical rule changing the verb's semantic representation (see Levin and Rappaport Hovav 1995). Each such lexical rule carries out a specified meaning change on any verb with the appropriate semantics, with syntactic changes emerging as a consequence.

However, consider a marginal but interpretable example like *He sang his mother out of the house,* where *sang,* under this line of analysis, would mean "to cause Y to move by singing." Why couldn't there be a verb which meant *only* this and did not also mean what *sang* usually does? The best answer is that this is not a possible word meaning, but then it cannot be the meaning of *sang* as used here. Some current work suggests that effects such as this extended use of *sang* are due to an interaction between the verb meaning and the syntactic and semantic context the verb appears in, which makes it possible to construe the verb in a certain way. From this perspective, related to that developed by Pustejovsky (1995) and in Construction Grammar (Goldberg 1994), verbs that do not alternate have some special property prohibiting alternation; massive alternation is the norm rather than the exception.

The Functional Lexicon

Although the argument structure of the predicate of a clause determines the number and kind of arguments that can appear in it, the grammatical structure of the entire clause is determined by properties of the function words, previously labeled misleadingly as "minor categories." A noun along with its satellite expressions forms a noun phrase of which it is the "head," the element that determines the properties of the phrase as a whole. Remarkably, it turns out that the same is true for the "minor" syntactic categories, like complementizer and determiner: they also head phrases. Thus the head of the entire complement clause in *I think that it is raining* is *that,* and not, as previously thought, *raining* or a phrase of some kind. It follows then that the primary item determining the grammatical properties of the clause is the complementizer itself (see HEAD MOVEMENT and X-BAR THEORY). Since this discovery, the field has faced a completely new question: what properties does the lexicon of functional morphemes have? Clearly, notions like thematic role are entirely irrelevant for words like *that* and *the*. These morphemes code properties like "type" (e.g., interrogative versus propositional) or definiteness. How much crosslinguistic variation can be shown to follow from differences in the functional lexicon? Related work on learning attempts to establish whether these morphemes and associated phrases are present in early child language (Déprez and Pierce 1993; Clahsen 1990/91; Radford 1990; see also PARAMETER-SETTING APPROACHES TO ACQUISITION, CREOLIZATION, AND DIACHRONY; and MINIMALISM).

The content-function word distinction has a long history in cognitive science (see Halle, Bresnan, and Miller 1978). The lexical representation of both types of morpheme is now an issue of central importance within linguistic theory.

Lexicon, Neural Basis of

The lexical processing system is the collection of mechanisms that are used to store and retrieve our knowledge of the words of the language. Knowing a word means knowing its meaning, its phonological and orthographic forms, and its grammatical properties. How is this knowledge organized and represented in the brain? Two types of evidence have been used to answer this question. The major source of evidence has been the patterns of lexical deficits associated with brain damage in aphasic patients. More recently, functional neuroimaging methods—POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI)—have played an increasingly important role. Evidence from neuropsychological and neuroimaging studies has converged on one widely shared conclusion: the mental LEXICON is organized into relatively autonomous neural subsystems in the left hemisphere, each dedicated to processing a different aspect of lexical knowledge.

One of the classic syndromes of APHASIA, anomia—a deficit in retrieving words for production—provides prima facie evidence for distinct representation of meaning and of lexical forms in the brain. Studies of anomic patients have shown that they are unable to produce the names of objects despite normal ability to recognize and define them, indicating a selective deficit in processing lexical forms. These patients tend to have more narrowly circumscribed damage, involving most often the left temporal lobe, but sometimes the parietal or frontal lobe or both. There is also evidence that the semantic system can be damaged independently of knowledge of lexical forms. The latter evidence has been obtained both with patients who have sustained focal brain damage due to strokes and patients with degenerative disorders such as Alzheimer's disease. Both types of patients

make semantic errors (e.g., they might produce "table" in naming a chair or "tastes good, a fruit" in naming a pear) in all lexical processing tasks. Patients with selective damage to the semantic component of the lexicon typically have extensive left hemisphere damage involving the temporal, parietal, and frontal lobes. Converging evidence in support of the view that semantic information is distributed widely in the left hemisphere has been obtained in functional neuroimaging studies with PET.

Some brain-damaged patients are selectively impaired in retrieving only the orthographic form (e.g., the spelling of the word *chair*) or only the phonological form of words (e.g., the sound of the word *chair*). Patients of this type can be entirely normal in their ability to understand and define words, but fail to retrieve the correct word form in one, but not the other, modality of output. These patterns of performance attest to the autonomy of phonological and orthographic lexical forms from each other and from meaning. Converging evidence for this conclusion comes from functional neuroimaging studies which have shown that distinct brain regions are activated when neurologically intact participants are engaged in processing the phonological (frontal-temporal) versus the orthographic (parietal-occipital) forms of words.

Damage to the semantic system can lead to disproportionate difficulties with specific semantic categories. The most frequently observed category-specific deficits have concerned the contrast between living and nonliving things. However, the deficits can be quite selective, affecting (or sparing) only animals or only plant life. The lesion sites typically associated with these deficits include the left temporal lobe, the posterior frontal lobe, and the inferior junction of the parietal and occipital lobes. The existence of semantic category-specific deficits was originally interpreted as reflecting a modality-based organization of conceptual knowledge in the brain. It was proposed that visual and functional/associative properties are represented in distinct areas of the brain and that these two sets of properties are differentially important in distinguishing between living and nonliving things, respectively. On this view, selective damage to one of the modality-specific knowledge subsystems would result in a semantic category-specific deficit. However, recent results have shown that category-specific deficits are not the result of damage to modality-specific but rather to modality-independent knowledge systems. These results, and the fact that the reliable categories of category-specific deficits are those of animals, plant life, artifacts, and conspecifics, have led to the proposal that conceptual knowledge is organized into broad, evolutionarily determined domains of knowledge. Functional neuroimaging results with neurologically intact participants have confirmed that the inferior temporal lobe and parts of the occipital lobe are activated in response to animal pictures and words, whereas more dorsal areas of the temporal lobe and parts of the frontal lobe are activated in response to artifacts.

One of the classic features of the speech of some aphasic patients is agrammatic production—a form of speech characterized by a relative paucity of function or closed-class words (articles, prepositions, auxiliaries, etc.). The disproportionate difficulty in producing closed-class words in some

patients is in contrast to patients who show the reverse pattern of dissociation—selective difficulty with open-class words (nouns, verbs, and adjectives). But, the dissociations of lexical processing deficits can be even more fine-grained than that: some patients are disproportionately impaired in producing verbs while others are disproportionately impaired in producing nouns, and some patients can be disproportionately impaired in comprehending one or the other class of words. Grammatical class effects can even be restricted to one modality of output or input. For example, there are patients who are impaired in producing verbs only in speaking (they can write verbs and can produce nouns both in speaking and in writing) and patients who are impaired in producing nouns only in speaking; and there are patients who fail to understand written but not spoken verbs. The fact that grammatical class effects can also be modality-specific implies a close link between word form and grammatical information. These results challenge the view that there exists a modality-neutral lexical node mediating between modality-specific lexical representations and word meaning. Damage to the left frontal lobe is typically associated with disproportionate difficulty in processing verbs and closed-class words, while damage to the left temporal lobe is associated with disproportionate difficulty in producing and comprehending nouns. Recent investigations with PET and event-related potentials (ERPs) have confirmed this general characterization of the roles of the frontal and temporal lobes in processing words of different grammatical classes.

Brain damage can also selectively affect different parts of words, revealing their internal structure. It is now well established that some aphasic patients have no difficulty in processing the stem of words (e.g., *walk* in *walked*) but fail to retrieve their correct inflectional suffixes (e.g. the *-ed* in *walked*), and that some patients can process normally the morphological affixes of words but not their stems. This double dissociation in processing different types of morphemes implies that the units of lexical representation in the brain are stems and inflectional affixes, and not whole words. Detailed single-case studies of aphasic patients have confirmed this conclusion, and have shown that difficulties in processing inflectional morphology tend to be associated with damage to more frontal areas of the left hemisphere, while difficulties in processing the stems of words are more likely to be associated with temporal lobe damage.

Although we still do not have a detailed understanding of the neural substrates of the lexicon, its general outlines are beginning to emerge, and it looks to be as follows: (1) the lexical processing system is distributed over a large area of the left hemisphere, involving the temporal, frontal, and parietal lobes; (2) different parts of the left hemisphere are dedicated to the storage and computation of different aspects of lexical knowledge—meaning, form, and grammatical information are represented autonomously; and (3) within each of the major components of the lexicon, the semantic and lexical form components, there are further fine-grained functional and neural distinctions.

Lightness Perception

The term *lightness* refers to the perceived whiteness or blackness of an opaque surface. The physical counterpart of lightness is *reflectance,* or the percentage of light a surface reflects. A good white surface reflects about ninety percent of the light that illuminates it, absorbing the rest; black reflects only about three percent. The eye, having no reflectance detectors, must compute lightness based only on the light reflected from the scene. But the intensity of light reflected from any given surface, called *luminance,* is a product of both its reflectance and the level of illumination. And although luminance thus varies with every change of illumination, lightness remains remarkably stable, an achievement referred to as *lightness constancy.*

There is a perceptual quality that corresponds to luminance called *brightness.* Brightness is to lightness as perception of visual angle is to perception of object size (see SPATIAL PERCEPTION). While brightness might be said to refer to our sensation of light intensity, lightness refers to a perceived property of the object itself and is essential to object recognition (see SURFACE PERCEPTION).

Despite the remarkable correlation between lightness and physical reflectance, neither the stimulus variable on which it is based nor the computation that finally produces lightness has been agreed upon. HELMHOLTZ (1866), recognizing that lightness cannot be based simply on luminance, argued that the level of illumination is unconsciously taken into account, but this approach has remained vague and unconvincing. Wallach (1948) avoided the whole issue of computing the illumination with the dramatically simple proposal that lightness depends on the ratio between the luminance of a surface and the luminance of its background. He demonstrated that such a local edge ratio predicts perceived lightness in very simple displays such as a disk surrounded by an annulus. And he observed that, even for complex images, luminance ratios, unlike absolute luminance values, tend to remain invariant when the illumination changes. Others (Hurvich and Jameson 1966; Cornsweet 1970), lured by the prospect of a physiological account of lightness, have sought to reduce Wallach's ratio findings to the neural mechanism of lateral inhibition.

Subsequent research has suggested that what gets encoded are luminance ratios at edges, not the absolute luminances of points, and that lateral inhibition plays a key role in the neural encoding of these ratios. But both Wallach's ratio principle and its physiological reduction are now viewed as much too simplistic an account of lightness. Recent work has dealt with three important limitations: (1) the computation is too local; (2) it produces large errors when applied to illuminance edges; and (3) only relative lightness values can be determined, unless an anchoring rule is also given.

1. The first of these can be illustrated in simultaneous lightness contrast, the familiar textbook illusion, shown in figure 1. On its face this contrast illusion appears to provide further evidence of the relational determination of lightness. But if lightness depended simply on local luminance ratios, the two targets should look as different as black and white. So, in fact, the very weakness of the illusion shows that lightness is not tied to background luminance as strongly as Wallach's ratio rule implies. Quantitative work (Gilchrist 1988) has shown that lightness is just as independent of background luminance as it is of illumination level and this appears to require the ability to compute luminance ratios between remote regions of the image. In the early 1970s several writers (Land and McCann 1971; Arend, Buehler, and Lockhead 1971; Whittle and Challands 1969) proposed a process of edge integration by which all edge ratios along a path between two remote regions are mathematically combined.

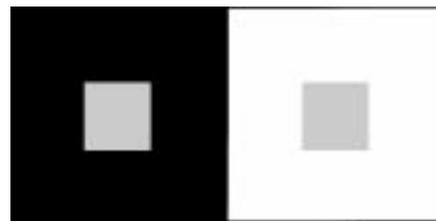
2. Gilchrist (1979), noting that many edges in the retinal image represent changes in the illumination (such as shadow boundaries), not changes in reflectance, argued that edge integration cannot work without some prior process of edge classification (see figure 2). Recent computational models (Bergström 1977; Adelson 1993; Gilchrist 1979) have relied on concepts like edge integration and edge classification to decompose the retinal image into component images—called intrinsic images—that represent the physical values of surface reflectance and illumination. This approach has the advantage of providing an


Figure 1. Simultaneous lightness contrast. Although this illusion shows an influence of the target/background luminance ratio, the weakness of the illusion shows that lightness is no simple product of that ratio.
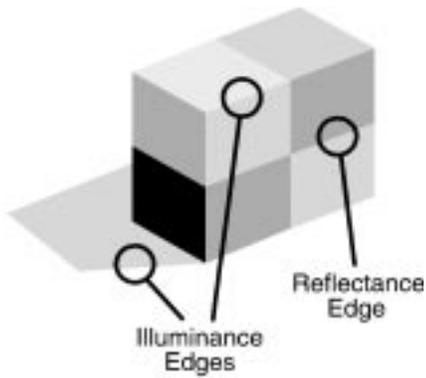

Figure 2. Lightness could not be based on local edge ratios unless the edges were first classified. (After Adelson 1993.)

account of our perception of the illumination, not just of surface lightness.

3. Computing absolute or specific shades of gray requires an anchoring rule, a rule that ties some locus on the scale of perceived grays to some feature of the retinal image. One candidate rule, endorsed by Wallach (1948) and by Land and McCann (1971), says that the highest luminance is white, with lower luminances scaled relative to this standard. An alternative rule, implicit in concepts like the *gray world assumption* and Helson's adaptation-level theory (1964), says that the average luminance is middle gray, with higher and lower values scaled relative to the average. When these rules are tested by presenting a display consisting of a very restricted range of grays, it is found that the highest luminance appears white, but the average does not appear middle gray (Cataliotti and Gilchrist 1995; Li and Gilchrist in press). But relative area also plays an important role. An increase in the area of the darker regions at the expense of the lighter causes the darker regions to lighten in gray value and the lightest region to appear self-luminous.

These rules of anchoring by highest luminance and relative area apply to both simple visual displays and to frameworks or groups embedded within complex images. In complex images, however, perceived lightness can be predicted by a compromise between lightness values computed within these relatively local frameworks and lightness values computed across the entire visual field. The weighting in this compromise increasingly shifts to the local framework as that becomes larger and more highly articulated. If the study of anchoring has undermined the portrait of a highly ratiomorphic lightness computation recovering veridical values of reflectance and illumination, it has nevertheless provided a remarkable account of perceptual errors. Emerging anchoring models portray a more rough-and-ready system (see MID-LEVEL VISION) that, while subject to apparently unnecessary errors, is nevertheless quite robust in the face of a wide variety of challenges to perceptual veridicality.

Limbic System

Much as other systems with a historic origin (e.g., the reticular system), the limbic system (LS) is difficult to define as it has gone through numerous modifications, adaptations, refinements, and expansions during the more than 100 years of its existence. Furthermore, problems with its description arise from the facts that it is frequently composed of only

portions of larger units (e.g., only a minority of the thalamic nuclei are included), and that it varies considerably among species (e.g., the olfactory system, a portion of the LS, first expands considerably in mammals as opposed to nonmammals such as birds, but then shrinks again in whales and primates). Basically the LS constitutes an agglomerate of brain structures with a cortical core around the corpus callosum and within the medial temporal lobe and with a number of subcortical structures extending from the hindbrain to the forebrain (figure 1). Many of these structures are central to the processing of EMOTIONS and MEMORY, including the evaluation of sensory functions such as PAIN.

The term *le grand lobe limbique* was coined by BROCA (1878) as an anatomical structure. Broca and his contemporaries nevertheless thought that the limbic structures were largely olfactory and might therefore be subsumed under the term *rhinencephalon* (cf. Laurent 1997 for olfactory processing). Later research shifted the dominant functional implications of the LS to the processing of emotions and memory and modified the regions to be subsumed under this term. This discussion has continued until today (Papez 1937; MacLean 1952, 1970; Nauta 1979; LeDoux 1996; Nieuwenhuys 1996). While the LS (the term was introduced by MacLean 1952) is frequently regarded as an ancient brain system which regresses during phylogeny, numerous more recent studies have shown that, on the contrary—with the exception of the olfactory regions—most

structures of this system expand and increase in differentiation (e.g., Stephan 1975; Armstrong 1986). (This expansion is, however, less prominent than that of neocortical areas.)

Based on comparative anatomy and evolutionary theory, MacLean (1970) divided the brain into three general compartments: (1) a protoreptilian portion (spinal cord, parts of the midbrain and diencephalon, BASAL GANGLIA); (2) a paleomammalian one—in principle the LS—, and (3), a neomammalian one, largely the neocortical mantle. The LS therefore constitutes a link between the oldest and the newest attributes of the mammalian, in particular the human, brain. It includes (1) the limbic cortex, a circumscribed cortical region along the medial rim of the cerebrum; (2) the limbic nuclei of the tel-, di-, and mesencephalon; and (3) the fiber tracts interconnecting these structures. The limbic cortex is further subdividable into an inner ("allocortical," i.e., constituted of the phylogenetically oldest, three-layered cortex) and an outer ring ("juxtallocortical," i.e., constituted of transitional, four- or five-layered cortex; Isaacson 1982).

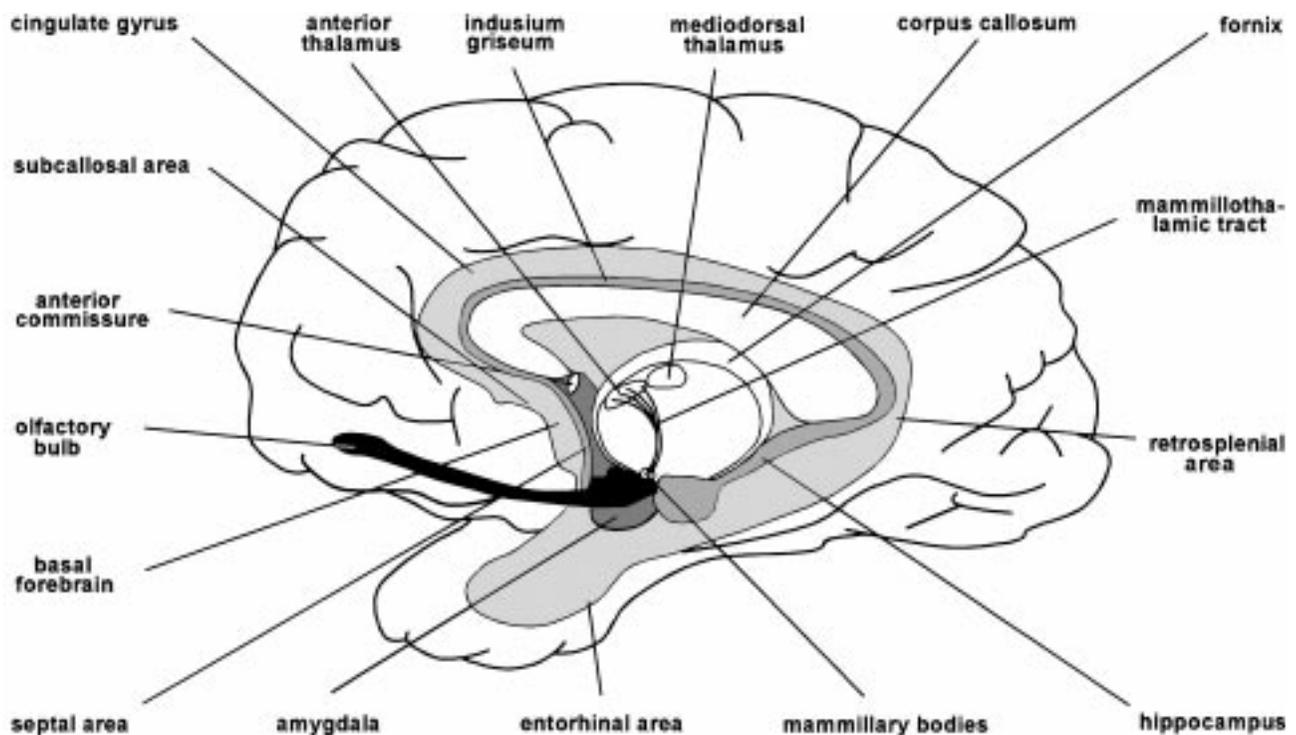
The core of the LS is included in the so-called Papez circuit (Papez 1937) or medial limbic circuit (see figure 1). This circuit is primarily engaged in the transfer of information from short-term to long-term memory. Another circuit that is more closely related to emotional processing but still relevant to mnemonic information processing as well is the


Figure 1. Schematic section through the forebrain (i.e., without the brain stem) showing the ringlike arrangement of the limbic structures around the corpus callosum and below it. The Papez circuit is formed principally by the HIPPOCAMPUS, mammillary bodies, anterior thalamus, cingulate gyrus, and is interconnected via the fornix, mammillothalamic tract, fibers from the anterior

thalamus to the cingulate gyrus and to portions of the hippocampal region, and the cingulum fibers that run near the indusium griseum, an extension of the hippocampal formation (Irle and Markowitsch 1982). All other structures mentioned are usually regarded as belonging to the limbic system as well. Some brain stem nuclei might be added.

basolateral limbic circuit, or lateral limbic circuit (Sarter and Markowitsch 1985). It is constituted by the triangle formed by the amygdala, the mediodorsal thalamic nucleus, and the basal forebrain regions. Interconnecting fibers are the ventral amygdalofugal pathway, the anterior thalamic peduncle, and the bandeletta diagonalis (the circuit is depicted in figure 48.4 of Markowitsch 1995).

As mentioned above, there have been various attempts to expand the LS (Isaacson 1982; Nauta 1979; Nieuwenhuys 1996). All of these nevertheless agree in principle with MacLean's (1970) proposal to see this system as the mediator between the neocortical mantle (dealing with sensory processing, memory storage, and the initiation and supervision of behavior) and the "lower," largely motoric regions of the brain stem and the basal ganglia.

Though the structures of the LS are predominantly involved in emotional, motivational, and memory-related aspects of behavior, some subclustering should be noted: the septal region, the amygdala, and the cingulate cortex are largely engaged in the control of emotions ranging from heightened ATTENTION and arousal to rage and aggression. In evaluating emotions the septum may partly act in opposition to amygdala and cingulate cortex. The amygdala is furthermore involved in motivational regulations and in evaluating information of biological or social significance (and therefore indirectly in memory processing). Damage to the amygdala may result in conditions of tameness, hypersexuality, amnesia, agnosia, aphagia, and hyperorality (Klüver-Bucy syndrome). The hippocampal formation and surrounding structures are principally engaged in transferring memories from short-term to long-term storage, but do have additional functions (e.g., in the spatial and possibly also in the time domains). Anterior and medial nuclei of the thalamus and the mammillary body of the hypothalamus control memory transfer as well ("bottleneck structures"; Markowitsch 1995). Also, these nuclear configurations (to which nonspecific thalamic nuclei belong as well) control further forms of behavior ranging from sleep to possibly consciousness. Between different species, functional shifts of limbic structures have been noted.

There is consequently both functional unity and diversity within the LS. As an example, it is still largely unknown whether the medial temporal lobe structures (with the hippocampus as core) and the medial diencephalic structures (medial and anterior thalamus, mammillary bodies) constitute one or two memory systems. One reason for this uncertainty can be sought in the multitude of fiber bundles interconnecting LS structures in an extensive network. High-resolution dynamic imaging research (e.g., POSITRON EMISSION TOMOGRAPHY) may provide answers in the near future.

Linguistic Relativity Hypothesis

The linguistic relativity hypothesis is the proposal that the particular language one speaks influences the way one thinks about reality. The hypothesis joins two claims. First, languages differ significantly in their interpretations of experience—both what they select for representation and how they arrange it. Second, these interpretations of experience influence thought when they are used to guide or support it. Because the first claim is so central to the hypothesis, demonstrations of linguistic differences in the interpretation of experience are sometimes mistakenly regarded as demonstrations of linguistic relativity and demonstrations of some commonalities are taken as disproof, but the assessment of the hypothesis necessarily requires evaluating the cognitive influence of whatever language differences do exist. Accounts vary in the proposed mechanisms of influence and in the power attributed to them—the strongest version being a strict linguistic determinism (based, ultimately, on the identity of language and thought). Linguistic relativity proposals should be distinguished from more general concerns about how speaking any natural language whatsoever influences thinking (e.g., the general role of language in human intellectual functioning) and discourse-level concerns with how using language in a particular way influences thinking (e.g., schooled versus unschooled). Ultimately, however, all these levels interrelate in determining how language influences thought.

Interest in the intellectual significance of the diversity of language categories has deep roots in the European tradition (Aarsleff 1982). Formulations related to contemporary ones appeared in England (Locke), France (Condillac, Diderot), and Germany (Hamman, Herder) near the beginning of the eighteenth century. They were stimulated by opposition to the universal grammarians, by concerns about the reliability of language-based knowledge, and by practical efforts to consolidate national identities and cope with colonial expansion. Work in the nineteenth century, notably that of Humboldt in Germany and SAUSSURE in Switzerland and France, drew heavily on this earlier tradition and set the stage for contemporary approaches. The linguistic relativity proposal received new impetus and reformulation in America during the early twentieth century in the work of anthropological linguists SAPIR (1949) and Whorf (1956) (hence the common designation as "the Sapir-Whorf hypothesis"). They emphasized direct study of diverse languages and rejected the hierarchical rankings of languages and cultures characteristic of many European approaches.

Despite enduring philosophical interest in the question (e.g., Quine 1960), there has been little empirical research that both compares linguistic meaning structures and then independently assesses thought (Lucy 1992a). This stems partly from the interdisciplinary nature of the problem and partly from concern about the implications of relativism and determinism. Empirical efforts fall into three broad types.

Structure-centered approaches begin with an observed difference between languages, elaborate the interpretations of reality implicit in them, and then seek evidence for their influence on thought. The approach remains open to unexpected interpretations of reality but often has difficulty establishing a neutral basis for comparison. The classic example of a language-centered approach is Whorf's pioneering comparison of Hopi and English (1956) in which he argues for different conceptions of 'time' in the two languages as a function of whether cyclic experiences are classed as like ordinary objects (English) or as recurrent events (Hopi). The most extensive recent effort to extend and improve the comparative fundamentals in a structure-centered approach has sought to establish a relation between variations in grammatical number marking and attentiveness to number and form (Lucy 1992b).

Domain-centered approaches begin with a domain of experienced reality, typically characterized independently of language(s), and ask how various languages select from and organize it. The approach facilitates controlled comparison but often at the expense of regimenting the linguistic data rather narrowly. The classic example of this approach shows that some colors are more lexically encodable than others and that more codable colors are remembered better (Brown and Lenneberg 1954). This approach was later extended to argue that there are cross linguistic universals in the encoding of the color domain such that a small number of "basic" color terms emerge in languages as a function of biological constraints (Berlin and Kay 1969). This research has been widely accepted as evidence against the linguistic relativity hypothesis, although it actually deals with constraints on linguistic diversity. Subsequent research has challenged the universal claim and shown that different color term systems do influence COLOR CATEGORIZATION and memory. The most successful effort to improve the quality of the linguistic comparison in a domain-centered approach has sought to show cognitive differences in the spatial domain between languages favoring the use of body coordinates to describe arrangements of objects (e.g., the man is left of the tree) and those favoring systems anchored in cardinal direction terms or topographic features (e.g., the man is east/uphill of the tree; Levinson 1996).

Behavior-centered approaches begin with a marked difference in behavior that the researcher comes to believe has its roots in a pattern of thinking arising from language practices. The behavior at issue typically has clear practical consequences (either for theory or for native speakers), but because the research does not begin intending to address the linguistic relativity question, the theoretical and empirical analyses of language and reality are often weak. An example of a behavior-centered approach is the effort to account for differences in Chinese and English speakers' facility with counterfactual or hypothetical reasoning by

reference to the marking of counterfactuals in the two languages (Bloom 1981).

The continued relevance of the linguistic relativity issue seems assured by the same impulses found historically: the patent relevance of language to human sociality and intellect, the reflexive concern with the role of language in intellectual method, and the practical encounter with diversity.

Linguistic Theory

See INTRODUCTION: LINGUISTICS AND LANGUAGE

Linguistic Universals and Universal Grammar

A child's linguistic system is shaped to a significant degree by the utterances to which that child has been exposed. That is why a child speaks the language and dialect of his family and community. Nonetheless, there are aspects of the linguistic system acquired by the child that do *not* depend on input data in this way. Some cases of this type, it has been argued, reflect the influence of a genetically prespecified body of knowledge about human language. In the literature on GENERATIVE GRAMMAR, the term *Universal Grammar*—commonly abbreviated UG—refers to this body of "hardwired" knowledge.

Questions concerning the existence and nature of UG arise in all areas of linguistics (see discussion in SYNTAX, PHONOLOGY, and SEMANTICS). Research on these questions constitutes a principal point of contact between linguistics and the other cognitive sciences.

Three streams of evidence teach us about the existence and nature of UG. One stream of evidence comes from crossling-

uistic investigation of linguistic universals, discussed in the article on TYPOLOGY. Crosslinguistic investigations help us learn whether a property found in one language is also found in other unrelated languages, and, if so, why. Another stream of evidence concerning UG comes from investigation of LANGUAGE ACQUISITION and learnability, especially as these investigations touch on issues of POVERTY OF THE STIMULUS ARGUMENTS. Work on acquisition and learnability helps us understand whether a property found in the grammar of an individual speaker is acquired by imitation of input data or whether some other reason for the existence of this property must be sought. Finally, evidence bearing on the specially *linguistic* nature of UG comes from research on MODULARITY AND LANGUAGE. Features of language whose typological and acquisitional footprint suggests an origin in UG may be confirmed as reflections of UG if they reflect aspects of cognition that are to some degree language-specific and "informationally encapsulated." If a fact about an individual speaker's grammar turns out to be a fact about grammars of all the world's languages, if it is demonstrably not a fact acquired in imitation of input data, and if it appears to be specific to language, then we are warranted to suspect that the fact arose from a specific feature of UG.

The questions one asks in the process of building the theory of UG are varied and complex. Suppose the linguist discovers that a property P of one language is present in a variety of other languages. It is often possible that P arises from some more general property of cognition. For example, the repertoire of linguistically relevant THEMATIC ROLES such as "experiencer" or "agent" may reflect language-independent facts about the categorization of events —and therefore fall outside of UG. On the other hand, while the repertoire of thematic roles may be language-independent, the opposite is true of the apparently universal mapping of specific thematic roles onto specific designated syntactic positions—for example, the fact that agents are mapped universally onto a structurally more prominent position than patients (e.g., subject position). This specifically linguistic mapping thus constitutes one of the properties attributed to UG.

It is also important to try to distinguish UG-based universals from apparent universals that merely reflect usability conditions on languages that must serve a communicative function (*functional* universals). For example, there is probably a lower bound to the size of a language's phonemic inventory. Does this restriction form part of UG? Not necessarily. It is equally possible that the limitation merely reflects a consequence of usability conditions for linguistic systems. The words of a language whose only phonemes are /m/ and /a/ would be extraordinarily long and hard to distinguish. Such a language might fall within the range permitted by UG, yet never occur in nature because of its dysfunctionality.

Because of the ever-present possibility that a universal may have a functional explanation, researchers interested in discovering properties of language that derive from UG often focus on those universals for which functional explanations are the *least* likely. For example, syntactic research has paid particular attention to a number of limitations on form-meaning pairs that have just this property of "dysfunc-

tionality." One example is a set of restrictions specific to *how* and *why* questions. *How did you think Mary solved the problem?* can be a question about Mary's problem-solving methods, but the sentence *How did you ask if Mary solved the problem?* cannot. (It can only be a question about methods of asking.) The restriction concerns the domains from which WH-MOVEMENT may apply, which in turn correlates with sentence meaning. The restriction appears to be a genuine universal, already detected in a wide variety of languages whose grammars otherwise diverge in a number of ways. Crucially, the restriction makes no evident contribution to usability. Just the opposite: it prevents speakers from posing perfectly sensible questions, except through circumlocution—for example, *I know that you asked if Mary had solved the problem in some particular way. What was that way?* The study of such seemingly dysfunctional aspects of language has provided an especially clear path to a preliminary understanding of UG. This fact also explains why the data of generative grammar stray so often from "everyday" linguistic facts—a central difference between the concerns of generative grammarians and those researchers more concerned with "everyday" language use (a group that includes some sociolinguists as well as computational linguists interested in practical language technologies).

The existence of "Universal Grammar" (uppercase) does not necessarily entail the existence of a "universal grammar" (lowercase)—in the sense of a usable linguistic system wholly determined by genetic factors. UG must allow for language variation, though by its very nature it restricts the range of variation. This is why certain nonuniversal properties of language nonetheless recur in widely scattered, unrelated languages, while other equally imaginable properties are never found. For example, the placement of the finite verb in "second" position characteristic of the Germanic languages (see HEAD MOVEMENT) is also found in Vata (Ivory Coast; Koopman 1983), Kashmiri (Bhatt 1995), and Karitiana (Brazil; Storto 1996). By contrast, in no known language are verbs obligatorily placed in third position. In other words, UG allows languages to vary—but only up to a point.

There are several theories of how variation is built into UG. One proposal holds that the principles of UG define the parameters of possible variation. Language acquisition involves "setting" these parameters (see PARAMETER-SETTING APPROACHES TO ACQUISITION, CREOLIZATION, AND DIACHRONY). Another suggestion, advanced by Borer (1981) and Borer and Wexler (1987), holds that true variation is limited to the LEXICON (one aspect of language that we know must vary from language to language). Apparent syntactic variation on this view arises from the differing syntactic requirements of lexical items (see also SYNTAX, ACQUISITION OF). Another proposal, developed within OPTIMALITY THEORY, attributes variation to differences in the ability of particular grammatical principles to nullify the action of other principles with which they conflict (i.e., differences in "constraint ranking").

It is not entirely clear what aspects of UG are subject to variation. In particular, though no one doubts that syntactic and phonological systems vary across languages, the question of variation in semantics is more contested. The details of semantic interpretation are probably less obvious to

young children acquiring language than are the details of word positioning and word pronunciation that provide evidence about syntax and phonology. Consequently, it is conceivable (though not inevitable) that the laws governing compositional semantic interpretation of syntactic structures are wholly determined by UG—hence invariant across languages. In fact, the notion and the term was borrowed by Chomsky (1965, 1966) from an earlier grammatical tradition that explicitly sought universal semantic roots of syntax (for example, the 1660 Port-Royal *Grammaire génerale et raisonée*). Semantic universals do exist, of course. Not only basic laws of semantic composition (Heim and Kratzer 1998), but also many details recur in language after language. For example, the classification of predicates into something like "states" versus "events," and the interaction of this classification with such properties as quantifier interpretation, seems to be invariant (or nearly so) across the languages that have been studied. On the other hand, other facts might cause one to doubt whether all languages command exactly the same semantic resources. For example, although "multiple questions" such as *Who bought what?* receive similar interpretations in many languages (as questions whose answer provides a list of pairs; e.g., *John bought the wine and Mary bought the dessert*), this semantic possibility is entirely absent in some languages, including Italian and Irish. To native speakers of these languages, the counterparts to *Who bought what?* (e.g., Italian **Chi a comprato che cosa?*) seem quite uninterpretable. Whether such facts indicate the existence of semantic variation, or merely reveal lexical or syntactic differences with a predictable impact on semantics, remains an open question.

The fact that variation is "built into" some aspects of UG does not preclude the possibility that UG might characterize a usable "default" grammar on its own. This is also a matter of considerable controversy. Bickerton (1981), for example, has suggested that CREOLES represent the spontaneous flowering of a purely UG-based grammar, but this view is controversial (Mufwene 1996, 1999). Furthermore, a precedent for "usable UG" is provided elsewhere in the animal kingdom by songbird species whose song is partly learned rather than totally innate. Researchers have identified a "UG" for the song of several such species. When birds of these species are reared in isolation, they spontaneously develop a song that falls recognizably within the parameters of their UG, though rudimentary in many ways (Marler 1991, 1996; see also ANIMAL COMMUNICATION). The UG of songbirds is of importance for another reason. Among those who have not made a study of the relevant evidence, theories of UG are often thought to require special pleading, as if the hypothesis of species-specific innate knowledge constituted a violation of Occam's razor. The evidence from songbirds makes it clear that a priori objections to UG are nothing more than a prejudice. The nature of human UG remains, however, a topic of lively debate and continued research.

Linguistics, Philosophical Issues

As with any rapidly developing science, GENERATIVE GRAMMAR has given rise to a number of interesting philosophical puzzles and controversies. These controversies range from disputes about the object of study in linguistics, to issues about the relation between the language faculty and the external world, to questions about the legitimacy of appeal to rules and representations, to questions about proper empirical methodology.

One of the prominent philosophical debates in generative grammar has centered around the question of what sort of objects languages and grammars are. Katz (1985) distinguishes three general approaches to the question, roughly paralleling three traditional approaches to the nature of abstract objects: platonism, conceptualism, and nominalism. The platonist view would take the object of study in linguistics to be an abstract mathematical object outside of space and time, the conceptualist position would be a position like Chomsky's in which the object of study is a mental object of some form, and the nominalist view would hold that the object of study is a corpus of inscriptions or utterances.

The platonist view has been advanced most visibly by Katz (1981), although it may be that the position rests on a confusion. For example, Higginbotham (1983) has observed that even if grammars are abstract objects, there is still the

empirical question of which grammar a particular agent is employing. George (1989) has further clarified the issue, holding that we need to distinguish between a grammar, which is the abstract object that we know, a psycho-grammar, which is the cognitive state that constitutes our knowledge of the grammar, and a physio-grammar, which is the physical manifestation of the psycho-grammar in the brain. If this picture is right, then the platonist/conceptualist dispute in linguistics may be trading on a failure to distinguish between grammars and psycho-grammars.

Perhaps more pressing is the dispute between the nominalist and conceptualist positions, a dispute that Chomsky (1986) has characterized as being between E-language and I-language conceptions of language. From the E-language perspective, a natural language is a kind of social object, the structure of which is purported to be established by convention (see Lewis 1975), and persons may acquire varying degrees of competence in their knowledge and use of that social object. On Chomsky's views, such objects would be of little scientific interest if they did exist (since they would not be "natural" objects), but in any case such objects don't exist. Alternatively, an I-language is not an external object but is rather a state of an internal system that is part of our biological endowment. An agent might have I-language representations of English sentences, but those internal representations are not to be confused with spoken or written English sentences. They are rather data structures in a kind of internal computational system.

Chomsky understands the I-language computational system to be individualistic (see INDIVIDUALISM). That means that the properties of the system can be specified independently of the environment that the agent is embedded in. Thus, it involves properties like the agent's rest mass and genetic make-up (and unlike relational properties like the agent's weight and IQ).

By itself, the dispute between I-language and E-language approaches has little philosophical traction; the actual direction of the field presumably settles the issue as to which is the object of study. Nevertheless, some normative claims have been offered. For example, Soames (1984) has suggested that if we attend to the leading questions of linguistics in the past, then linguistics has been (and ought to be) concerned with E-language. Of course, one might wonder why past investigations should restrict the direction (and leading questions) of current research. Chomsky (1993, 1995) not only disputes this historical story but has argued that E-languages are not suitable for naturalistic inquiry, because they constitute artifacts rather than natural objects. In other words, it is fine to talk about E-languages as long as one doesn't think one is doing science.

As we will see, the choice between these two general approaches to language is very rich in consequences. Both the claim that I-language is individualistic and the claim that it is computational have led to a number of philosophical skirmishes.

One of the immediate questions raised by the idea that I-language is individualistic has to do with the nature of SEMANTICS, and in particular *referential* semantics—construed as theories of the relation between linguistic forms and aspects of the external world (see REFERENCE, THEORIES

OF). In short, the worry is this: Putnam (1975) and many other philosophers have held that we need referential semantics to characterize linguistic MEANING—that meanings "ain't in the head." But if this is right, then it is hard to see how semantics can be part of the language faculty, which is supposed to be individualistic (and hence "in the head").

This tension between I-language and referential semantics has led commentators such as Hornstein (1984) and Chomsky (1993, 1995) to be skeptical of the possibility of a referential semantics. However, Ludlow (forthcoming) has argued that the tension in these views is apparent only, because the connection between I-languages and referential semantics would parallel the connection between individualistic and relational sciences in other domains (for example, it would be similar to the connection that holds between the studies of primate physiology and primate ecology—facts about physiology can shed light on the primate's relation to its environment, and vice versa). Inferences between individualistic and relational sciences are imperfect, but data from one domain can nevertheless be relevant to the other.

The idea that linguistic theory involves the investigation of RULES AND REPRESENTATIONS (or principles and parameters) of an internal computational system has also led to philosophical questions about the nature of these rules and representations. For example, Quine (1970) has argued that because many possible grammars may successfully describe an agent's linguistic behavior, there is no way in principle for us to determine which grammar an agent is using. For his part, Chomsky (1980) has argued that if we consider the *explanatory adequacy* of a grammar in addition to its *descriptive adequacy,* then the question of which grammar is correct is answerable in principle. That is, if we consider that a grammar must be consistent with the theory of LANGUAGE ACQUISITION, acquired language deficits, and more generally with cognitive psychology, then there are many constraints available to rule out competing grammatical theories.

Another set of worries about rule following have stemmed from Kripke's (1982) reconstruction of arguments in Wittgenstein (1953, 1956). The idea is that there can be no brute fact about what rules and representations a system is running apart from the intentions of the designer of the system. Because, when studying humans, we have no access to the intentions of the designer, there can be no fact of the matter about what rules and representations underlie our linguistic abilities. The conclusion drawn by Kripke is that "it would seem that the use of the idea of rules and of competence in linguistics needs serious reconsideration, even if these notions are not rendered meaningless." (1982: 31 fn 22)

Chomsky (1986) appears to argue that one can know certain facts about computers in isolation, but Chomsky's current position (1995) is that computers, unlike the human language faculty, are artifacts and hence the product of human intentions. The language faculty is a natural object and embedded within human biology, so the facts about its structure are no more grounded in human intentions than are facts about the structure of human biology.

If the language faculty is an internal computational/representational system, a number of questions arise about how

to best go about investigating and describing it. For example, there has been considerable attention paid to the role of formal rigor in linguistic theory. On this score, a number of theorists (e.g., Gazdar, Klein, Pullum, and Sag 1985; Bresnan and Kaplan 1982; Pullum, 1989) have argued that the formal rigor of their approaches—in particular, their use of well-defined recursive procedures—counts in their favor. However, Ludlow (1992) has argued that this sort of approach to rigorization would be out of synch with the development of other sciences (and indeed, branches of mathematics) where formalization follows in the wake of the advancing theory.

A second methodological issue relates to the use of PARSIMONY AND SIMPLICITY in the choice between linguistic theories. Although tight definitions of simplicity within a linguistic theory seem to be possible (see Halle 1961; Chomsky and Halle 1968; Chomsky 1975), finding a notion of simplicity that allows us to chose between two competing theoretical frameworks is another matter. Some writers (e.g., Postal 1972; Hornstein 1995) have argued that generative semantics and the minimalist program (see MINIMALISM), respectively, are simpler than their immediate competitors because they admit fewer levels of representation. In response, Ludlow (1998) has maintained that there is no objective criterion for evaluating the relative amount of theoretical machinery across linguistic theories. Ludlow offers that the only plausible definition of simplicity would be one that appealed to "simplicity of use," suggesting that simplicity in linguistics may not be a feature of the object of study itself but rather our ability to easily grasp and utilize certain kinds of theories.

Finally, there is the matter of the nature of evidence available for investigating the language faculty. Evidence from a written or spoken corpus is at best twice removed from the actual object of investigation, and given the possibility of performance errors, is notoriously unreliable at that. Much of the evidence adduced in linguistic theory has therefore been from speakers' intuitions of acceptability, as well as intuitions about possible interpretations. This raises a number of interesting questions about the reliability of introspective data (see INTROSPECTION) and the kind of training required to have reliable judgements. There is also the question of why we should have introspective access to the language faculty at all. It is fair to say that these questions have not been adequately explored to date (except in a critical vein; see Devitt 1995; Devitt and Sterelny 1987).

Katz (1985: Introduction) offers that the philosophy of linguistics could soon emerge as a domain of inquiry in its own right, on the model of the philosophy of physics and the philosophy of biology. Given the number of interesting questions and disputes that have arisen in the interim, it is fair to say that Katz's prediction is coming true. The issues canvassed above provide a mere sketch of the current topics under discussion and point to a rich field of investigation in the years to come.

Literacy

Literacy is competence with a written language, a script. This competence includes not only an individual's ability to read and write a script but also one's access to and competence with the documentary resources of a literate society. Literacy holds a prominent place in the political goals of both developed and developing nations as manifest in universal, compulsory education where literacy is seen as a means to personal, social, and economic fulfillment. Literacy is a more general concept than READING and writing, including not only competence with and uses of reading and writing but also the roles that reading and writing play in the formation and accumulation of the procedures, laws, and texts that serve as the primary embodiment of historical culture. Literate, bureaucratic, or "document" societies are those in which such archival texts and documents play a central and authoritative role. Such societies depend on highly literate specialists.

Writing and communication   Writing has obvious advantages over speech for communication across space and through time, factors which various media, including the book, the printing press, the telegraph, and computer technologies, exploit and extend in various ways. Writing played an essential role in the formation and operation of the first large-scale societies, whether as cities, nations, or empires in ancient China, Sumer, Egypt, and Mesoamerica, where it played a critical role in record keeping (Nissen, Damerow, and Englund 1993), codification and publication of law (Harris 1989), the development of literature (Havelock 1963), and the accumulation of knowledge whether as history or science (Eisenstein 1969).

Writing and representation   Not only does writing alter patterns of communication, written texts and commentaries on texts build up a tradition of scholarship. Such accumulations tend to lose their connections with personal authorship and may come to be treated as objects in their own rights, as Scripture, as Law, or as Science. Consequently, writing comes to serve as a mode of representation of what is taken as "known." Three aspects of this problem have been taken up in the cognitive sciences: the relation between speech and writing, the acquisition of literacy, and the effects of literate representations on the formation of mind.

Speech and writing   Although scripts are not designed according to fixed principles, WRITING SYSTEMS may be classified according to type, each type bearing a particular relation to the structure of speech. Each type of script, consequently, requires a reader to carve up the stream of speech in a distinctive, graphically determined way. The problem for the learner is to analyze, that is, conceive of, oral speech in terms of the categories offered by the script (Shankweiler and Liberman 1972; Faber 1992; Harris 1986; Olson 1994).

On this view, the properties of speech available for INTROSPECTION, such as words, sentences, syllables, and phonemic segments, are the consequence of literacy, of applying written models to speech. A major problem in learning to read is learning to "hear" speech in a new way, that is, in a way compatible with the items—words and letters—composing the script. Studies of nonliterate adults' (Morais, Alegria, and Content 1987) and of prereading children's beliefs about writing (Ferreiro and Teberosky 1982) as well as the vast literature on metalinguistic awareness (Goswami and Bryant 1990) tend to support this view.

Writing and the mind   Although the mind as a biological organ is common to all humans, mind as a conscious, conceptual system is in part the product of culture. In a modern bureaucratic culture, mind is closely linked to literacy but just how remains the subject of research and theory. Although the theory linking forms of writing with levels of culture and thought is to be found in such eighteenth-century writers as Vico and Condorcet, modern theory is more clearly traced to Levy-Bruhl's theory of "primitive thought," now widely criticized, and the theories that first appeared in the 1960s by Goody (1968), McLuhan (1962), Havelock (1963), and later Ong (1982), which contrasted "orality" and "literacy" both as modes of communication and modes of thought. Writing allowed, it was argued, a particular form of study and contemplation, the formation of logics and dictionaries, a focus on "verbatim" interpretation and memorization with an interpretive bias to literalism. Although the increasing and pervasive reliance on written records and other written documents in many societies is undeniable (Clanchy 1992; Thomas 1992), the relations between "orality" and "literacy" continue to be debated. CULTURAL PSYCHOLOGY attempts to understand the cognitive implications of such developments. Although writing never replaces speaking but rather preserves aspects of speech and other forms of information as permanent visible artifacts, these literate artifacts may in turn alter the very linguistic and conceptual practices of a social group, activities that blur, almost to the point of obliterating, the distinction between orality and literacy.

Literate thought   Although mind reflects as well as invents culture and although human competence must be analyzed in terms of the available technologies (Clark 1996: 61), the technology of greatest importance for understanding conceptual and intellectual advance in the arts and sciences is the invention of writing and other notational systems (Donald 1991; Olson 1994).

Conceptual development in children is, in part, the consequence of the acquisition of these systems for representing thought (VYGOTSKY 1986). Furthermore, writing is instrumental to thinking in general as a form of metalinguistic knowledge—that is, knowledge *about* the lexical, grammatical, and logical properties of the language. Vocabulary knowledge, for example, is greatly extended by reading (Anglin 1993; Anderson 1985), and reflective knowledge about words serves as a major aspect of measured intelligence in a literate society (Stanovich 1986).

Literacy and social development   Because literacy plays such a prominent role in modern societies, it is often

assumed that the route to social development is through teaching people to read and write (UNESCO 1985). Current research and practice has shown that in order to bring about cultural and social transformation, literacy must be seen as an activity embedded in social and cultural practice. Literacy, bureaucratic institutional structures with explicit procedures and accountability, and democratic participation are mutually reinforcing. Rather than being seen simply as a goal, literacy has come to be seen as a means to fuller participation in the institutions of the society, whether in law, science, or literature (Street 1985) as well as a means for their transformation.

Logic

> All the children in Lake Woebegone are above average.
> Most people in Lake Woebegone are children.
> Therefore, most people in Lake Woebegone are above average.

No matter what "Lake Woebegone" refers to, what time is being talked about, exactly what kind of majority "most" refers to, or what sense of "above average" is meant, this little proof is valid—as long as the meaning of these terms is held constant. If we replace "most" by the determiner "all," "some," or "at least three," the proof remains valid, but if we replace it by "no" or "few," the proof becomes invalid. As the science of reasoning, logic attempts to understand such phenomena.

It is instructive to compare logic with linguistics, the science of language. Reasoning and using language have a number of properties in common. Both characterize human cognitive abilities. Both exhibit INTENTIONALITY—they refer to objects, events, and other situations typically outside the skin of the agent. And both involve an interaction of SYNTAX, SEMANTICS, and PRAGMATICS. Given these similarities, one might expect logic and linguistics to occupy similar positions vis-à-vis cognitive science, but while lin-

guistics is usually considered a branch of cognitive science, logic is not. To understand why, we must recognize that, apart from the properties noted above, logic and linguistics are strikingly dissimilar. What constitutes a proper sentence varies from language to language. Linguistics looks for what is common to the world's many languages as a way to say something about the nature of the human capacity for language. By contrast, what constitutes a proper (i.e., valid) piece of reasoning is thought to be universal. Twentieth-century logic holds that no matter what language our sample argument is couched in, it will remain valid, not because of some cognitive property of human beings, but because valid reasoning is independent of how it was discovered, produced, or expressed in natural language.

Since antiquity Euclidean geometry, with its system of postulates and proofs, was taken as the shining example of a logical edifice, having its foundations in what we would now call "cognitive science." Under the influence of KANT, nineteenth-century mathematicians and philosophers had assumed that the truth of Euclid's postulates was built into human perceptual abilities, and that methods of proof embodied laws of thought. For example, the great mathematical logician David Hilbert (1928 p. 475) wrote, "The fundamental idea of my proof theory is none other than to describe the activity of our understanding, to make a protocol of the rules according to which our thinking actually proceeds."

Given this historical relationship between logic, geometry, and cognition, it is not surprising that logic was profoundly influenced by the discovery of non-Euclidean geometries, which challenged the Kantian view, and which brought with them both a deep distrust of psychology and an urgent need to understand the differences between valid and invalid reasoning. What were the valid principles of reasoning? What made a principle of reasoning valid or invalid? Refocusing on such normative questions led logicians, following Gödel and Tarski in the mid-twentieth century, to the semantic aspects of logic—truth, reference, and meaning—whose relationships must be honored in valid reasoning. In particular, a valid proof clearly demonstrates that whenever the premises of an argument are true, its conclusion is also true. That is why our sample argument is valid, not because of cognitive abilities of humans, but because, if its premises are true, so is its conclusion.

Cognitive science, on the other hand, is concerned with mechanism, with *how* humans reason. Why do they make the reasoning errors they do? Systematic reasoning errors are at least as interesting as valid reasoning if one is looking for clues as to how people reason. Why are some inferences harder than others? For example, people seem to take longer on average to process the inference in our original sample argument than they do the one in the variant where "most" is replaced by "some" or "at least three," even though all three versions are valid. (This claim is based on informal surveys; I know of no careful work on this question.)

The logician's distrust of psychological aspects of reasoning has led to a de facto division of labor. The relationship between mind and representation is considered the subject matter of psychology, that between representation and the world the subject matter of logic. (There is no such division of labor involving linguistics since it has long been interested in mechanism.) This division has resulted in a distance between the fields of logic and cognitive science. Still, ideas and results from logic have had a profound influence on cognitive science.

Late-nineteenth- and early-twentieth-century logicians (e.g., Hilbert, FREGE, Russell, and Gentzen, before the shift to semantics noted above), developed FORMAL SYSTEMS, mathematical models of reasoning based on the syntactic manipulation of sentencelike representations. The import of "formal" in this context is that the acceptability of an inference step should be a function solely of the shape or "form" of the representations, independent of what they mean. Within linguistics, this has led to the view that a sentence has an underlying LOGICAL FORM that represents its meaning, and that reasoning involves computations over logical forms.

One might postulate that the logical forms involved in our sample argument are something like

> All C are A
> Most P are C
> Most P are A

(Early work did not treat determiners such as "most" and "few" at all—only "every," "some," and others that could be defined in terms of them.) In this view, recognizing the validity of the argument would be a matter of computing the logical forms of the natural language sentences and then recognizing the validity of the inference in terms of these forms (see, for example, Rips 1994).

As models of valid reasoning, formal systems have important uses within mathematical logic and computer science, but as models of human performance, they have been frequently criticized for their poor predictions of successes, errors, and difficulties in human reasoning. Johnson-Laird and Byrne (1991) have argued that postulating more imagelike MENTAL MODELS make better predictions about the way people actually reason. Their proposal, applied to our sample argument, might well help to explain the difference in difficulty in the various inferences mentioned earlier, because it is easier to visualize "some people" and "at least three people" than it is to visualize "most people." Cognitive scientists have recently been exploring computational models of reasoning with diagrams. Logicians, with the notable exceptions of Euler, Venn, and Peirce, have until the past decade paid scant attention to spatial forms of representation, but this is beginning to change (Hammer 1995).

In the 1930s, Alan TURING, a pioneer in computability theory, developed his famous machine model of the way people carry out routine computations using symbols, a model exploited in the design of modern-day digital computers (Turing 1936). Combining Turing's machines and the formal system model of reasoning, cognitive scientists (e.g., Fodor 1975) have proposed formal symbol processing as a metaphor for all cognitive activity: the so-called COMPUTATIONAL THEORY OF MIND. Indeed, some cognitive scientists go so far as to define cognitive science in terms of this metaphor. This suggestion has played a very large role in cognitive science, some would say a defining role, and it is

implicit in Turing's original work. Still the idea is highly controversial; connectionists, for example, reject it.

A third contribution of logic to cognitive science arose from research in logic on semantics. Most famously, the logician Montague (1974), borrowing ideas from modern logic, developed the first serious account of the semantics of natural languages; known as "Montague grammar", it has proven quite fruitful. One successful development in this area has been use of generalized QUANTIFIERS to interpret natural language determiners and their associated noun phrases (Barwise and Cooper 1981). The meaning of each determiner is modeled by a binary relation between sets; the relations themselves have very different properties, properties that can be used in accounting for associated logical and processing differences.

Our final application has to do with cognitive interpretations of the first of GÖDEL'S THEOREMS. This theorem, one of the most striking achievements of logic, demonstrates strict limitations on what can be done using formal systems and hence digital computers. Various writers, most famously Penrose (1991), have attempted to use Gödel's first theorem to argue that because there are things people can do that computers in principle cannot do, the formal systems of logic are irrelevant to understanding human cognition, although this argument is very controversial (see, for example, Feferman 1996).

If it is to be the science of full-fledged reasoning, logic still has much to accomplish. What features might this more complete logic have? The logician C. S. Peirce suggested that the relationship between mind, language, and the world was irreducibly ternary, that one could not give an adequate account of the binary relation between mind and language, or between language and the world, without giving an account of the relationship among all three. According to this view, the division of labor depicted above, and with it the divorce of logic from cognition, is misguided. Peirce's thinking has been reincarnated in the situated cognition movement, which argues that any adequate cognitive theory must take account of the agent's physical embeddedness in its environment and its exploitation of regularities in that environment (see SITUATEDNESS/EMBEDDEDNESS).

Situatedness infects reasoning and logic (Barwise 1987). The ease or difficulty of an inference, for example, depends on the agent's context in many ways. Even the validity of an inference is in a limited sense a situated matter because validity depends not just on the sentences used, but on how they are used by the agent. This arises in our sample argument in the requirement that the meaning of the terms be held constant. The way the agent is situated in the world in part determines whether this caveat is satisfied. For example, if the agent uttered the two premises in different years, the conclusion would not follow.

Logic has had a profound impact on cognitive science, as the above examples show. The impact in the other direction has been less than one might have expected, due to the distrust of cognitive aspects of reasoning by the logic community. One hopes that the synergy between the two fields will be greater in years to come.

Logic Programming

Logic programming is the use of LOGIC to represent programs and of deduction to execute programs in LOGICAL

FORM. To this end, many different forms of logic and many varieties of deduction have been investigated. The simplest form of logic, which is the basis of most logic programming, is the Horn clause subset of logic, where programs consist of sets of implications: A_0 if A_1 and A_2 and ... and A_n. Here each A_i is a simple (i.e., atomic) sentence.

Because deduction by backward reasoning interprets such implications as procedures, it is usual to write them backward: to solve the goal A_0, solve the subgoals A_1 and A_2 and . . . and A_n. The number of conditions, n, can be 0, in which case the implication is simply a fact, which behaves as a procedure which solves goals directly without introducing subgoals.

The procedural interpretation of implications can be used for declarative programming, where the programmer describes information in logical form and the deduction mechanism uses backward reasoning to achieve problem solving behavior. Consider, for example, the implication

> X is a citizen of the United States
> if X was born in the United States.

Backward reasoning treats the sentence as a procedure:

> To show X is a citizen of the United States,
> show that X was born in the United States.

In fact, backward reasoning can be used, not only to show a particular person is a citizen, but also to find people who are citizens by virtue of having been born in the United States.

Logic programs are nondeterministic in the sense that many different procedures might apply to the same goal. For example, naturalization and being the child of a citizen provide alternative procedures for obtaining citizenship. The nondeterministic exploration of alternative procedures, to find one or more which solve a given goal, can be performed by many different search strategies. In the logic programming language Prolog, search is performed depth-first, trying procedures one at a time, in the order in which they are written, backtracking in case of failure.

Declarative programming is an ideal. The programmer specifies what the problem is and what knowledge should be used in solving problems, and the computer determines how the knowledge should be used. The declarative programming ideal works in some cases where the knowledge has a particularly simple form. But it fails in many others, where nondeterminism leads to an excessively inefficient search. This failure has led many programmers to reject logic programming in favor of conventional, imperative programming languages.

The following example shows the kind of problem that can arise with declarative programming:

> There is a path from X to Y if there is a step from X to Y.
>
> There is a path from X to Y if there is a path from X to Z and there is a path from Z to Y.

Given no other information and the goal of showing whether there is a path from a node *a* to a node *b,* Prolog fails to find a step from *a* to *b* using the first procedure. It therefore tries to find a path from *a* to some Z using the second procedure. There is no step from *a* to any Z using the

first procedure. So Prolog tries to find a path from *a* to some Z' using the second procedure. Continuing in this way, it goes into an infinite loop, looking for paths from *a* to Z, to Z' to Z'', ...

The alternative to rejecting logic programming because of such problems or of restricting it to niche applications, is for the programmer to take responsibility for both the declarative correctness and the procedural efficiency of programs. The following is such a correct and efficient logic program for the path-finding problem. It incrementally constructs a path of nodes already visited and ensures that no step is taken that revisits a node already in the path. The goal of showing there is a path from X to Y is reformulated as the goal of extending the path consisting of the single node X to a path ending at Y. For simplicity, a path is regarded as a trivial extension of itself.

> The path P can be extended to a path ending at Y
> if P ends at Y.
> The path P can be extended to a path ending at Y
> if P ends at X
> and there is a step from X to Z
> and Z is not in P
> and P' extends P by adding Z to the end of P
> and the path P' can be extended to a path ending at Y.

It is usual to interpret the negation in a condition, such as "Z is not in P" above, as negation by failure. A subgoal of the form "not A" is deemed to hold if and only if the positive subgoal "A" cannot be shown to hold. Programs containing such negative conditions, extending the Horn clause subset of logic programming, are called "normal logic programs."

The use of negation as failure renders logic programming a NONMONOTONIC LOGIC, where addition of new information may cause a previously justified conclusion to be withdrawn. A simple example is the sentence

> X is innocent if not X is guilty.

The condition "not X is guilty" is interpreted as "it cannot be shown that X is guilty."

Many extensions of normal logic programming have been investigated. Among the most important of these is the extension that includes METAREASONING. For example, the following implication is a fragment of a metalevel logic program that can be used to reason about the interval of time for which a conclusion holds:

> "R" holds for interval I
> if "R if S" holds for interval I_1
> and "S" holds for interval I_2
> and I is the intersection of I_1 and I_2.

Similar metalevel programs are used to construct explanations and to implement resource-bounded reasoning and reasoning with UNCERTAINTY.

Among the other extensions of logic programming being investigated are extensions to incorporate constraint processing, a second "strong" form of negation, disjunctive conclusions, and abductive reasoning. Methods are being developed both to execute programs efficiently and to transform inefficient programs into more efficient ones.

Applications range from natural language processing and legal reasoning to commercial knowledge management systems and parts of the Windows NT operating system.

Logical Form in Linguistics

The logical form of a sentence (or utterance) is a formal representation of its logical structure—that is, of the structure that is relevant to specifying its logical role and properties. There are a number of (interrelated) reasons for giving a rendering of a sentence's logical form. Among them is to obtain proper inferences (which otherwise would not follow; cf. Russell's theory of descriptions), to give the proper form for the determination of truth-conditions (e.g., Tarski's method of truth and satisfaction as applied to quantification), to show those aspects of a sentence's meaning that follow from the logical role of certain terms (and not from the lexical meaning of words; cf. the truth-functional account of conjunction), and to formalize or regiment the language in order to show that it is has certain metalogical properties (e.g., that it is free of paradox or that there is a sound proof procedure).

Logical analysis—that is, the specification of logical forms for sentences of a language—presumes that some distinction is to be made between the grammatical form of sentences and their logical form. In LOGIC, of course, there is no such distinction to be drawn. By design, the grammatical form of a sentence specified by the syntax of, for instance, first-order predicate logic simply is its logical form. In the case of natural language, however, the received wisdom of the tradition of FREGE, Russell, Wittgenstein, Tarski, Carnap, Quine, and others has been that on the whole, grammatical form and logical form cannot be identified; indeed, their nonidentity has often been given as the *raison d'être* for logical analysis. Natural languages have been held to be insufficiently specified in their grammatical form to reveal directly their logical form, and that no mere paraphrase within the language would be sufficient to do so. This led to the view that, as far as natural languages were concerned, logical analysis was a matter of rendering sentences of the language in some antecedently defined logical (or formal) language, where the relation between the sentences in the languages is to be specified by some sort of contextual definition or rules of translation.

In contemporary linguistic theory, there has been a continuation of this view in work inspired largely by Montague (especially, Montague 1974). In large part because of technical developments in both logic (primarily in the areas of type theories and POSSIBLE WORLDS SEMANTICS) and linguistics (with respect to categorial rule systems), this approach has substantially extended the range of phenomena that could be treated by translation into an interpreted logical language, shedding the pessimism of prior views as to how systematically techniques of logical analysis can be formally applied to natural language (see Partee 1975; Dowty, Wall, and Peters 1981; Cooper 1983). Within linguistic theory, however, the term "logical form" has been much more closely identified with a different view that takes natural language to be in an important sense logical, in that grammatical form can be identified with logical form. The hallmark of this view is that the derivation of logical forms is continuous with the derivation of other syntactic representations of a sentence. As this idea was developed initially by Chomsky and May (with precursors in generative semantics), the levels of syntactic representation included Deep Structure, Surface Structure, and Logical Form (LF), with LF—the set of syntactic structures constituting the "logical forms" of the language—derived from Surface Structure by the same sorts of transformational rules that derived Surface Structure from Deep Structure.

As with other approaches to logical form, quantification provides a central illustration. This is because, since Frege, it has been generally accepted that the treatment of quantification requires a "transformation" of a sentence's surface form. On the LF approach, it was hypothesized (originally in May 1977) that the syntax of natural languages contains a rule—QR, for Quantifier Raising—that derives representations at LF for sentences containing quantifier phrases, functioning syntactically essentially as does WH-MOVEMENT (the rule that derives the structure of "What did Max read?"). By QR, (1) is derived as the representation of

"Every linguist has read *Syntactic Structures*" at LF, and because QR may iterate, the representations in (2) for "Every linguist has read some book by Chomsky".

(1) [every linguist$_1$ [t$_1$ has read *Syntactic Structures*]]

(2) a. [every linguist$_1$ [some book by Chomsky$_2$ [t$_1$ has read t$_1$]]]
   b. [some book by Chomsky$_2$ [every linguist$_1$ [t$_1$ has read t$_2$]]]

With the aid of the syntactic notions of "trace of movement" (t$_1$, t$_2$) and "c-command" (both of which are independently necessary within syntactic theory), the logically significant distinctions of open and closed sentence, and of relative scope of quantifiers, can be easily defined with respect to the sort of representations in (1) and (2). Interpreting the trace in (1) as a variable, "t$_1$ has read *Syntactic Structures*" stands as an open sentence, falling within the scope of the c-commanding quantifier phrase "every linguist$_1$;" similar remarks hold for (2), except that (2a) and (2b) can be recognized as representing distinct scope orderings of the quantifiers (see Heim 1982; May 1985, 1989; Hornstein and Weinberg 1990; Fox 1995; Beghelli and Stowell 1997; and Reinhart 1997 for further discussion of the treatment of quantification within the LF approach). A wide range of arguments have been made for the LF approach to logical form. Illustrative of the sort of argument presented is the argument from antecedent-contained deletion (May 1985). A sentence such as "Dulles suspected everyone that Angleton did" has a verb phrase elided (its position is marked by the pro-form "did"). If, however, the ellipsis is to be "reconstructed" on the basis of the surface form, the result will be a structural regress, as the "antecedent" verb phrase, "suspected everyone that Angleton did" itself contains the ellipsis site. However, if the reconstruction is defined with respect to a structure derived by QR:

(3) everyone that Angleton did [Dulles suspected t],

the antecedent is now the VP "suspected t," obtaining, properly, an LF-representation comparable in form to that which would result if there had been no deletion:

(4) everyone that Angleton suspected t [Dulles suspected t].

Among other well-known arguments for LF are weak crossover (Chomsky 1976), the interaction of quantifier scope and bound variable anaphora (Higginbotham 1980; Higginbotham and May 1981), superiority effects with multiple *wh*-constructions (Aoun, Hornstein, and Sportiche 1981) and *wh*-complementation in languages without overt *wh*-movement (Huang 1982). Over the past two decades, there has been active discussion in linguistic theory of the precise nature of representations at LF, in particular with respect to the representation of binding (see BINDING THEORY) as this pertains to quantification and ANAPHORA, and of the semantic interpretation of such representations (cf. Larson and Segal 1995). This has taken place within a milieu of evolving conceptions of SYNTAX and SEMANTICS and has led to considerable refinement in our conceptions of the structure of logical forms and the range of phenomena

that can be analyzed. Constant in these discussions has been the assumption that logical form is integrated into syntactic description generally, and hence that the thesis that natural languages are logical is ultimately an empirical issue within the general theory of syntactic rules and principles.

Logical Form, Origins of

When philosophers use the expression "the Logical Form of a sentence," they refer to a linguistic representation whose desirable properties the surface grammatical form of the sentence either masks or lacks completely. Because philosophers have found ever so many desirable properties hidden or absent in grammatical form, there are ever so many different notions of Logical Form.

According to one tradition, which one might call the "descriptive conception" of Logical Form, the Logical Form of a sentence is something like the "deep structure" of that sentence (e.g., Harman 1972), and we may discover that the "real" structure of a natural language sentence is in fact quite distinct from its surface grammatical form. Talk of Logical Form in this sense involves attributing hidden complexity to natural language, complexity that may be revealed by philosophical, and indeed empirical, inquiry (see LOGICAL FORM IN LINGUISTICS). However, perhaps more common in the recent history of philosophy is what one might call the "revisionary conception" of Logical Form. According to it, natural language is defective in some fundamental way. Appeals to Logical Form are appeals to a kind of linguistic representation which is intended to replace natural language for the purposes of scientific or mathematical investigation (e.g., Frege 1879, preface; Whitehead and Russell 1910, introduction; Russell 1918, 58).

Nineteeth-century debates concerning the foundations of the calculus are one source of the revisionary flavor of some contemporary conceptions of Logical Form (e.g., Quine 1960, 248ff.). Perhaps the most vivid example is the overthrow of the infinitesimal calculus, which began with the work of Cauchy in the 1820s. Cauchy took the notation of the infinitesimal calculus, which contained explicit reference to infinitesimals, and reanalyzed it in terms of a notation that exploited the limit concept, and made no reference to infinitesimals. It subsequently emerged that the limit concept was analyzable in terms of logical notions, such as quantification, together with unproblematic numerical concepts. Thus progress in nineteenth-century mathematics involved replacing a notation that made explicit reference to undesirable entities (viz., infinitesimals) with a notation in which reference to such entities was replaced by logical and numerical operations on more acceptable ones (noninfinitesimal real numbers).

Bertrand Russell (e.g., 1903) was clearly affected by the developments in nineteenth-century mathematics, though his proposals (1905) have both revisionary and descriptive aspects. In them Russell treated the problem of negative existential sentences, such as "Pegasus does not exist." The difficulty with this sentence is that its grammatical form suggests that endorsing its truth commits one to the existence of a denotation for the proper name "Pegasus," which could be none other than that winged horse. Yet what the sentence seems to assert is precisely the nonexistence of such a being.

According to Russell, the problem lies in taking the grammatical form to be a true guide to the structure of the proposition it expresses, that is, in taking the surface grammatical form to exhibit the commitments of its endorsement. In Russell's view, the structure of the proposition expressed by "Pegasus does not exist" differs markedly from the grammatical form. Rather than being "about" Pegasus, its structure is more adequately reflected by a sentence such as "It is not the case that there exists a unique thing having properties F, G, and H," where F, G, and H are the properties we typically associate with the fictional winged horse. Once this is accepted, we may endorse the truth of "Pegasus does not exist" without fear of admitting Pegasus into the realm of being.

Russell took himself not as proposing a special level of linguistic representation, but rather as proposing what the true structure of the (nonlinguistic) proposition expressed by the sentence was. Russell's early writings are therefore no doubt the origin of the occasional usage of "Logical Form" as referring to the structure of a nonlinguistic entity such as a proposition or a fact (e.g., Wittgenstein 1922, 1929; Sainsbury 1991, 35). However, Russell's proposal could just as easily be adopted as a claim about a special sort of linguistic representation, one that allows us to say what we think is true, while freeing us from the absurd consequences endorsement of the original grammatical form would entail (Russell, after his rejection of propositions, himself construed it in this way). Thus arises a conception of Logical Form as a level of linguistic representation at which the metaphysical commitments of the sentences are completely explicit. This conception of Logical Form was later to achieve full articulation in the works of Quine (e.g., 1960, chaps. 5, 7).

Nineteenth-century mathematics not only provided successful examples of notational revision; it also provided many examples of notational confusion (Wilson 1994 argues that this was not necessarily a tragic situation). One of Frege's central purposes (1879, Preface) was to provide a

notation free of such confusion, devoid of vagueness, ambiguity, and context dependence, whose purpose was "to provide us with the most reliable test of the validity of a chain of inferences and to point out every presupposition that tries to sneak in unnoticed . . . ." Frege's remarks here suggest a test of the validity of arguments in terms of the syntax of his idealized language. According to this criterion, a chain of reasoning is logically valid if and only if its translation into his idealized "Begriffsschrift" proceeds by transitions, each of which is of the right syntactic form. Thus arises a conception of Logical Form as a linguistic representation for which it is possible to designate certain syntactic forms such that all and only basic logical transitions are translatable into instances of those forms (see LOGIC).

The purpose of formalization into Logical Form is to replace one notation by another, which has desirable properties which the original notation lacked. In the case of the Quinean conception of Logical Form, the purpose of formalization is to replace a notation (in the usual case, natural language) by one which more accurately reveals ontological commitments. In the case of the Fregean conception, the purpose of formalization is to replace notations which obscure the logical structure of sentences by one which makes this structure explicit (these are not necessarily conflicting goals). Many other conceptions of Logical Form have been proposed. For example, Richard Montague's favored way of giving an interpretation to a fragment of natural language involved translating that fragment into an artificial language, for example, the language of "tensed intensional logic" (Montague 1973), and then giving a formal semantic interpretation to the artificial language. This produces a conception of Logical Form as a level of linguistic representation at which a compositional semantics is best given (see COMPOSITIONALITY and SEMANTICS).

Strictly revisionary conceptions of Logical Form involve abstracting from features of the original notation that are problematic in various ways. Because notations may be problematic in some ways and not in others, in such a use of "Logical Form," there is no issue about what the "correct" notion of Logical Form is. Descriptive conceptions, on the other hand, involve claims about the "true" structure of the original notation, structure that is masked by the surface grammatical form. Someone who makes a proposal, in the purely descriptive mode, about the "true" Logical Form of a natural language sentence thus runs the risk that her claims will be vitiated by linguistic theory. To avoid this danger, most philosophers vascillate between a revisionary and descriptive use of the expression "Logical Form."

The tension between descriptive and revisionary conceptions of Logical Form mirrors a tension in the cognitive sciences generally. According to some, cognitive science should be interested in explaining the possession of abstract cognitive abilities such as thinking and language use in humans, and we should be interested, not in the most ideal representations of thought and language, but rather in how humans think and speak. If so, we should be interested in Logical Form only insofar as it is plausibly associated with natural language on some level of empirical analysis. According to others, cognitive sciences should be interested in the abstract properties of thinking and speaking, and we

should be interested in arriving at an ideal representational system, one that may abstract from the defects of human natural language. Among such thinkers, the revisionary project of replacing natural language by a representation more suitable for scientific purposes is fundamental to the aims of cognitive science.

Logical Omniscience, Problem of

Knowers or believers are *logically omniscient* if they know or believe all of the consequences of their knowledge or beliefs. That is, x is a logically omniscient believer (knower) if and only if the set of all of the propositions believed (known) by x is closed under logical consequence. It is obvious that if belief and knowledge are understood in their ordinary sense, then no nonsupernatural agent, real or artificial, will be logically omniscient. Despite this obvious fact, many formal representations of states of knowledge and belief, and some explanations of what it is to know or believe, have the consequence that agents are logically omniscient. This is why there is a problem of logical omniscience.

There are a number of different formal representations of knowledge and belief that face a problem of logical omniscience. POSSIBLE WORLDS SEMANTICS for knowledge and

belief, first developed by Jaakko Hintikka, represent a state of knowledge by a set of possible worlds—the worlds that are epistemically possible for the knower. According to this analysis, x knows that P if and only if P is true in all epistemically possible worlds. Epistemic models using this kind of analysis have been widely applied by theoretical computer scientists studying distributed systems (see MULTIAGENT SYSTEMS), and by economists studying GAME THEORY. As Hintikka noted from the beginning of the development of semantic models for epistemic logic, this analysis implies that knowers are logically omniscient.

Because all logical truths in any probability function must receive probability one, and because any logical consequences of a proposition P must receive at least as great a probability as P (at least if one holds fixed the context in which probability assessments are made; see RATIONAL DECISION MAKING), any use of probability theory to represent the beliefs and partial beliefs of an agent will face a version of the problem of logical omniscience.

It is not only abstract formal representations, but also some philosophical explanations of the nature of belief and knowledge that seem to imply that knowers and believers are logically omniscient. First, pragmatic or INTENTIONAL STANCE accounts of belief assume that belief and desire are correlative dispositions displayed in rational action. Roughly, according to such accounts, to believe that P is to act in ways that would be apt in situations in which P (together with one's other beliefs) is true. This kind of analysis of belief will imply that believers are logically omniscient. Second, because the logical consequences of any information carried by some state of a system are also information implicit in the state (see also INFORMATIONAL SEMANTICS and PROPOSITIONAL ATTITUDES), any account of knowledge based on INFORMATION THEORY will face a prima facie problem of logical omniscience.

There are two contrasting ways to reconcile a theory implying that agents are logically omniscient with the obvious fact that they are not. First, one may take the theory to represent a special sense of knowledge or belief that diverges from the ordinary one. For example, one may take the theory to be modeling *implicit knowledge*, understood to include, by definition, all of the consequences of one's knowledge; ordinary knowers are logically omniscient with respect to their implicit knowledge, but have no extraordinary computational powers. Alternatively, one may take the theory to be modeling the knowledge (in the ordinary sense) of an idealized agent, a fictional ideal agent with infinite computational capacities that enable her to make all her implicit knowledge explicit.

Either of these approaches may succeed in reconciling the counterintuitive consequences of theories of belief and knowledge with the phenomena, but there remains a problem, for the first approach, of explaining what explicit knowledge is, and how it is distinguished from merely implicit knowledge. And the second approach must explain the relevance an idealized agent, all of whose implicit beliefs are available, to the behavior of real agents. If the knowledge and beliefs of nonideal agents—agents who have only BOUNDED RATIONALITY—are to contribute to an explanation of their behavior, we need to be able to distinguish the beliefs that are accessible or available to the agent, and to do this, we need an account of what it means for a belief to be available. Because a belief might be available to influence the rational behavior of an agent even if the agent is unable to produce or recognize a linguistic expression of the belief, it will not suffice to distinguish *articulate* beliefs—those beliefs that an agent can express or to which he is disposed to assent. And because one's beliefs about one's beliefs may themselves be merely implicit, and unavailable, one cannot explain the difference between available and merely implicit belief in terms of higher-order belief.

It may appear to be an advantage of a LANGUAGE OF THOUGHT account of belief that it avoids the problem of logical omniscience. If it is assumed that an agent's explicit beliefs are beliefs encoded in a mental language and stored in the "belief box," then one's theory will not imply that the consequences of the agent's explicit beliefs are also explicit beliefs. But explicit belief in this sense is neither necessary nor sufficient for a plausible notion of accessible or available belief. Although the immediate and obvious consequences of one's explicit beliefs may count intuitively as beliefs in the ordinary sense, thus also as available beliefs even if they are not explicitly represented, beliefs that are explicitly represented may nevertheless remain inaccessible. If the set of explicit beliefs is large, the search required to access an explicit belief could be a nontrivial computational task.

A general problem for the analysis of available belief is that one can distinguish between beliefs that are available or accessible and those that are not only in relation to the particular uses of the belief. Consider the talented but inarticulate chess player whose implicit knowledge of the strategic situation is available to guide her play, but not to explain or justify her choices.

While it is obvious that real agents are never logically omniscient, it is not at all clear how to give a plausible account of knowledge and belief that does not have the consequence that they are.

Logical Reasoning Systems

Logical reasoning systems derive sound conclusions from formal declarative knowledge. Such systems are usually defined by abstract *rules of inference.* For example, the rule of modus ponens states that given P, and "P implies Q" (usually written $P \rightarrow Q$), we can infer Q. Logical systems have a rich history, starting with Greek syllogisms and continuing through the work of many prominent mathematicians such as DESCARTES, Leibniz, Boole, FREGE, Hilbert, Gödel, and Cohen. (For a good discussion of the history of logical reasoning systems, see Davis 1983.)

Logical reasoning provides a well-understood general method of symbolic COMPUTATION. Symbolic computation manipulates expressions involving variables. For example, a computer algebra system can simplify the expression $x(x + 1)$ to $x^2 + x$. The equation $x(x + 1) = x^2 + x$ is true under any interpretation of x as a real number. Unlike numerical computation, symbolic computation derives truths that hold under a wide variety of interpretations and can be used when only partial information is given, for example, that x is some (unknown) real number. Logical inference systems can be used to perform symbolic computation with variables that range over conceptual domains such as sets, sequences, graphs, and computer data structures. Symbolic computation underlies essentially all modern efforts to formally verify computer hardware and software.

There are at least two ways in which symbolic inference is relevant to cognitive science. First, symbolic inference rules have traditionally been used as models of human mathematical reasoning. Second, symbolic computation also provides a model of certain commonsense inferences. For example, suppose one is given a bag of marbles and continues removing marbles from the bag for as long as it remains nonempty. People easily reach the conclusion that, barring unusual or magical circumstances, the bag will eventually become empty. They reach this conclusion without being told any particular number of marbles—they reach a conclusion about an arbitrary set *s.* Computer systems for drawing such conclusions based on "visualization" do not currently work as well as approaches based on symbolic computation (McAllester 1991).

Here I will divide symbolic computation research into five general approaches. First are the so-called symbolic algebra systems such as Maple or Mathematica (Wolfram 1996), designed to manipulate expressions satisfying certain algebraic properties such as those satisfied by the real numbers. Although they have important applications in the physical sciences, these systems are not widely used for hardware or software verification and seem too specialized to provide plausible models of commonsense reasoning. Second are the symbolic model-checking systems (Burch et al. 1990), which perform symbolic inference where the variables range over finite sets such as the finite set of possible states of a certain piece of computer hardware. Although very effective for the finitary problems where they apply, these systems are too restricted for software verification and also seem too restricted to provide plausi-

ble models of commonsense reasoning. The remaining three approaches to symbolic computation all claim to be general purpose or domain independent. I will call these the "first-order approach," the "higher-order approach," and the "induction approach," respectively, and discuss each in turn.

The first-order approach is based on making inferences from axioms written in first-order LOGIC, which includes a wide variety of resolution and term-rewriting systems (Fitting 1996). For problems that can be naturally axiomatized in first-order logic, the first-order approach seems superior to other approaches. Unfortunately, most mathematical theorems and verification problems have no natural first-order formulation. Although detailed discussion of first-order logic and inference methods is beyond the scope of this entry, it is possible to give a somewhat superficial description of its limitations. First-order logic allows us to state properties of concepts, but not generally to *define* concepts. For example, suppose we want to describe the concept of a finite set. We can write a formal expression stating, "A set is finite if it is either empty or can be derived by adding a single element to some other finite set." Unfortunately, this statement does not uniquely determine the concept—it is also true that "a set is countable if it is either empty or can be derived by adding a single element to some other countable set." Statements true of a concept often fail to uniquely specify them. Finiteness is not definable in first-order logic. The bag of marbles inference mentioned above implicitly relies on finiteness. Almost all program verfication problems involve concepts not definable in first-order logic. Methods of simulating more expressive logics in first-order logic are generally inferior in practice to systems specifically designed to go beyond first-order logic.

Higher-order systems allow quantification over predicates (i.e., concepts; Gordon 1987). Finiteness is definable in higher-order logics—by quantifying over predicates, we can say that "finite" is the *least* predicate satisfying the condition given in the paragraph above. Unfortunately, because higher-order logic makes automation difficult, computer systems based on higher-order logic typically verify human-written derivations rather than attempt to find derivations automatically.

Induction systems represent a middle ground between the expressively weak first-order resolution and term-rewriting systems and the expressively strong systems based on higher-order logic (Boyer and Moore 1979). Induction systems are "first-order" in the sense that they do not typically allow quantification over predicates. But, unlike true first-order systems, all objects are assumed to be finite. A variable in a symbolic expression ranges over infinitely many different possible values, each of which is a finite object. This is different from symbolic model checking, where each variable ranges over only a finite number of possible values. Also, induction systems allow well-founded recursive definitions of the kind used in functional programming languages. The underlying logic of an induction system is best viewed as a programming language, such as cons-car-cdr Lisp. But unlike traditional implementations of a programming language, an induction system

can derive symbolic equations that are true under any allowed interpretation of the variables appearing in the expressions, such as the following:

append(x,append(y,z)) = append(append(x,y),z).

Induction systems seem most appropriate for program verification and for modeling commonsense reasoning about an arbitrary (or unknown) finite set.

Long-Term Potentiation

Long-term potentiation (LTP) is operationally defined as a long-lasting increase in synaptic efficacy in response to high-frequency stimulation of afferent fibers. The increase in synaptic efficacy persists from minutes to days and is thus a robust example of a long-term increase in synaptic strength. LTP was first observed in the rabbit hippocampus (Bliss and Lomo 1973), but has since been observed in numerous brain structures, including the cortex, brain stem, and amygdala. LTP is not limited to the mammalian brain, but occurs in other vertebrates such as fish, frogs, birds, and reptiles, as well as in some invertebrates (Murphy and Glanzman 1997).

LTP occurs at all three major synaptic connections in the HIPPOCAMPUS: the perforant path synapse to dentate gyrus granule cells, mossy fibers to CA3 pyramidal cells, and the Schaffer collaterals of CA3 cells to CA1 pyramidal cells. Based on its prevalence and initial discovery there, LTP is most often studied in the hippocampus. Within the hippocampus, the cellular and molecular mechanisms that underlie the induction and expression of LTP are varied. In the dentate gyrus and area CA1, the induction of LTP occurs through activation of the postsynaptic *N*-methyl-*D*-aspartate (NMDA) type of glutamate receptor and consequent calcium influx (Collingridge, Kehl, and McLennan 1983), while its expression is accompanied by an increase in postsynaptic current mediated by the AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) type of glutamate receptor. In contrast, the induction of mossy fiber LTP in area CA3 is not dependent on NMDA receptor activation, but is dependent on an increase in presynaptic glutamate release (Castillo et al. 1997).

A primary focus of those involved in LTP research is to elucidate the cellular and molecular mechanisms necessary for sustaining the increase in synaptic efficacy over long periods of time. Most of these studies are conducted in neural tissue that is excised and maintained in an in vitro slice environment for physiological recording. Using this technique, it has been determined that the late phases of LTP maintenance are dependent on protein synthesis and there is some evidence that gene transcription is required. Although controversial, it has been proposed that LTP in the dentate gyrus and CA1 is expressed as an increase in affinity or number of postsynaptic AMPA receptors (Lynch and Baudry 1991). Others postulate that the expression is mediated by a persistent increase in the release of presynaptic glutamate, which is induced by a release of retrograde messengers from the postsynaptic neuron during LTP induction. In area CA1 and the dentate gyrus, the long-term expression of LTP is likely to be mediated by a combination of postsynaptic and presynaptic events, and a consequence of activation of various enzyme systems (Roberson, English, and Sweatt 1996; Abel et al. 1997). There is some evidence that LTP induces structural changes at the synapse (Buchs and Muller 1996), as well as induction of new sites of synaptic transmission (Bolshakov et al. 1997). Based on this cursory review, it should be clear that LTP is a complex phenomenon that involves the interaction of multiple cellular and molecular systems; the exact contribution of each has yet to be determined.

In addition to being a robust example of persistent changes in synaptic plasticity, LTP has been promoted as a putative neural mechanism of associative MEMORY formation or storage in the mammalian brain. It is generally believed that memory formation occurs through a strengthening of connections between neurons. In 1949, Donald HEBB wrote that, "When an axon of cell A ... excite(s) cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells so that A's efficiency as one of the cells firing B is increased" (p. 62). This supposition, known as Hebb's rule, is similar to the operational definition of LTP and is often cited as theoretical support for the putative role of LTP in learning and memory. In addition to theoretical support, the biological characteristics of LTP are in some respects similar to those of memory. First, LTP is prominent in the hippocampus, a structure considered necessary for aspects of declarative and spatial memory (Squire 1992). Second, LTP is long lasting, as is memory. Most forms of electrophysiological plasticity last milliseconds to seconds, while LTP persists from minutes to hours, even days (Staubli and Lynch 1987). In addition, LTP possesses physiological cor-

relates of associativity and cooperativity, both properties of learning associated with classical CONDITIONING (Brown, Kairiss, and Keenan 1990). Finally, hippocampal LTP is optimally induced with a pattern of stimulation that mimics "theta," a naturally occurring brain rhythm (Larson and Lynch 1989). Theta rhythms are most often associated with motor activity and dreaming (Vanderwolf and Cain 1994), although they have been reported to occur in the hippocampus during learning (Otto et al. 1991) and stressful experience (Vanderwolf and Cain 1994; Shors and Matzel 1997).

Many behavioral studies addressing the role of LTP in memory take advantage of the fact that most types of LTP are dependent on NMDA receptor activation (Collingridge, Kehl, and McLennan 1983). When these receptors are blocked with competitive antagonists, rats are impaired in their ability to perform the Morris water maze, a spatial memory task that requires the hippocampus for acquisition. Recent evidence suggests that even during NMDA receptor blockade, rats can learn the location of new spatial cues if they were previously trained on a similar spatial task (Saucier and Cain 1995; Bannerman et al. 1995). Thus, NMDA receptor activation may not be necessary for learning about spatial cues per se, but may be involved in other aspects of performance necessary for successful completion of the task (Morris and Frey 1997; Shors and Matzel 1997). In addition to maze performance, NMDA receptor antagonists prevent fear conditioning (Kim et al. 1991), fear-potentiated startle (Campeau, Miserendino, and Davis 1992) and classic eye-blink conditioning (Servatius and Shors 1996). These tasks are not dependent on the hippocampus but rather are dependent on the AMYGDALA and CEREBELLUM, respectively. Thus, if LTP does play a role in memory, it may not be limited to hippocampal-dependent memories.

The relationship between LTP and learning has also been addressed using genetic techniques. Using a transgenic mouse in which a mutated and calcium-independent form of calmodulin (CaM) kinase II was expressed, researchers reported that LTP in response to theta-burst stimulation was reduced, as was the acquisition of spatial memories. In addition, the mutant mice possessed unstable and imprecise place cells in the hippocampus (Rotenberg et al. 1996). In another study, researchers expressed an inhibitory form of a protein kinase A regulatory subunit in mice and observed deficits in the late phase of LTP as well as deficits in hippocampal-dependent conditioning (Abel et al. 1997). Because the genes are altered throughout the life span, some deficits in plasticity and learning could be due to the abnormal developmental responses. Recently, transient knockouts have become available, providing more temporally and anatomically discrete lesions. Removal of a specific subunit of the NMDA receptor in the hippocampus after development disrupted LTP and spatial learning in the Morris water maze (Tsien, Huerta, and Tonegawa 1996).

A long-term increase in synaptic strength and efficacy is considered by many to be the best candidate to date for mediating the storage and retrieval of memories in the mammalian brain. This application of synaptic potentiation would constitute a memory system with massive storage capacity and fine resolution. Although appealing in principle, it remains to be determined whether increases in synaptic efficacy, such as LTP, are necessary for memory storage, whether they modify the rate and efficiency of memory formation (Shors and Matzel 1997), or do neither.

Luria, Alexander Romanovich

Alexander Romanovich Luria (1902–1977) was born in Kazan, an old Russian university city east of Moscow. He entered Kazan University at the age of 16 and obtained his degree in 1921 at the age of 19. While still a student, he established the Kazan Psychoanalytic Association and planned on a career in psychology. His earliest research sought to establish objective methods of assessing Freudian ideas about abnormalities of thought and the effects of fatigue on mental processes.

In 1923 Luria's use of reaction time measures to study thought processes in the context of work settings won him a position at the Institute of Psychology in Moscow where he developed a psychodiagnostic procedure, the "combined motor method," for diagnosing individual subjects' thought processes. In this method (described in detail in Luria 1932), subjects are asked to carry out three tasks simulta-

neously. One hand is to be held steady while the other is used to press a key or squeeze a rubber bulb in response to verbal stimuli presented by the experimenter, to which the subject is asked to respond verbally with the first word to come to mind. Preliminary trials are presented until a steady baseline of coordination is established. At this point, "critical" stimuli which the experimenter believes to be related to specific thoughts in the subject are presented. Evidence for the ability to "read the subject's mind" is the selective disruption of the previously established coordinated system by the critical test stimuli. This method was applied to a variety of naturally occurring and experimentally induced cases, providing a model system for psychodiagnosis that won widespread attention in the West when it was published. The book describing these studies has to date never been published in Russian, owing to its association with psychoanalytic theorizing which was disapproved of by Soviet authorities.

In 1924 Luria met Lev Semionovich VYGOTSKY, whose influence was decisive in shaping his future career. Together with Vygotsky and Alexei Nikolaivitch Leontiev, Luria sought to establish an approach to psychology that would enable them to "discover the way natural processes such as physical maturation and sensory mechanisms become intertwined with culturally determined processes to produce the psychological functions of adults" (Luria 1979: 43). Vygotsky and his colleagues referred to this new approach variably as "cultural," "historical," and "instrumental" psychology. These three labels all index the centrality of cultural mediation in the constitution of specifically human psychological processes, and the role of the social environment in structuring the processes by which children appropriate the cultural tools of their society in the process of ontogeny. An especially heavy emphasis was placed on the role of language, the "tool of tools" in this process; the acquisition of language was seen as the pivotal moment when phylogeny and cultural history are merged to form specifically human forms of thought, feeling, and action.

From the late 1920s until his death, Luria sought to elaborate this synthetic, cultural-historical psychology in different content areas of psychology. In the early 1930s he led two expeditions to central Asia where he investigated changes in perception, problem solving, and memory associated with historical changes in economic activity and schooling. During this same period he carried out studies of identical and fraternal twins raised in a large residential school to reveal the dynamic relations between phylogenetic and cultural-historical factors in the development of LANGUAGE AND THOUGHT.

In the late 1930s, largely to remove himself from public view during the period of purges initiated by Stalin, Luria entered medical school where he specialized in the study of aphasia, retaining his focus on the relation between language and thought in a politically neutral arena. The onset of World War II made his specialized knowledge of crucial importance to the Soviet war effort, and the widespread availability of people with various forms of traumatic brain injury provided him with voluminous materials for developing his theories of brain function and methods for the remediation of focal brain lesions. It was during this period that

he developed the systematic approach to brain and cognition which has come to be known as the discipline of neuropsychology. Central to his approach was the belief that "to understand the brain foundations for psychological activity, one must be prepared to study both the brain and the system of activity" (1979: 173). This insistence on linking brain structure and function to the proximal, culturally organized environment provides the thread of continuity between the early and later parts of Luria's career.

Following the war Luria sought to continue his work in neuropsychology. His plans were interrupted for several years when he was removed from the Institute of Neurosurgery during a period of particularly virulent antisemitic repression. During this time he pursued his scientific interests through a series of studies of the development of language and thought in mentally retarded children.

In the late 1950s Luria was permitted to return to the study of neuropsychology, which he pursued until his death of heart failure in 1977. In the years just prior to his death, he returned to his earliest dreams of constructing a unified psychology. He published two case studies, one of a man with an exceptional and idiosyncratic memory (Luria 1968), the other of a man who suffered a traumatic brain injury (Luria 1972). These two case studies illustrate his blend of classic, experimental approaches with clinical and remediational approaches, a synthesis that stands as a model for late twentieth-century cognitive science.

Machiavellian Intelligence Hypothesis

The Machiavellian intelligence hypothesis takes several forms, but all stem from the proposition that the advanced cognitive processes of primates are primarily adaptations to *the special complexities of their social lives,* rather than to nonsocial environmental problems such as finding food, which were traditionally thought to be the province of intelligence. The new "social" explanation for the evolution of INTELLIGENCE arose in the context of proliferating field studies of primate societies in the 1960s and 1970s. The paper generally recognized as pivotal in launching this wave of studies was Nicholas Humphrey's "The Social Function of Intellect" (1976), the first to spell out the idea explicitly, although important insights were offered by earlier writers, notably Alison Jolly (see Whiten and Byrne 1988a for a review). By 1988 the idea had inspired sufficient interesting empirical work to produce the volume *Machiavellian Intelligence* (Byrne and Whiten 1988; now see also Whiten and Byrne 1997), which christened the area.

The Machiavellian intelligence hypothesis has been recognized as significant beyond the confines of primatology, however. On the one hand, it is relevant to all the various disciplines that study human cognitive processes. Because the basic architecture of these processes is derived from the legacy of our primate past, a more particular Machiavellian subhypothesis is that developments in specifically human intelligence were also most importantly shaped by social complexities. On the other hand, looking beyond primates, the hypothesis has been recognized as of relevance to any species of animal with sufficient social complexity.

Why "Machiavellian" intelligence? Humphrey talked of "the social function of intellect" and some authors refer to the "social intelligence hypothesis" (Kummer et al. 1997). But "social" is not really adequate as a label for the hypothesis. Many species are social (some living in much larger groups than primates) without being particularly intelligent; what is held to be special about primate societies is their *complexity,* which includes the formation of sometimes fluid and shifting alliances and coalitions. Within this context, primate social relationships have been characterized as manipulative and sometimes deceptive at sophisticated levels (Whiten and Byrne 1988b). Primates often act as if they were following the advice that Niccolo Machiavelli offered to sixteenth-century Italian prince-politicians to enable them to socially manipulate their competitors and subjects (Machiavelli 1532; de Waal 1982). "Machiavellian intelligence" therefore seemed an appropriate label, and it has since passed into common usage.

An important prediction of the hypothesis is that greater social intellect in some members of a community will exert selection pressures on others to show greater social expertise, so that over evolutionary time there will be an "arms race" of Machiavellian intelligence. Indeed, one of the questions the success of the hypothesis now begins to raise is why such escalation has not gone further than it has in many species.

But the way in which the hypothesis highlights competitive interactions must not be interpreted too narrowly. "Machiavellianism" in human affairs is often taken to include only a subset of social dealings characterized by their proximally selfish and exploitative nature (Wilson, Near, and Miller 1996). Although animal behavior is expected to be ultimately selfish in the face of natural selection (by definition a competition), COOPERATION with some individuals against others can be one means to that end. Primate coalitions provide good examples. Indeed, because an important component of exploiting one's social environment

includes learning socially from others, primate "culture" also comes within the scope of Machiavellian intelligence.

As noted at the outset, the Machiavellian hypothesis is not so much a single hypothesis as a cluster of related hypotheses about the power of social phenomena to shape cognitive processes. Two main variants may be distinguished here. In one version of the hypothesis, intelligence is seen as a relatively domain-general capacity, with degrees of intelligence in principle distinguishable among different taxa of animals. In this case, the hypothesis proposes that different grades of intelligence will be correlated significantly and most closely with variations in the social complexity of the taxa concerned. This should apply to any taxon with the right kind of social complexity. Although primate research was the arena from which the ideas sprang, related kinds of complexity are now being described in other taxa, like the alliances of dolphins and hyenas (Harcourt and de Waal 1992).

Another version of the hypothesis proposes that the very nature of the cognitive system will be shaped to handle social phenomena: a domain-specific social intelligence (see DOMAIN SPECIFICITY). This possibility has been examined in both human and nonhuman primates, with the bulk of work done on humans. Influential research includes the work of Cosmides (1989) on the power of cheater detection mechanisms to handle logical problems humans find difficult in equivalent nonsocial contexts (see EVOLUTIONARY PSYCHOLOGY). Another well-documented case is our everyday THEORY OF MIND, whose social domain specificity is highlighted by autistic individuals' difficulty in reading other minds, despite high levels of nonsocial intelligence (Baron-Cohen 1995; see AUTISM). For nonhuman primates, Cheney and Seyfarth (1990) report the results of both observational and experimental studies in which vervet monkeys demonstrate social expertise in excess of that operating in equivalent nonsocial contexts. For example, the monkeys may discriminate as targets of aggression those individuals whose kin have fought their own kin, yet fail to read the signs of a recent python track entering a bush (see SOCIAL COGNITION IN ANIMALS).

A different kind of test of the Machiavellian hypothesis is based on examining the correlates of relative brain size across primate and other animal taxa. Contrary to some earlier findings, the strongest predictors of encephalization that have emerged consistently in recent studies are not measures of physical ecological complexity such as home range size, but the size of the social group or clique, an indicator (even if a crude one) of social complexity (Dunbar 1995; Barton and Dunbar 1997). Although this approach conflates the two alternative versions of the hypothesis discriminated above (because we do not know how modular the mechanisms are that contribute to greater encephalization) the results obviously support the Machiavellian intelligence hypothesis in the general form stated at the start of this entry.

Machine Learning

The goal of machine learning is to build computer systems that can adapt and learn from their experience. Different learning techniques have been developed for different performance tasks. The primary tasks that have been investigated are SUPERVISED LEARNING for discrete decision-making, supervised learning for continuous prediction, REINFORCEMENT LEARNING for sequential decision making, and UNSUPERVISED LEARNING.

The best-understood task is one-shot decision making: the computer is given a description of an object (event, situation, etc.) and it must output a classification of that object. For example, an optical character recognizer must input a digitized image of a character and output the name of that character ("A" through "Z"). A machine learning approach to constructing such a system would begin by collecting training examples, each consisting of a digitized image of a character and the correct name of that character. These would be analyzed by a learning ALGORITHM to produce an optical character recognizer for classifying new images.

Machine learning algorithms search a space of candidate classifiers for one that performs well on the training examples and is expected to generalize well to new cases. Learning methods for classification problems include DECISION TREES, NEURAL NETWORKS, rule-learning algorithms (Cohen 1995), nearest-neighbor methods (Dasarathy 1991), and certain kinds of BAYESIAN NETWORKS.

There are four questions to answer when developing a machine learning system:

1. How is the classifier represented?
2. How are the examples represented?
3. What objective function should be employed to evaluate candidate classifiers?
4. What search algorithm should be used?

Let us illustrate these four questions using two of the most popular learning algorithms, C4.5 and backpropagation.

The C4.5 algorithm (Quinlan 1993) represents a classifier as a decision tree. Each example is represented as a vector of features. For example, one feature describing a printed character might be whether it has a long vertical line segment (such as the letters B, D, E, etc.).

Each node in the decision tree tests the value of one of the features and branches to one of its children, depending on the result of the test. A new example is classified by starting at the root of the tree and applying the test at that node. If the test is true, it branches to the left child; other-wise, it branches to the right child. The test at the child node is then applied, recursively, until one of the leaf nodes of the tree is reached. The leaf node gives the predicted classification of the example.

C4.5 searches the space of decision trees through a constructive search. It first considers all trees consisting of only a single root node and chooses one of those. Then it considers all trees having that root node and various left children, and chooses one of those, and so on. This process constructs the tree incrementally with the goal of finding the decision tree that minimizes the so-called pessimistic error, which is an estimate of classification error of the tree on new training examples. It is based on taking the upper endpoint of a confidence interval for the error of the tree (computed separately for each leaf).

Although C4.5 *constructs* its classifier, other learning algorithms begin with a *complete* classifier and modify it. For example, the backpropagation algorithm for learning neural networks begins with an initial neural network and computes the classification error of that network on the training data. It then makes small adjustments in the weights of the network to reduce this error. This process is repeated until the error is minimized.

There are two fundamentally different theories of machine learning. The classical theory takes the view that, before analyzing the training examples, the learning algorithm makes a "guess" about an appropriate space of classifiers to consider (e.g., it guesses that decision trees will be better than neural networks). The algorithm then searches the chosen space of classifiers hoping to find a good fit to the data. The Bayesian theory takes the view that the designer of a learning algorithm encodes all of his or her prior knowledge in the form of a prior probability distribution over the space of candidate classifiers. The learning algorithm then analyzes the training examples and computes the posterior probability distribution over the space of classifiers. In this view, the training data serve to reduce our remaining uncertainty about the unknown classifier.

These two theories lead to two different practical approaches. The first theory encourages the development of large, flexible hypothesis spaces (such as decision trees and neural networks) that can represent many different classifiers. The second theory encourages the development of representational systems that can readily express prior knowledge (such as Bayesian networks and other stochastic models).

The discussion thus far has focused on discrete classification, but the same issues arise for the second learning task: supervised learning for continuous prediction (also called "regression"). In this task, the computer is given a description of an object and it must output a real-valued quantity. For example, given a description of a prospective student (high school grade-point average, SAT scores, etc.), the system must predict the student's college grade-point average (GPA). The machine learning approach is the same: a collection of training examples describing students and their college GPAs is provided to the learning algorithm, which outputs a predictor to predict college GPA. Learning methods for continuous prediction include neural networks, regression trees (Breiman et al. 1984), linear and additive

models (Hastie and Tibshirani 1990), and kernel regression methods (Cleveland and Devlin 1988). Classification and prediction are often called "supervised learning" tasks, because the training data include not only the input objects but also the corresponding output values (provided by a "supervisor").

We now turn from supervised learning to reinforcement learning tasks, most of which involve sequential decision making. In these tasks, each decision made by the computer affects subsequent decisions. For example, consider a computer-controlled robot attempting to navigate from a hospital kitchen to a patient's room. At each point in time, the computer must decide whether to move the robot forward, left, right, or backward. Each decision changes the location of the robot, so that the next decision will depend on previous decisions. After each decision, the environment provides a real-value reward. For example, the robot may receive a positive reward for delivering a meal to the correct patient and a negative reward for bumping into walls. The goal of the robot is to choose *sequences* of actions to maximize its long-term reward. This is very different from the standard supervised learning task, where each classification decision is completely independent of other decisions.

The final learning task we will discuss is unsupervised learning, where the computer is given a collection of objects and is asked to construct a model to explain the observed properties of these objects. No teacher provides desired outputs or rewards. For example, given a collection of astronomical objects, the learning system should group the objects into stars, planets, and galaxies and describe each group by its electromagnetic spectrum, distance from earth, and so on.

Although often called "cluster analysis" (Everitt 1993), unsupervised learning arises in a much wider range of tasks. Indeed, there is no single agreed-upon definition of unsupervised learning, but one useful formulation views unsupervised learning as density estimation. Define a probability distribution P(X) to be the probability that an object X will be observed. The goal of unsupervised learning is to find this probability distribution, given a sample of the Xs. This is typically accomplished by defining a family of possible stochastic models and choosing the model that best accounts for the data.

For example, one might model each group of astronomical objects as having a spectrum that is a multivariate normal distribution (centered at a "typical" spectrum). The probability distribution P(X) describing the whole collection of astronomical objects could then be modeled as a mixture of normal distributions—one distribution for each group of objects. The learning process determines the number of groups and the mean and covariance matrix of each multivariate distribution. The Autoclass program discovered a new class of astronomical objects in just this way (Cheeseman et al. 1988).

Another widely used unsupervised learning model is the HIDDEN MARKOV MODEL (HMM). An HMM is a stochastic finite-state machine that generates strings. In speech recognition applications, the strings are speech signals, and one HMM is trained for each word in the vocabulary (Rabiner 1989).

Once a stochastic model has been fitted to a collection of objects, that model can be applied to classify new objects. Given a new astronomical object, we can determine which multivariate Gaussian is most likely to have generated it, and we can assign it to the corresponding group. Similarly, given a new speech signal, we can determine which HMM is most likely to have generated it, and thereby guess which word was spoken. A general algorithm schema for training both HMMs and mixture models is the expectation maximization (EM) algorithm (Dempster, Laird, and Rubin 1976).

Machine Translation

Machine translation (MT), which celebrated its fiftieth anniversary in 1997, uses computers to translate texts written in one human language, such as Spanish, into another human language, such as Ukrainian. In the ideal situation, sometimes abbreviated as FAHQMT (for Fully Automated

High Quality Machine Translation) the computer program produces fully automatic, high-quality translations of text. Programs that assist human translators are called "machine-aided translators" (MATs).

MT is the intellectual precursor to the field of COMPUTATIONAL LINGUISTICS (also called NATURAL LANGUAGE PROCESSING), and shares interests with computer science (artificial intelligence), linguistics, and occasionally anthropology. Machine translation dates back to the work of Warren Weaver (1955), who suggested applying ideas from cryptography, as employed during World War II, and information theory, as outlined in 1947 by Claude Shannon, to language processing. Not surprisingly, the first large-scale MT project was funded by the U.S. government to translate Russian Air Force manuals into English. After an initial decade of naive optimism, the ALPAC (for Automatic Language Processing Advisory Committee) report (Pierce et al. 1966), issued by a government-sponsored study panel, put a damper on research in the United States for many years. Research and commercial development continued largely in Europe and after 1970 also in Japan. Today, over fifty companies worldwide produce and sell translation by computer, whether as translation services to outsiders, as in-house translation bureaus, or as providers of on-line multilingual chat rooms. Some 250 of the world's most widely spoken languages have been translated, at least in pilot systems. By some estimates, expenditures for MT in 1989 exceeded $20 million worldwide, involving 200–300 million pages per year (Wilks 1992).

Translation is not easy—even humans find it hard to translate complex texts such as novels. Current technology produces output whose quality level varies from perfect (for very circumscribed domains with just a few hundred words) to hardly readable (for unrestricted domains requiring lexicons of a quarter million words or more). Research groups continue to investigate unsolved issues. Recent large government-sponsored research collaborations include CICC in Japan (Tsujii 1990), Eurotra in Europe (Johnson, King, and des Tombes 1985), and the DARPA MT effort in the United States (White et al. 1992–1994). (For reviews of the history, theory, and applications of MT, see Hutchins and Somers 1992; Nirenburg et al. 1992; and Hovy 1993; useful collections of papers can be found in AMTA 1996, 1994; CL 1985.)

Before producing their output, all MT systems perform some analysis of the input text. The degree of analysis largely determines what type of translation is being performed, and what the average output quality is. Generally, the more refined or "deeper" the analysis, the better the output quality. Three major levels of analysis are traditionally recognized:

1. *Direct replacement.* The simplest systems perform very little analysis of the input, essentially replacing source language (input) words with equivalent target language (output) words, inflected as necessary for tense, number, and so on. When the source and target languages are fairly similar in structure and word use, as between Italian, Spanish, and French, this approach can produce surprisingly understandable results. However, as soon as the word order starts to differ (say, if the verb appears at the end of the sentence, as in Japanese), then some syntactic analysis is required.

Modern research using this approach has focused on the semiautomated construction of large word and phrase correspondence "tables," extracting this information from human translations as examples (Nirenburg, Beale, and Domashnev 1994) or using statistics (Brown et al. 1990, 1993).

2. *Transfer.* In order to produce grammatically appropriate translations, syntactic transfer systems include so-called parsers, transfer modules, and realizers or generators (see NATURAL LANGUAGE GENERATION). A *parser* is a computer program that accepts a natural language sentence as input and produces a parse tree of that sentence as output. A *transfer module* applies transfer rules to convert the source parse tree into a tree conforming to the requirements of the target language grammar—for example, by shifting the verb from the end of the sentence (Japanese) to the second position (English). A *realizer* then converts the target tree back into a linear string of words in the target language, inflecting them as required. (For more details, see Kinoshita, Phillips, and Tsujii 1992; Somers et al. 1988; and Nagao 1987.)

Unfortunately, syntactic analysis is often not enough. Effective translation may require the system to "understand" the actual meaning of the sentence. For example, "I am small" is expressed in many languages using the verb "to be," but "I am hungry" is often expressed using the verb "to have," as in "I have hunger." For the translation system to handle such cases (and their more complex variants), it needs to have information about the meaning of size, hunger, and so on (see SEMANTICS). Often such information is represented in *case frames*, small collections of attributes and their values. The translation system then requires an additional analysis module, usually called the "semantic analyzer," additional (semantic) transfer rules, and additional rules for the realizer. The *semantic analyzer* produces a case frame from the syntax tree, and the transfer module converts the case frame derived from the source language sentence into the case frame required for the target language.

3. *Interlinguas.* Although transfer systems are common, because a distinct set of transfer rules must be created for each language pair in each direction—for N languages, one needs about N^2 pairs of rule sets—they require a great deal of effort to build. The solution is to create a single intermediate representation scheme to capture the language-neutral meaning of any sentence in any language. Then only 2N sets of mappings are required—from each language into the interlingua and back out again.

This idea appeals to many. Despite numerous attempts, however, it has never yet been achieved on a large scale; all interlingual MT systems to date have been at the level of demonstrations (a few hundred lexical items) or prototypes (a few thousand). A great deal has been written about interlinguas, but no clear methodology exists for determining exactly how one should build a true language-neutral meaning representation, if such a thing is possible at all (Nirenburg et al. 1992; Dorr 1994; Hovy and Nirenburg 1992).

Machine translation applications are classified into two traditional and one more recent types:

1. *Assimilation.* People interested in tracking the multilingual world use MT systems for assimilation—to produce (rough) translations of many externally created

documents, from which they then select the ones of interest (and then possibly submit them for more refined, human translation). Typical users are commercial and government staff who monitor developments in areas of interest. The desired output quality need not be very high, but the MT system should cover a large domain, and it should be fast.

2. *Dissemination.* People wishing to disseminate their own documents to the world in various languages use MT systems to produce the translations. Typical users are manufacturers such as Caterpillar, Honda, and Fujitsu. In this case, the desired output quality should be as high as possible, but the system need cover only the application domain, and speed is not generally a consideration.

3. *Interaction.* People wanting to converse with others in foreign countries via E-mail or chat rooms use MT systems on-line to translate their messages. Typical users are chat room participants and business travelers setting up meetings and reserving hotel rooms. CompuServe currently supports MT for some of its highly popular chat rooms at the cost of one cent per word. The desired output quality should be as high as possible, given the requirements of system speed and relatively broad coverage.

A great deal of effort has been devoted to the evaluation of MT systems (see White et al. 1992–1994: AMTA 1992: Nomura 1992; Church and Hovy 1993; King and Falkedal 1990; Kay 1980; and Van Slype 1979). No single measure can capture all the aspects of a translation system. While, from the ultimate user's point of view, the major dimensions will probably be cost, output quality, range of coverage, and degree of automation, numerous more specific evaluation metrics have been developed. These range from system-internal aspects such as number of grammar rules and treatment of multisentence phenomena to user-related aspects such as the ability to extend the lexicon and the quality of the system's interface.

Machine Vision

Machine vision is an applied science whose objective is to take two-dimensional (2-D) images as input and extract information about the three-dimensional (3-D) environment adequate for tasks typically performed by humans using vision. These tasks fall into four broad categories:

1. *Reconstruction.* Examples are building 3-D geometric models of an environment, determining spatial layout by finding the locations and poses of objects, and estimating surface color, reflectance, and texture properties.
2. *Visually guided control of locomotion and manipulation.* Locomotion tasks include navigating a robot around obstacles or controlling the speed and direction of a car driving down a freeway. Manipulation tasks include reaching, grasping, and insertion operations (see MANIPULATION AND GRASPING).
3. *Spatiotemporal grouping and tracking. Grouping* is the association of image pixels into regions corresponding to single objects or parts of objects. *Tracking* is matching these groups from one time frame to the next. Grouping is used in the segmentation of different kinds of tissues in an ultrasound image or in traffic monitoring to distinguish and track individual vehicles.
4. *Recognition of objects and activities.* Object recognition tasks include determining the class of particular objects that have been imaged ("This is a face") and recognizing specific instances such as faces of particular individuals ("This is Nixon's face"). Activity recognition includes identifying gaits, expressions, and gestures. (See VISUAL OBJECT RECOGNITION, AI Ullman 1996 provides a book-length account.)

Reconstruction Tasks

The most basic fact about vision, whether machine or human, is that images are produced by perspective projection. Consider a coordinate system with origin at the optical center of a camera whose optical axis is aligned along the Z axis. A point P with coordinates (X,Y,Z) in the scene gets imaged at the point P', with image plane coordinates (x,y) where

$$x = \frac{-fX}{Z}, y = \frac{-fY}{Z},$$

and f is the distance from the optical center of the camera to the image plane. All points in the 3-D world that lie on a ray passing through the optical center are mapped to the same point in the image. During reconstruction, we seek to recover the 3-D information lost during perspective projection.

Many cues are available in the visual stimulus to make this possible, including structure from motion, binocular stereopsis, texture, shading, and contour. Each of these relies on background assumptions about the physical scene (Marr 1982).

The cues of stereopsis and structure from motion rely on the presence of multiple views, either acquired simultaneously from multiple cameras or over time from a single camera during the relative motion of objects. When the projections of a sufficient number of points in the world are observed in multiple images, it is theoretically possible to deduce the 3-D locations of the points as well as of the cameras (Faugeras 1993; for further discussion of the mathematics, see STEREO AND MOTION PERCEPTION).

Shape can be recovered from visual TEXTURE—a spatially repeating pattern on a surface such as windows on a building, spots on a leopard, or pebbles on a beach. If the arrangement is periodic, or at least statistically regular, it is possible to recover surface orientation and shape from a single image (Malik and Rosenholtz 1997). While the sizes, shapes, and spacings of the texture elements (*texels*) are roughly uniform in the scene, the projected size, shape, and spacing in the image vary, principally because

1. Distances of the different texels from the camera vary. Recall that under perspective projection, distant objects appear smaller. The scaling factor is 1/Z.
2. Foreshortening of the different texels varies. This is related to the orientation of the texel relative to the line of sight of the camera. If the texel is perpendicular to the line of sight, there is no foreshortening. The magnitude of the foreshortening effect is proportional to $\cos \sigma$, where σ is the angle between the surface normal and the ray from the viewer.

Expressions can be derived for the rate of change of various image texel features, for example, area, foreshortening, and density (GIBSON's texture gradients), as functions of surface shape and orientation. One can then estimate the surface shape, slant, and tilt that would give rise to the measured texture gradients.

Shading—spatial variation in the image brightness—is determined by the spatial layout of the scene surfaces, their reflectance properties, and the arrangement of light sources. If one neglects interreflections—the fact that objects are illuminated not just by light sources but also by light reflected from other surfaces in the scene—then the shading pattern is determined by the orientation of each surface patch with respect to the light sources. For a diffusely reflecting surface, the brightness of the patch varies as the cosine of the angle between the surface normal and the light source direction. A number of techniques have been developed that seek to invert the process—to recover the surface orientation and shape giving rise to the observed brightness pattern (Horn and Brooks 1989).

Humans can perceive 3-D shape from line drawings, which suggests that useful information can be extracted from the projected image of the contour of an object (Koenderink 1990). It is easiest to do this for objects that belong to parametrized classes of shapes, such as polyhedra or surfaces of revolution, for which the ambiguity resulting from perspective projection can be resolved by considering only those scene configurations that satisfy the constraints appropriate to the particular class of shapes.

Finally, it should be noted that shape and spatial layout are only some of the scene characteristics that humans can

infer from images. Surface color, reflectance, and texture are also perceived simultaneously. In machine vision, there has been some work in this direction. For example, attempts have been made to solve the color constancy problem—to estimate true surface color, given that the apparent color in the image is determined both by the surface color and the spectral distribution of the illuminant.

Visually Guided Control

One of the principal uses of vision is to provide information for manipulating objects and guiding locomotion. Consider the use of vision in driving on a freeway. A driver needs to

1. Keep moving at a reasonable speed.
2. Control the lateral position of the vehicle in its lane—make sure it stays in the center and is oriented properly.
3. Control the longitudinal position of the vehicle—keep a safe distance from the vehicle in front of it.

The lateral and longitudinal control tasks do not require a complete reconstruction of the environment. For instance, lateral control of the car only requires the following information: the position of the car relative to the left and right lane markers, its orientation relative to the lanes, and the curvature of the upcoming road. A feedback control law can be designed using these measurements and taking into account the dynamics of the car. Several research groups (e.g., Dickmanns and Mysliwetz 1992) have demonstrated vision-based automated driving.

For dynamic tasks, it is important that measurements can be integrated over time to yield better estimates—Kalman filtering provides one formalism. Often the motion of the sensing device is known (perhaps because it has been commanded by the agent) and estimation of relevant scene properties can be made even more robust by exploiting this knowledge.

It is worth noting that even a partial reconstruction of scene information, as suggested above, may not be necessary. Lateral control could be achieved by feedback directly on image (as opposed to scene) measurements. Just steer so that the left and right lane markers are seen by the forward pointing camera in a symmetric position with respect to the center of the image. For the more general task of navigation around obstacles, other variables computable from the optical flow field have been proposed.

Grouping and Tracking

Humans have a remarkable ability to organize their perceptual input—instead of a collection of values associated with individual photoreceptors, we perceive a number of visual groups, usually associated with objects or well-defined parts of objects. This ability is equally important for machine vision. To recognize objects, we must first separate them from their backgrounds. Monitoring and surveillance applications require the ability to detect individual objects, and track them over time. Tracking can be viewed as grouping in the temporal dimension.

Most machine vision techniques for grouping and tracking can be viewed as attempts to construct algorithmic implementations of various grouping factors studied in the context of humans under the rubric of GESTALT PERCEPTION. For instance, the Gestaltists listed similarity as a major grouping factor—humans readily form groups from parts of an image that are uniform in color, such as a connected red patch, or uniform in texture, such as a plaid region. Computationally, this has motivated edge detection, a technique based on marking boundaries where neighboring pixels have significant differences in brightness or color. If we look for differences in texture descriptors of image patches, suitably defined, we can find texture edges.

Similarity is only one of the factors that can promote grouping. Good continuation suggests linking edge segments that have directions consistent with being part of a smoothly curving extended contour. Relaxation methods and dynamic programming approaches have been proposed to exploit this factor.

Earlier work in machine vision was based primarily on local methods, which make decisions about the presence of boundaries purely on the information in a small neighborhood of an image pixel. Contemporary efforts aim to make use of global information. A number of competing formalisms, such as Markov random fields (Geman and Geman 1984), layer approaches (Wang and Adelson 1994) based on the expectation maximization technique from statistics, and cut techniques drawn from spectral graph theory (Shi and Malik 1997) are being explored. Some of these allow for the combined use of multiple grouping factors such as similarity in brightness as well as common motion.

The temporal grouping problem, visual tracking, lends itself well to the Kalman filtering formalism for dynamic estimation. At each frame, the position of a moving object is estimated by combining measurements from the current time frame with the predicted position from previous data. Generalizations of this idea have also been developed (see Isard and Blake 1996).

Machines and Cognition

See INTRODUCTION: COMPUTATIONAL INTELLIGENCE; INTRODUCTION: PHILOSOPHY

Magic and Superstition

We generally call something magical or superstitious if it involves human agency (as distinct from religion), and invokes causes inconsistent with *current* understandings, by relevant "experts," (e.g., Western scientists) of how the world operates.

Magical beliefs and activities have been understood by historians (Thomas 1971), psychologists (Freud 1950; Piaget 1929), and anthropologists (Frazer 1890; Mauss 1902) as primitive attempts to understand and control the world. Some of these authors posit an "evolutionary" or developmental course, with magic replaced over historical time, first by religion and ultimately by science. This hypothesized progression cannot account for the high incidence of magical beliefs in educated late twentieth century adults in the developed world, in the face of the great advances of science in the twentieth century.

Why do these beliefs (and actions) persist? The adaptive human tendency to understand, control, and make meaning out of occurrences in the world probably lies at the heart of magic and religion. Reliance by scientific explanations on impersonal forces and random events fails to satisfy the human mind, which is inclined to personalize and humanize accounts of events in the world. The pervasiveness of magical beliefs can probably be attributed to three causes: (1) this type of thinking is natural and intuitive for the human mind (though some, e.g., Sperber 1985, propose that ideas such as this may survive because they strikingly depart from intuition and expectations); (2) magical thinking often makes moderately accurate predictions; and (3) a major function of magical acts and rituals is performative (Tambiah 1990).

Why do magical beliefs take the particular form they do? They seem heavily guided by natural intuitions about the nature of the world, and are selected for their ability to give satisfying (including anxiety-reducing) as much as accurate accounts. These intuitions may derive from primary process thought (FREUD), failure to distinguish the self from the world (PIAGET), preprogrammed or readily acquired cognitive heuristics, or the very nature of symbolic thinking.

Since some "magical" beliefs have proven true over time (e.g., the folk belief in mid-19th-century America that cholera was contagious), and since scientific knowledge is by definition open to continuous revision, we focus on the form rather than the accuracy of magical beliefs. We examine two principles that are widespread, specific, and relatively well studied. These are two of the three "laws of sympathetic magic," originally described as aspects of the "primitive" mind by Tylor (1879), Frazer (1890), and Mauss (1902). The laws were conceived as basic features of human thought, projected onto the world, leading to beliefs that things associated or symbolically related in the mind actually go together, and may be causally linked, in the world (see Rozin and Nemeroff 1990; Nemeroff and Rozin 1998; Tambiah 1990 for reviews).

The law of similarity has been summarized as "like produces like," "like goes with like," or "the image equals the object." Likeness is elevated to a basic, often causal principle; the simplest example confounds likeness with identity, hence "appearance equals reality." The adaptive value of this law is clear: generally speaking, if it looks like a tiger, it *is* a tiger. For humans, this law becomes problematic because humans make artifacts that are imitations of entities in the world, as in drawings or photographs, or more abstractly, the words that represent them. A picture of a tiger does not justify fear. Similarity functions in nonhumans and in young children (presumably from birth); one feature of development is learning about situations in which appearance does not correspond to reality.

Examples of similarity include burning effigies of persons in order to cause harm to them, or reliance on appearance in judging objects when the appearance is known to be deceiving (e.g., avoidance by educated adults of chocolate shaped to look like feces; or difficulty experienced in throwing darts at a picture of a respected person). In the domain of words, Piaget (1929) described as "nominal realism" the child's difficulty in understanding the arbitrary relation of word and referent. Similarly, educated people have difficulty disregarding a label on a bottle (e.g., "poison") that they know does not apply.

The law of contagion holds that when two objects come into even brief physical contact, properties are permanently transmitted between them ("once in contact, always in contact"). Contagion typically flows from a valenced source (e.g., a detested or favorite person), often through a vehicle (e.g., clothing or food) to a target, usually a person. Traditional examples include the idea that food or objects that have been in contact with death, disease, or enemies will cause harm if eaten or contacted, or that damage done to a separated part of a person (e.g., a piece of hair) will damage that person (sorcery).

Contagion has clear adaptive value by reducing the risk of transmitting microbes. It is closely associated with the

emotion of disgust (disgusting entities are contaminating, i.e., negative contagion), and may have originated in the food context. On the positive side, contagion provides a concrete representation of kinship as shared blood, and may serve as the proximal means to induce kin preferences.

Contagion, in opposition to similarity, holds that things are often not what they appear to be, since they bear invisible "traces" of their histories. Consistent with this sophistication, contagion seems to be absent in young children and all nonhumans. However, contagion is probably present in all normal adult humans.

Magical contagion is shown by educated adults, who, for example, reject a preferred beverage after brief contact with a dead cockroach (Rozin and Nemeroff 1990). Western subjects in situations such as these generally attribute their aversion to health risks; however, they quickly realize that this account is insufficient when their aversion remains after the contaminant has been rendered harmless (e.g., sterilized). Magical thinking often exposes such "head vs. heart" conflicts.

Other examples of contagion in everyday life include celebrity token hunting, valuing of family heirlooms, and the reluctance of many individuals to share or buy used clothing. Sources capable of producing positive contagion ("transvaluation") include loved ones and celebrities. Those capable of producing substantial aversions include virtually any disgusting substance, and a wide variety of people; even unknown healthy others contaminate for most persons, and contamination is enhanced if the person is described as ill or morally tainted.

Some properties of contagion (Rozin and Nemeroff 1990) across situations and cultures are: (1) Physical contact is either definitionally necessary or almost always present; (2) Effects are relatively permanent; (3) Even very brief contact with any part of the source produces almost the full effect (dose and route insensitivity); (4) Negative contagion is more widespread and powerful than positive (negativity dominance); (5) Properties passed may be physical or mental, including intentions and "luck"; (6) Contagion can operate in a "backward" direction, with effects flowing from recipient or vehicle back on to the source (as when one attempts to harm someone by burning a lock of their hair).

The contagious entity or "essence" may be mentally represented in at least three ways (depending on culture, nature of the source, and individual within-culture differences). One is pure association (which does not entail contact, and can be thought of as an artifactual account of contagion), a second is the passage of a material-like essence, and a third is the passage of a spiritual, nonmaterial essence (Nemeroff and Rozin 1994).

Magical thinking varies substantially in quality and quantity across cultures, lifetimes, and history, as well as among adults within a culture. Contagion, particularly via contact with those perceived as undesirable, is omnipresent, and is potentially crippling. While this type of interpersonal contagion is universal, in Hindu India and many of the cultures in Papua, New Guinea (Meigs 1984), it is especially salient in daily life, and has an overt moral significance.

Magnetic Fields

See ELECTROPHYSIOLOGY, ELECTRIC AND MAGNETIC EVOKED FIELDS

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is based on the phenomenon of nuclear magnetic resonance (NMR), first described in landmark papers over fifty years ago (Rabi et al. 1938; Rabi, Millman, and Kusch 1939; Purcell et al. 1945; Bloch, Hansen, and Packard 1946). In the presence of an external magnetic field, atomic nuclei with magnetic moments, such as ^{1}H, ^{13}C, and ^{31}P nuclei, encounter a separation in the energy levels of their quantum mechanically allowed orientations relative to the external field. Transitions between these orientations can be induced with electromagnetic radiation typically in the radiofrequency range. The discrete frequency associated with such a transition is proportional to the external magnetic field strength and to two parameters that are determined by the intrinsic properties of the nucleus and its chemical environments, the nuclear gyromagnetic ratio, and the chemical shift, respectively. Based on the ability to obtain discrete resonances sensitive to the chemical environment, NMR has evolved rapidly to become an indispensable tool in chemical and biological research focused on molecular composition, structure, and dynamics.

In 1973, a novel concept of using NMR of the hydrogen atoms in the human body as an imaging modality was introduced (Lauterbur 1973). While all NMR applications of the time were singularly concerned with eliminating inhomogeneities in magnetic field magnitude over the sample, this new concept embraced them and proposed to utilize them to extract spatial information. Consequently, today magnetic resonance is solidly established as a noninvasive imaging technique suitable for use with humans.

MRI is essentially based on two fundamental ideas, "spatial encoding" and "contrast." The former is the means by which the NMR data contain information on the spatial origin of the NMR signal. The latter must provide the ability to distinguish and visualize different structures or processes occurring within the imaged object and is ultimately translated into gray scale or color coding for presentation. Spatial encoding is accomplished by external magnetic fields whose magnitude depend linearly on spatial coordinates in

any one of three orthogonal directions. Contrast is achieved either based on the regional density of the nuclear species imaged or by the impact of the chemical and biological environment on parameters that determine the behavior or relaxation of a population of spins from a nonequilibrium state toward thermal equilibrium. Improving contrast and spatial encoding strategies are central to developments in MRI as the field strives to image faster, with higher resolution and structural detail, and image not only anatomy but also physiological processes such as blood flow, perfusion, organ function, and intracellular chemistry.

An avidly pursued new dimension in the acquisition of physiological and biochemical information with MRI is mapping human brain function, referred to as fMRI. The first fMRI image of the human brain was based on measurements of task-induced blood volume change assessed with intravenous bolus injection of an MRI contrast agent, a highly paramagnetic substance, into the human subject and tracking the bolus passage through the brain with consecutive, rapidly acquired images (Belliveau et al. 1991). However, this method was quickly rendered obsolete with the introduction of totally noninvasive methods of fMRI. Of the two current ways of mapping alterations in neuronal activation noninvasively, the most commonly used method relies on the weak magnetic interactions between the nuclear spins of water protons in tissue and blood, and the paramagnetic deoxyhemoglobin molecule, termed BOLD (blood oxygen level–dependent) contrast, first described for the brain by Ogawa (Ogawa et al. 1990a, 1990b; Ogawa and Lee 1990) and is similar to the effect described for blood alone by Thulborn et al. (1982). The presence of paramagnetic deoxyhemoglobin, compartmentalized in red blood cells and in blood vessels, generates local magnetic field inhomogeneities surrounding these compartments which are dynamically (due to rapid diffusion) or statically averaged over the smallest volume element in the image and lead to signal loss when a delay is introduced between signal excitation and subsequent sampling.

In the original papers describing the BOLD effect, functional mapping in the human brain using BOLD was anticipated (Ogawa et al. 1990a) based on data documenting regional elevation in blood flow and glucose metabolism without a commensurate increase in oxygen consumption rate during increased neuronal activity (Fox and Raichle 1985; Fox et al. 1988); these data would predict a task-induced decrease in deoxyhemoglobin content in the human brain and a consequent alteration in MRI signal intensity when the signal intensity difference between two states, for example, in the absence and presence of a mental task or sensory stimulation, is examined. This was demonstrated and the first BOLD-based fMRI images of the human brain were published in 1992 by three groups in papers submitted within five days of each other (Bandettini et al. 1992; Kwong et al. 1992; Ogawa et al. 1992). Initial functional brain mapping studies were focused on simple sensory stimulation and regions of the brain that are relatively well understood. These studies were aimed at demonstrating and evaluating the validity of the technique rather than addressing the plethora of as yet unanswered questions concerned with aspects of brain function. In the short period of time

since its introduction, however, BOLD fMRI has been used to map functions in the whole brain, including subcortical nuclei, with a few millimeters resolution and has been shown to display specificity at the level of ocular dominance columns in humans at the high magnetic field of 4 tesla (Menon, Ogawa, and Ugurbil 1996; Menon et al. 1997). At present field strengths, the sensitivity and hence the spatial resolution attainable, however, is at the margin of what is required for visualizing human ocular dominance columns which are approximately 1×1 mm in cross-sectional dimensions.

A second approach to generating functional maps of the brain with fMRI relies on the task-induced increase in regional blood flow alone. This method is analogous to the POSITRON EMISSION TOMOGRAPHY (PET)–based functional brain mapping using water labeled with a positron emitter ($H_2{}^{15}O$). In the noninvasive MRI approach, however, the label is simply the collective spins of the water molecules whose net bulk magnetization is inverted or nulled (saturated) either within a slice to be imaged or outside of the slice to be imaged. For example, if the slice to be imaged is inverted, the inverted magnetization must relax back to its thermal equilibrium value and does so in a few seconds; in the absence of flow, this occurs with what is termed spin-lattice relaxation mechanisms. However, when flow is present, apparent relaxation occurs because of replacement of inverted spins by unperturbed spins coming from outside the inversion slice. Such flow-based fMRI methods were first demonstrated in 1992 (Kwong et al. 1992), and significantly refined subsequently (Edelman et al. 1992; Kim 1995). While flow-based techniques have some advantages over BOLD methods, such as simplicity of interpretation and ability to poise the sensitivity to perfusion as opposed to macrovascular flow, rapid imaging of large sections of the brain or whole brain is not yet possible.

fMRI techniques rely on secondary and tertiary responses, metabolic and hemodynamic, to increased neuronal activity. Hence, they are subject to limitations imposed by the temporal characteristics and spatial specificity of these responses. Current data suggest that BOLD images, when designed with appropriate paradigms, may have spatial specificity down to the millimeter to submillimeter scale (e.g., ocular dominance columns) presumably because the spatial extent of altered oxygen consumption, hence deoxyhemoglobin alterations, coupled to neuronal activity, is confined accurately to the region of elevated neuronal activity; this scale may be coarser, possibly in the range of several millimeters, for perfusion images if blood flow response extends beyond the region of increased activity (Malonek and Grinvald 1996). With respect to temporal resolution, the sluggish metabolic response and even more sluggish hemodynamic response to changes in neuronal activity suggest that better than approximately 0.5-sec time resolution may not be achievable with current fMRI techniques even though image acquisition can be accomplished in as little as 20 to 30 msec. While this excludes a very large temporal domain of interest, the plethora of mental processes accomplished in the seconds domain by the human brain remains accessible to fMRI.

Malinowski, Bronislaw

Bronislaw Malinowski (1884–1942), founder of British social anthropology and first thorough-going practitioner (if not the inventor) of the fieldwork method known as "participant observation," continues to be read with fascination and admiration. His reputation rests on six classic monographs he wrote between 1922 and 1935 about the lives and ideas of the world of the people of the Trobriands, a group of islands off the northeast coast of Papua New Guinea.

Malinowski was born in Cracow in 1884 to aristocratic parents. His father—a linguist and professor of Slavic philology at the University of Cracow—died when he was 12. His evidently clever mother taught herself Latin and mathematics in order to tutor him during a long illness in his mid-teens. In 1902 he entered the University of Cracow to study physics and philosophy and graduated with a Ph.D. in 1908—his thesis influenced by the empiricist epistemology of Ernst Mach. Afterward, at Leipzig, he studied economic history with Bucher and psychology with WUNDT, whose "folk psychology" concerned people's day-to-day ideas and their interconnections—their language, customs, art, myths, religion—in short, their "culture." Frazer's *The Golden Bough* was another definitive influence (see Kuper 1996: 1–34; Stocking 1995: 244–297).

In 1910 Malinowski left Leipzig for the London School of Economics where, under Westermarck, he worked on *The Family among the Australian Aborigines,* published in 1913. In 1914, aged 30, he made his first field trip to Papua New Guinea, where, following the wishes of his mentor, W. H. R. Rivers, he worked for some months among the Mailu; but this was "no more than an apprentice's trial run, conventional enough in method and results" (Kuper 1966: 12). The ground-breaking fieldwork came in 1915–1916 and 1917–1918 in Kiriwina, the largest of the Trobriand Islands.

Malinowski's first Trobriand ethnography was written in Australia in 1916. *Baloma: The Spirits of the Dead in the Trobriand Islands* (1916) is an engaging study of magic, witchcraft, and religious beliefs that also reveals Malinowski's tenacity in investigation. *Argonauts of the Western Pacific* (1922) describes the ceremonial exchange known as the Kula; a key text for anthropologists, it influenced, for example, Marcel Mauss and Claude LÉVI-STRAUSS. *Crime and Custom in Savage Society* (1926) examines reciprocity as an underlying principle of social control. *Sex and Repression in Savage Society* (1927) looks at the implications for Freudian theory of relations within the Trobriand family. *The Sexual Life of Savages* (1929) focuses on sexuality, marriage, and kinship and includes vivid descriptions of children's daily lives. *Coral Gardens and their Magic* (1935, two volumes) deals with horticulture, land tenure, and the language of magic and gardening. Here Malinowski draws out his idea of "the context of situation," first put forward in an essay published twelve years earlier: "The conception of meaning as contained in an utterance is false and futile. A statement, spoken in real life, is never detached from the situation in which it has been uttered" (1952: 307). This perspective on language—radical in its time—is consistent with Malinowski's empiricism, which was always tempered by an awareness that "any belief or any item of folklore is not a simple piece of information . . . [it] must be examined in the light of diverse types of minds and of the diverse institutions in which it can be traced. To ignore this social dimension [of belief] . . . is unscientific" (1974: 239–240).

Malinowski's evolutionist view took for granted the cultural superiority of Europeans over other peoples; this idea is evident in his various works, especially in his private Trobriand diaries, which, being somewhat at odds with the ethnographies, caused controversy when they were published posthumously in 1967. Even so, and despite his sometimes patronizing and even spiteful asides on "the natives," Malinowski was clearly genuine both in his pursuit of his fieldwork aims and in the often admiring respect for Trobriand people he expressed in his works and in person to his students (Firth 1957, 1989; Young 1979).

A charismatic teacher, revered by his students at the London School of Economics, where he held the first chair in social anthropology, Malinowski spent a good deal of his intellectual force engaged in the battle to make his functionalist theory of human behavior dominant in social anthropology. He argued that "culture is essentially an instrumental apparatus by which man is put in a position the better to cope with the concrete specific problems that face him in his environment in the course of the satisfaction of his needs" (1944: 150). This perspective had stood Malinowski in good stead in gathering field data, but it assumed "culture" to be an integrated whole, left no place for change as a condition of human existence, and lacked any analytical power to explain cross-cultural similarities and differences.

In 1938 Malinowski went to the United States, where he was caught by the outbreak of World War II and remained, as a visiting professor at Yale, until he died suddenly in 1942. His work was developed and sometimes amended by later ethnographers of the Trobriands, but "the legacy of his Trobriand ethnography continues to play an unprecedented role in the history of anthropology" (Weiner 1988: 4).

Manipulation and Grasping

Manipulation and grasping are branches of robotics and involve notions from kinematics, mechanics, and CONTROL THEORY. Grasping is concerned with characterizing and achieving the conditions that will ensure that a robot gripper holds an object securely, preventing, for example, any motion due to external forces. Manipulation, on the other hand, is concerned with characterizing and achieving the conditions under which a robot or a part held by a robot will perform a certain motion. Research in both areas has led to practical systems for picking up parts from a conveyor belt or a pallet, reorienting them, and inserting them into an assembly (e.g., Tournassoud, Lozano-Perez, and Mazer 1987; Peshkin and Sanderson 1988; Goldberg 1993), with promising applications in flexible manufacturing.

This entry focuses on a quasi-static model of mechanics that neglects inertial forces and dynamic effects. This is valid in typical grasping and manipulation tasks when all velocities are small enough, and allows for a geometric analysis of object motion under kinematic constraints. Our discussion of manipulation is restricted to the problem of characterizing the motion of an object pushed by one or several fingers, and it excludes some fundamental problems such as general robot motion planning in the presence of obstacles.

Grasping emerged as a field of its own in the early eighties with the introduction of dextrous multifinger grippers such as the Salisbury Hand (Salisbury 1982) and the Utah-MIT Dextrous Hand (Jacobsen et al. 1984). Much of the early work was conducted in Roth's research group at Stanford (e.g., Salisbury 1982; Kerr and Roth 1986) drawing on notions of form and force closure from *screw theory* (Ball 1900), which provides a unified representation for displacements and velocities as well as forces and torques using a line-based geometry. Namely, when a hand holds an object at rest, the forces and moments exerted by the fingers should balance each other so as not to disturb the position of this object. Such a grasp is said to achieve *equilibrium.* An equilibrium grasp achieves *force closure* when it is capable of balancing any external force and torque, thus holding the object securely. A *form closure* grasp achieves the same result by preventing any small object motion through the geometric constraints imposed by the finger contacts. Intuition suggests that the two conditions are equivalent, and it can indeed be shown that force closure implies form closure and vice versa (Mishra and Silver 1989). A secure grasp should also be *stable;* in particular, a compliant grasp submitted to a small external disturbance should return to its equilibrium state. Nguyen (1989) has shown that force or form closure grasps are indeed stable.

Screw theory can be used to show that, in the frictionless case, four or seven fingers are both necessary and, under very general conditions, sufficient (Lakshminarayana 1978; Markenscoff, Ni, and Papadimitriou 1990) to construct frictionless form or force closure grasps of two- or three-dimensional objects, respectively. As could be expected, friction "helps" and it can also be shown that only three or four fingers are sufficient in the presence of Coulomb friction (Markenscoff, Ni, and Papadimitriou 1990). In fact, it can also be shown that any grasp achieving equilibrium for some friction coefficient μ will also achieve form or force closure for any friction coefficient $\mu' > \mu$ (Nguyen 1988; Ponce et al. 1997).

Screw theory can also be used to characterize the geometric arrangement of contact forces that achieve equilibrium (and thus form or force closure under friction). In particular, two forces are in equilibrium when they oppose each other and share the same line of action, and three forces are in equilibrium when they add to zero and their lines of action intersect at a point. The four-finger case is more involved, but a classical result from line geometry is that the lines of action of four noncoplanar forces achieving equilibrium lie on the surface of a (possibly degenerated) hyperboloid (Ball 1990). In turn, these geometric conditions have been used in algorithms for computing optimal grasp forces given fixed finger positions (e.g., Kerr and Roth 1986), constructing at least one (maybe optimal) configuration of the fingers that will achieve force closure (e.g.,

Mishra, Schwartz, and Sharir 1987; Markenscoff and Papadimitriou 1989), and computing entire ranges of finger positions that yield force closure (e.g., Nguyen 1988; Ponce et al. 1997). The latter techniques provide some degree of robustness in the presence of the unavoidable positioning uncertainties of real robotic systems.

As shown in Rimon and Burdick (1993), for example, certain grasps that are not form closure nevertheless immobilize the grasped object. For example, three frictionless fingers positioned at the centers of the edges of an equilateral triangle cannot prevent an infinitesimal rotation of the triangle about its center of mass, although they can prevent any finite motion. Rimon and Burdick (1993) have shown how to characterize these grasps by mapping the constraints imposed by the fingers on the motion of an object onto its *configuration space,* that is, the set of object positions and orientations. In this setting, screw theory becomes a *first-order* theory of mobility, where the curved obstacle surfaces are approximated by their tangent planes, and where immobilized object configurations correspond to isolated points of the free configuration space. Rimon and Burdick have shown that second-order (curvature) effects can effectively prevent any finite object motion, and they have given operational conditions for immobilization and proven the dynamic stability of immobilizing grasps under various deformation models (Rimon and Burdick 1994). An additional advantage of this theory is that second-order immobility can be achieved with fewer fingers than form closure (e.g., four fingers instead of seven are in general sufficient to guarantee immobility in the frictionless case). Techniques for computing second-order immobilizing grasps have been proposed in Sudsang, Ponce, and Srinivasa (1997) for example.

Once an object has been grasped, it can of course be manipulated by moving the gripper while keeping its fingers locked, but the range of achievable motions is limited by physical constraints. For example, the rotational freedom of a gripper about its axis is usually bounded by the mechanics of the attached robot wrist. A simple approach to fine manipulation in the plane is to construct *finger gaits* (Hong et al. 1990). Assume that a disk is held by a four-finger hand in a three-finger force closure grasp. A certain amount of, say, counterclockwise rotation can be achieved by rotating the wrist. To achieve a larger rotation, first position the fourth finger so that the disk will be held in force closure by the second, third, and fourth fingers, then release the first finger and reposition it. By repositioning the four fingers in turn so that their overall displacement is clockwise, we can then apply a new counterclockwise rotation of the wrist, and repeat the process as many times as necessary. (See Li, Canny, and Sastry 1989 for a related approach to dextrous manipulation, which includes coordinated manipulation, as well as rolling and sliding motions.)

Thus far, our discussion has assumed implicitly that a workpiece starts *and remains* at rest while it is grasped. This will be true when the part is very heavy or bolted to a table, but in a realistic situation, it is likely to move when the first contact is established and contact may be immediately broken. Moreover, the actual position and orientation of the object with respect to the hand are usually (at best) close to the nominal ones. Mason (1986) proposed that an appropriate characterization of the mechanics of pushing would at the same time provide the means of (1) predicting (at least partially) the motion of the manipulated object once contact is established, and (2) reducing the uncertainty in object position without sensory feedback. Assuming Coulomb friction, he constructed a program that predicts the motion of an object with a known distribution of support forces being pushed at a single contact point. He also devised a simple rule for determining the rotation sense of the pushed object when the distribution is unknown.

Extensions of this approach have been applied to a number of other manipulation problems. Fearing (1986) has shown how to exploit local tactile information to determine how a polygonal object rotates while it is grasped, and demonstrated the capture of an object by the three-finger Salisbury hand as well as the execution of other complex manipulation tasks such as part "twirling." In the manufacturing domain, Peshkin and Sanderson (1988) have shown how to use static fences to reorient parts carried by a conveyor belt, and Goldberg (1993) has used a modified two-jaw gripper to plan a sequence of grasping operations that will reorient a part with unknown original orientation. A variant of this approach has also been used to plan a set of tray-tilting operations that will reorient a part lying in a tray (Erdmann and Mason 1988). More recently, Lynch and Mason (1995) have derived sufficient conditions for *stable pushing,* namely, for finding a set of pushing directions that will guarantee that the pushed object remains rigidly attached to the pusher during the manipulation task. They have also proven conditions for local and global controllability, and given an algorithm for planning pushing tasks in the presence of obstacles.

The kinematics of pushing are important as well, because they determine the relative positions and orientations of the gripper-object pair during the execution of a manipulation task. Brost (1991) has shown how to construct plans for pushing and compliant motion tasks through a detailed geometric analysis of the obstacle formed by a rigid polygon in the configuration space of a second polygon. More recently, Sudsang, Ponce, and Srinivasa (1997) have introduced the notion of *inescapable configuration space* (ICS) region for a grasp. As noted earlier, an object is immobilized when it rests at an isolated point of its free configuration space. A small motion of a finger away from the object will transform this isolated point into a compact region of free space (the ICS) that cannot be escaped by the object. For simple pushing mechanisms, it is possible to compute the maximum ICS regions and the corresponding range of finger motions, and to show that moving the finger from the far end of this range to its immobilizing position will cause the ICS to continuously shrink, ensuring that the object ends up in the planned immobilizing configuration. Thus a grasp can be executed in a robust manner, without requiring a model of the part motion at contact. More complex manipulation tasks can also be planned by constructing a graph of overlapping maximum ICS regions. This approach has been applied to grasping and in-hand manipulation with a multi-fingered reconfigurable gripper (Sudsang, Ponce, and Srinivasa 1997), and more recently, to manipulation tasks using disk-shaped mobile platforms in the plane.

Marr, David

David Marr (1945–1980), theoretical neurophysiologist and cognitive scientist, integrated neurophysiological and psychophysical studies with the computational methods of artificial intelligence (AI) to found a new, more powerful approach to understanding biological information-processing systems. The approach has come to redefine the standard for achieving a suitable comprehension of brain structure and function.

Marr was born in Essex, England on 19 January 1945 to Douglas and Madge Marr, and died at age thirty-five of leukemia. After attending Rugby, he entered Trinity College, Cambridge in 1963, obtaining the B.S. degree in mathematics in 1966 with first-class honors. Shortly thereafter, under the guidance of Giles Brindley, he began an intensive year of study on all aspects of brain function, with the intent of focusing on the neural implementation of efficient associative memories. By the end of 1968 he had submitted a dissertation for a title, a fellowship at Trinity College, and was elected. He received two advanced degrees from Trinity in 1971: an M.S. in mathematics and a Ph.D. in theoretical neurophysiology. The first part of his thesis was a theoretical analysis of the cerebellar cortex, published in the *Journal of Physiology* in 1969. This work was the first detailed theory on any really complex piece of neural machinery, with very specific predictions concerning the input-output relations and details of synaptic modifiabilities during the learning of new motor movements. The essence of this theory is still viable today, and continues to be the benchmark for further advances in understanding cerebellar cortex. Two other papers also appeared before 1971: one on the archicortex, the

other on the neocortex, both of which remain landmarks in theoretical neurophysiology.

After obtaining his Ph.D., Marr accepted an appointment at the MRC Laboratory of Molecular Biology under Sydney Brenner and Francis Crick, and he retained an affiliation with MRC until 1976. The thrust of Marr's work changed rather dramatically in 1972, however, following an interdisciplinary workshop on the brain where he met Marvin Minsky and Seymour Papert, who extended an invitation to visit the MIT Artificial Intelligence Laboratory. This visit reinforced Marr's growing conviction that a complete theory of any brain structure must go beyond interpreting anatomical and physiological facts to include an analysis of the task being performed, or more specifically, an understanding of the problem that the information-processing device was "solving." Equally important, he recognized the weakness of theories that appeared explanatory but were not demonstrative. However, demonstrative theories of brain function required large and flexible computing resources such as those available at MIT. Consequently, Marr's initial three-month visit to the AI lab oratory in 1973 became extended, extended again, and then by 1976 became permanent. In 1977 he was appointed to the faculty of the (current) Department of Brain and Cognitive Sciences, becoming full professor at MIT in 1980, while continuing to hold his AI Lab appointment.

Marr's years at the AI laboratory were incredibly productive. The goal was to understand both the competence as well as the performance of a biological information-processing system. Although some studies of movement continued, the primary thrust was understanding the mammalian visual system. Although small, Marr's remarkably talented group included Tomaso Poggio and Shimon Ullman. They shared Marr's conviction that explanations of a complex system are found at several levels. A complete study should address at least three levels: an analysis of the competence, the design of an algorithm and choice of representation, and an implementation. In order to provide a coherent framework for organizing and attacking visual problems—more properly, problems of "seeing"—Marr proposed separating perceptual processing tasks into three main stages: a primal sketch, where properties of the image are made explicit; a 2½-D sketch, which is a viewer-centered representation of the surface geometry and surface properties; and lastly a 3-D model representation, which is object centered rather than viewer based. His 1982 book, *Vision: A Computational Investigation into the Human Representation and Processing of Visual Information,* published posthumously, summarizes these ideas, as well as the contributions to image processing, grouping, color, stereopsis, motion, surface geometry, TEXTURE, SHAPE PERCEPTION, and OBJECT RECOGNITION. Many of these contributions had appeared by the late 1970s, and in recognition of this work, Marr received in 1979 the Computers and Thought Award from the International Joint Conference on Artificial Intelligence. More recently, "best paper" awards in the name of David Marr have been created by the International Conference on Computer Vision and by the Cognitive Science Society.

As a person, David Marr was charismatic and inspiring. He was both fun and brilliant, enjoying the adventures of

understanding brain structure and function, as well as life itself. He communicated his pleasure in clear and compelling ways, not only in personal exchanges and in his writing but also in music. He was an accomplished clarinetist. His early death was a great loss but even in his short life, he was able to bring together two previously diverse disciplines, set a higher standard for explanatory understanding, and open new doors to unraveling the mysteries of mind and brain.

McCulloch, Warren S.

Warren McCulloch (1898–1968) was a physician turned physiologist. After medical school, he trained in neurology from 1928–1931, studied mathematical physics in 1931–1932, worked as a clinician from 1932–34, then joined the Yale Laboratory of Neurophysiology and by 1941 became an assistant professor in the department. His main work at Yale was on the functional connections in the CEREBRAL CORTEX of primates. Dusser de Barenne, his mentor and collaborator, had developed the method of strychnine neuronography, a way of determining the direct projection of one architectonically specified region in the cortex of the forebrain to other regions. It is a clever and reliable technique that served well to show in a single day of experiment what would take years to work out by the standard anatomical procedures at the time. Little of what the technique revealed has been faulted, but it never caught on for a variety of reasons, the main one being a general misunderstanding of the underlying physiology.

In 1941 McCulloch came to the Illinois Neuropsychiatric Institute as Associate Professor of Psychiatry at the College of Medicine, University of Illinois. Percival Bailey, Professor of Neurosurgery, had worked with McCulloch at Yale, as had Gerhardt van Bonin, Professor of Anatomy. The neuronography of primate cortex work continued and attracted many visiting collaborators, and McCulloch developed an enduring interest in the bulbo-reticular system, due mainly to the innovative studies of Magvin and Snyder at Northwestern University.

In 1942 he took a medical student, Jerry Lettvin, together with his friend Walter PITTS, into his laboratory, and by midyear, into his home. Pitts, taking an interest in the nervous system, told McCulloch of Gottfried Wilhelm Leibniz's dictum that any task that can be completely and unambiguously set forth in logical terms can be performed by a logical engine. In the previous year, David Lloyd had demonstrated monosyllabic excitation, facilitation, and inhibition. And in 1936–37 Alan TURING had published his brilliant essay on the universal logical engine. It seemed to McCulloch and Pitts that neurons could be conceived as logical elements, pulsatile rather than two-state devices, and capable of realizing logical process. The ensuing paper, "A Logical Calculus of the Ideas Immanent in Nervous Activity" (McCulloch and Pitts 1943) became the inspiration for a new view of the nervous system, and a justification for the project of artificial intelligence.

In a later second paper, "On how we know universals: The perception of auditory and visual forms," Pitts and McCulloch implemented their notions by showing how the anatomy of the cerebral cortex might accommodate the identification of form independent of its angular size in the image, and other such operations in perception.

McCulloch at the same time carried on a full load of his studies in the physiology of the cortex and other parts of the nervous system. That was his daytime work. But, having become enamored of LOGIC, his evenings were devoted to problems in logical representation of mental operations. After all, he had developed a profound interest in philosophy while at Yale.

By the end of the 1940s, with John VON NEUMANN's first digital computers, Norbert Wiener's linear prediction theory, and the massive and singularly intellectual thrust of the military and industrial complex, it was evident that a new era was opening. In 1951, Jerome Wiesner, on Norbert Wiener's advice, offered a place at the Research Laboratory of Electronics at MIT to McCulloch, Pat Wall, and Lettvin. There McCulloch and Wall worked on spinal cord physiology. Pitts was already at MIT. At the time McCulloch was full professor at the University of Illinois, and Wall was assistant professor at the University of Chicago. Although the move brought loss of academic status and a serious cut in pay, the three of them accepted the invitation.

Beginning in 1951, McCulloch became a magnet for a most diverse company of those concerned with the new communications revolution. Benoit Mandelbrot, Manuel Blum, Marvin Minsky, Seymour Papert, and a host of others, then young and eager and hungry for discovery, visited frequently and stayed for long discussions.

Several major works were issued before 1960. One that charmed McCulloch particularly was the arduous source-sink analysis of currents in the spinal cord. Pitts had laid out the general method behind the effort; published in 1954–1955, it was the first demonstration of presynaptic inhibition between the collaterals of dorsal root fibers. A year and a half had been spent on computations that would occupy about an hour on today's machines. Then there was the

demonstration of the action of strychnine, which provided the ground needed to justify strychnine neuronography. Wall turned his interest to the mechanism involved in pain. H. R. Maturana joined the group from Harvard and, thanks to his patience and skill, "What the Frog's Eye Tells the Frog's Brain" was published (Lettvin et al. 1959).

Bob Gesteland joined the group as McCulloch's graduate student, addressing himself, under the urging of Pitts and McCulloch, to the problem of olfaction. His were the first recordings of the activity of single olfactory cells in the nasal mucosa of frogs. And his results—namely, that every cell responds to almost every odorant but with different coding patterns of activity, for different odorants, and that cells differ among themselves in their coding patterns for the odorants—are just bearing fruit today. In short, McCulloch was the center of a new thrust in nervous physiology, even more fascinating than what he envisioned before coming to MIT.

McCulloch had great generosity of spirit. He treated everyone as an equal and made an effort to encourage the best in everyone he met. He never showed the faintest hint of malice or envy or deviousness, but spoke, wrote, and carried himself as a nineteenth-century cavalier. A complete list of his publications is given in his *Collected Works,* and a small indication of his influence is evidenced by the Further Readings below.

Meaning

The meaning of an expression, as opposed to its form, is that feature of it which determines its contribution to what a speaker says in using it. Meaning conveyed by a speaker is the speaker's communicative intent in using an expression, even if that use departs from the expression's meaning. Accordingly, any discussion of meaning should distinguish speaker's meaning from linguistic meaning.

We think of meanings as what synonyms (or translations) have in common, what ambiguous expressions have more than one of, what meaningful expressions have and gibberish lacks, and what competent speakers grasp. Yet linguistic meaning is a puzzling notion. The traditional view is that the meaning of a word is the concept associated with it and, as FREGE suggested, what determines its reference, but this plausible view is problematic in various ways. First, it is not clear what CONCEPTS are. Nor is it clear what the relevant sort of association with words is, or, indeed, that every word has a concept, much less a unique concept, associated with it. Wittgenstein (1953) even challenged the Platonic assumption that all the items to which a word applies must have something in common. Unfortunately, there is no widely accepted alternative to the traditional view. Skepticism about meaning, at least as traditionally conceived, has also been registered in various ways by such prominent philosophers as Quine (1960), Davidson (1984), Putnam (1975), and Kripke (1982); for review of the debates these philosophers have generated see Hale and Wright 1997 (chaps. 8 and 14–17). Psychological approaches based on prototypes or on semantic networks, as well as COGNITIVE LINGUISTICS, seem to sever the connection between meaning and reference. The most popular philosophical approaches to sentence meaning, such as truth-conditional, model-theoretic, and POSSIBLE WORLDS SEMANTICS, also have their limitations. They seem ill equipped to distinguish meanings of expressions that necessarily apply in the same circumstances or to handle non-truth-conditional aspects of meaning.

Here are six foundational questions about meaning, as difficult as they are basic:

1. What are meanings?
2. What is it for an expression to have meaning?
3. What is it to know the meaning(s) of an expression? (More generally, what is it to understand a language?)

4. What is the relationship between the meaning of an expression and what, if anything, the expression refers to?
5. What is the relationship between the meaning of a complex expression and the meanings of its constituents?

An answer to question 1 would say whether meanings are psychological, social, or abstract, although many philosophers would balk at the question, insisting that meanings are not entities in their own right and that answering question 2 would take care of question 1. An answer to question 3 would help answer question 2, for what expressions mean cannot be separated from (and is perhaps reducible to) what people take them to mean. And question 4 bears on question 3. It was formerly assumed that the speaker's internal state underlying his knowledge of the meaning of a term determines the term's reference, but Putnam's (1975) influential TWIN EARTH thought experiments have challenged this "internalist" or "individualist" assumption. In reaction, Chomsky (1986, 1995) and Katz (1990) have defended versions of internalism about knowledge of language and meaning.

Question 5 points to the goal of linguistic theory: to provide a systematic account of the relation between form and meaning. SYNTAX is concerned with linguistic form, including LOGICAL FORM, needed to represent scope relationships induced by quantificational phrases and modal and other operators; SEMANTICS, with how form maps onto linguistic meaning. The aim is to characterize the semantic contributions made by different types of expression to sentences in which they occur. The usual strategy is to seek a systematic, recursive way of specifying the meanings of a complex expression (a phrase or sentence) in terms of the meanings of its constituents and its syntactic structure (see Larson and Segal 1995 for a detailed implementation). Underlying this strategy is the principle of semantic COMPOSITIONALITY, which seems needed to explain how a natural language is learnable (but see Schiffer 1987). Compositionality poses certain difficulties, however, regarding conditional sentences, PROPOSITIONAL ATTITUDE ascriptions, and various constructions of concern to linguists, such as genitives and adjectival modification. For example, although *Rick's team* is a so-called possessive phrase, Rick's team need not be the team Rick owns—it might be the team he plays for, coaches, or just roots for. Or consider how the force of the adjective *fast* varies in the phrases *fast car, fast driver, fast track,* and *fast race* (see Pustejovsky 1995 for a computational approach to such problems).

The study of speaker's meaning belongs to PRAGMATICS. What a speaker means in uttering a sentence is not just a matter of what his words mean, for he might mean something other than or more than what he says. For example, one might use "You're another Shakespeare" to mean that someone has little literary ability and "The door is over there" to mean also that someone should leave. The listener has to figure out such things, and also resolve any AMBIGUITY or VAGUENESS in the utterance and identify the references of any INDEXICALS AND DEMONSTRATIVES. GRICE (1989) ingeniously proposed that communicating involves a distinctive sort of audience-directed intention: that one's audience is to recognize one's intention partly on the suppo-

sition that they are intended to recognize it. This idea, which has important applications to GAME THEORY (communication is a kind of cooperative game), is essential to explaining how a speaker can make himself understood even if he does not make fully explicit what he means, as in IMPLICATURE. Understanding a speaker is not just a matter of understanding his words but of identifying his communicative intention. One must rely not just on knowledge of linguistic meaning but also on collateral information that one can reasonably take the speaker to be intending one to rely on (see Bach and Harnish 1979 for a detailed account). Communication is essentially an intentional-inferential affair, and linguistic meaning is just the input to the inference.

Memory

The term *memory* implies the capacity to encode, store, and retrieve information. The possibility that memory might not be a unitary system was proposed by William JAMES (1898) who suggested two systems which he named *primary* and *secondary memory.* Donald HEBB (1949) also proposed a dichotomy, suggesting that the brain might use two separate neural mechanisms with primary or short-term storage being based on electrical activation, while long-term mem-

ory reflected the growth of relatively permanent neuronal links between assemblies of cells.

Empirical support for a two-component view began to emerge in the late 1950s, when Brown (1958) and Peterson and Peterson (1959) observed that even small amounts of information would show rapid forgetting, provided the subject was prevented from maintaining it by active rehearsal. The characteristic forgetting pattern appeared to differ from that observed in standard long-term memory experiments, leading to the suggestion that performance depended on a separate short-term store. Such a view was vigorously opposed by Melton (1963), leading to a period of intense activity during the early 1960s that was concerned with the question of whether memory should be regarded as a unitary or dichotomous system.

By the late 1960s, the evidence seemed to strongly favor the dichotomous view. A particularly influential source of evidence was provided by a small number of neuropsychological patients who appeared to have a specific deficit of either the short-term or the long-term system. The clearest evidence of preserved short-term (STM) and impaired long-term memory (LTM) comes in the classic amnesiac syndrome. Particularly influential was case H.M. who underwent bilateral excision of the HIPPOCAMPUS in an attempt to treat intractable epilepsy. H.M. was left with a profound amnesia, unable to commit new material to memory, whether visual or verbal, and showing no capacity to learn his way around a new environment, to recognize people who worked with him regularly, or to remember the content of anything he read or saw. His STM, on the other hand, as evidenced by the capacity to hear and repeat back a string of digits such as a telephone number, was quite normal (Milner 1966).

The opposite pattern of memory deficit was demonstrated by Shallice and Warrington (1970) in a patient, K.F., who was unable to repeat back more than two digits, but whose long-term learning capacity and everyday memory were well within the normal range. His lesion was in the left hemisphere in an area known to be associated with language. Subsequent studies have shown that language and short-term phonological memory are often impaired in the same patient, but that the two areas are separable and the symptoms dissociable. When tested on the Petersons' short-term forgetting task, patients like K.F. proved to show very rapid forgetting, whereas densely amnesiac patients show normal performance, provided their amnesia is pure and unaffected by more general intellectual deficits (Baddeley and Warrington 1970).

Evidence from normal subjects paralleled the neuropsychological research in suggesting the need for at least two separate memory systems. Many memory tests appeared to show two separate components, one that was durable and long-term while the other showed rapid dissipation. For example, if a subject hears a list of twenty unrelated words and is asked to recall as many as possible in any order, there will be a tendency for the last few words to be well recalled, the so-called recency effect. However a delay of only a few seconds is sufficient for the effect to disappear, while recall of earlier items remains stable. When this paradigm was applied to neuropsychological patients, those with STM deficits showed preservation of the long-term component, but little or no recency, while amnesiac patients showed the opposite pattern.

Finally the learning characteristics of the two systems appeared to differ. The short-term system has a limited capacity, but appears to be relatively insensitive to speed of presentation, and in the case of verbal material to be sensitive to the sound or phonological characteristics of the material presented. The long-term system, on the other hand, has a huge capacity but a relatively slow rate of acquisition of new material, and a tendency to encode verbal material in terms of its meaning rather than sound (Baddeley 1966a, 1966b; Waugh and Norman 1965).

The 1960s saw a growing interest in developing mathematical models of learning and memory, with the most influential of these being that of Atkinson and Shiffrin (1968) which became known as the modal model. However, problems with a simple dichotomy rapidly emerged, leading to the wide-scale abandonment of the field by many of its investigators.

One problem stemmed from Atkinson and Shiffrin's assumption that the probability of an item being stored in LTM was a simple function of how long it was maintained in the short-term system. A number of studies demonstrated that active and vigorous verbal rehearsal might link to very little durable LTM (Craik and Watkins 1973; Bjork and Whitten 1974). This prompted Craik and Lockhart (1972) to propose their *levels of processing* theory of memory. This proposed that an item to be remembered, such as a word, could be processed at a series of encoding levels, beginning with the visual appearance of the word on the page, moving on to the sound of the word when pronounced, and, given further and deeper processing, to the meaning of that word and its relationship to other experiences of the subject. Craik and Lockhart suggested that the deeper the level of encoding, the more durable the memory trace. There is no doubt that this simple formulation does capture an important characteristic of long-term learning, namely, that encoding material richly and elaborately in terms of prior experience will lead to a comparatively durable and readily retrievable memory trace.

Note however that levels of processing is not an alternative to a dichotomous view; indeed Craik and Lockhart themselves postulate a primary memory system as part of their model, although this aspect of their work receives very much less attention than the concept of encoding levels.

A second difficulty for the modal model lay in the neuropsychological evidence. It may be recalled that patients with an STM deficit performed poorly on tasks such as immediate memory span and recency, but were normal in their LTM performance. The modal model suggested, however, that the short-term system acts as a crucial antechamber to long-term learning, hence predicting that such patients should have impaired learning capacity, and indeed should show poor performance on a wide range of tasks that were assumed to be dependent on the limited-capacity short-term system. They showed no evidence of this, with one such patient being an efficient secretary, while another ran a shop and raised a family.

This problem formed the focus of work by Baddeley and Hitch (1974), who attempted to simulate the neuropsychological STM deficit by means of a dual task technique. Subjects were required to hold and rehearse sequences of digits varying in length while at the same time performing a range of other tasks that were assumed to depend upon the limited-capacity store. It was assumed that longer sequences of digits would absorb more of the store, until eventually capacity was reached, leaving the main tasks to be performed without the help of the short-term system. A range of tasks were studied including long-term learning, reasoning, and comprehension. A clear pattern emerged suggesting that concurrent digits did impair performance systematically, but by no means obliterated it. This led to a reformulation of the STM hypothesis and the postulation of a multicomponent system which was termed *working memory.* It was suggested that this comprised a limited capacity attentional control system, the *central executive,* together with at least two slave systems, one concerned with maintaining visual-spatial information, the *sketchpad,* while the other was responsible for holding and manipulating speech-based information, the *phonological loop.*

The concept of working memory has proved extremely fruitful, not only in accounting for the initial neuropsychological evidence but also in being applicable to a wide range of tasks and subject groups, and more recently, providing a very fruitful basis for a range of neuroradiological studies concerned with the neuroanatomical basis of working memory (see Smith and Jonides 1995).

As in the case of STM, the concept of LTM has also undergone a detailed analysis in the last twenty years, again resulting in a degree of fractionation. One of the strongest cases for a basic distinction is that between implicit and explicit memory (see IMPLICIT VS. EXPLICIT MEMORY). Once again this distinction was heavily influenced by neuropsychological evidence, when it was observed that even densely amnesiac patients could nevertheless show comparatively normal learning on certain tasks, including the acquisition of motor skills, classical conditioning, and a whole range of procedures that come under the general term of *priming.* The classic demonstration within this area was that of Warrington and Weiskrantz (1968), who showed that amnesiac patients who were shown a list of words were totally unable to recall or recognize the words, but were able to demonstrate learning by perceiving the words more rapidly when they were presented in fragmented form. Subsequent work showed that learning was also preserved when tested by cueing with the first few letters of the word (e.g., present CROCODILE, test with CRO____), or with a fragment of the word, (C__O__O__I__E). Equivalent phenomena have been demonstrated in other modalities, and have shown to be widely demonstrable in normal subjects (see Roediger 1990 for a review).

Over the last decade there has been substantial controversy as to how best to explain this pattern of results. There is still some support for attempts to account for the data within a unitary system, but my own view (Baddeley 1998) is that this is no longer a tenable position. In particular, the neuropsychological evidence seems to argue for a distinction between an episodic LTM system (depending on a circuit linking the temporal lobes, the frontal lobes, and parahippocampal regions), and a whole range of implicit learning systems, each tending to reflect a different brain region.

While these systems are of considerable interest in their own right, and as ways of analyzing perceptual and motor processing, it can be questioned as to whether they should be referred to as *memory* systems, as they typically involve relatively automatic retrieval processes that are often not under the direct control of the subject. In contrast, episodic memory is the system that typifies our experience of recollecting the past. Indeed, Tulving (1985) suggests that its crucial and defining feature is the recollective process, accompanied by the feeling of familiarity, a process he refers to as *ecphory.* There have in recent years been a growing number of studies concerned with the phenomenological aspect of memory, often with considerable success (see Gardiner 1988).

A second proposed distinction within LTM is that between *semantic* and *episodic* memory (see EPISODIC VS. SEMANTIC MEMORY). Semantic memory refers to the stored knowledge of the world that underlies not only our capacity to understand language but also our ability to take advantage of prior knowledge in perceiving and organizing both the physical and social world around us. The need for such a store of information was initially made obvious by attempts to develop computer-based systems for comprehending text, such as that of Quillian (1969). These stimulated attempts to understand semantic memory in human subjects, and prompted Tulving (1972) to propose that semantic and episodic memory are distinct systems. At first sight, the evidence appeared persuasive. Densely amnesiac patients may perform normally on semantic memory tests while showing no evidence of new episodic learning (Wilson and Baddeley 1988). However, semantic memory tests typically involve accessing old memories, whereas episodic tests are principally concerned with the laying down of new memory traces. When amnesiac patients are required to extend their existing semantic memory systems, for example, by learning about the developing political system within their country, or learning new routes within their town, learning appears to be catastrophically bad. An alternative way of conceptualizing semantic memory is to suggest that it represents the residue of many episodic memories, with access being based on generic commonalities, rather than the retrieval of a specific episode. The nature of semantic memory and its neuroanatomical basis continues to be a very active research area, with neuropsychological evidence again being particularly cogent (see Patterson and Hodges 1996).

No survey of memory would be complete without comment on one aspect of memory that has been both active and controversial in recent years, namely, the attempt to apply the lessons learned in the laboratory to everyday functioning. Although the link between the laboratory and the field has occasionally appeared to be excessively confrontational (e.g., see Neisser 1978; Banaji and Crowder 1989), the interaction has on the whole been a fruitful one. This is particularly true of clinical applications of the psychology of

memory, where, as we have seen, the study of memory deficits in patients has been enormously influential in changing our views of the normal functioning of human memory.

Memory, Animal Studies

Information about which structures and connections in the brain are important for MEMORY has come from studies of amnesiac patients and from systematic experimental work with animals. Work in animals includes studies which assess the effects of selective brain lesions on memory, as well as studies using neurophysiological recording and stimulating techniques to investigate neural activity within particular brain regions (for discussions of the latter two approaches, see OBJECT RECOGNITION, ANIMAL STUDIES; FACE RECOGNITION; SINGLE-NEURON RECORDING). An important development that has occurred in the area of memory during the past two decades was the establishment of an animal model of human amnesia in the monkey (Mahut and Moss 1984; Mishkin 1982; Squire and Zola-Morgan 1983). In the 1950s, Scoville and Milner (1957) described the severe amnesia that followed bilateral surgical removal of the medial temporal lobe (patient H.M.). This important case demonstrated that memory is a distinct cerebral function, dissociable from other perceptual and cognitive abilities.

In monkeys, surgical lesions of the medial temporal lobe, which were intended to approximate the damage sustained by patient H.M., reproduced many features of human memory impairment. In particular, both monkeys and humans were impaired on tasks of declarative memory, but fully intact at skills and habit learning and other tasks of nondeclarative memory. This achievement set the stage for additional work in monkeys and for work in rodents that has identified structures in the medial temporal lobe that are important for declarative memory. These structures include

the hippocampal region (i.e., the cell fields of the HIPPO-CAMPUS, the dentate gyrus, and the subiculum), and adjacent cortical areas that are anatomically related to the hippocampal region, namely, the entorhinal, perirhinal, and parahippocampal cortices (Zola-Morgan and Squire 1993).

The midline diencephalon is another brain area important for memory, although less is known about which specific structures in this region contribute to memory function. Findings from work in animals, including the development of an animal model of alcoholic Korsakoff's syndrome in the rat (Mair et al., 1992), have been consistent with the anatomical findings from human amnesia in showing the importance of damage within the medial THALAMUS, especially damage in the internal medullary lamina, for producing memory loss. Lesions in the internal medullary lamina would be expected to disconnect or damage several thalamic nuclei, including intralaminar nuclei, the mediodorsal nucleus, and the anterior nucleus (Aggleton and Mishkin 1983; Mair et al. 1991; Zola-Morgan and Squire 1985). However, the separate contributions to memory of the mediodorsal nucleus, the anterior nucleus, and the intralaminar nuclei remain to be explored systematically with well-circumscribed lesions in animals.

A major criterion for demonstrating that an animal has a memory deficit is to show that performance is impaired at long-delay intervals, but is intact at short-delay intervals, that is, no impairment in perception, attention, or general intellectual function. A successful strategy for demonstrating intact short-term memory and impaired long-term memory has involved training normal monkeys and monkeys with medial temporal lobe lesions on the delayed nonmatching-to-sample task, a recognition memory task sensitive to amnesia in humans. In this task, the monkey first sees an object, and then after a prescribed delay the animal is given a choice between the previously seen object and a novel one. The key feature of this experimental approach is the use of very short delay intervals (e.g., 0.5 sec). The absence of an impairment at a delay of 0.5 sec would indicate that the medial temporal lobe lesions do not affect short-term memory. Using this strategy, Alvarez-Royo, Zola-Morgan, and Squire (1992) and Overman, Ormsby, and Mishkin (1990) showed that medial temporal lobe lesions impair memory at long delays, but not at very short delays. Studies in rats using delayed nonmatching-to-sample as well as a variety of other memory tasks have also demonstrated that long-term memory is impaired while short-term memory is spared following lesions that involve the hippocampal region (Kesner and Novak 1982; for recent reviews of work in rats, see Further Readings). These findings underscore the idea that medial temporal lobe lesions reproduce a key feature of human amnesia, that is, the distinction between intact short-term memory and impaired long-term memory.

It was originally supposed that damage to the AMYGDALA directly contributed to the memory impairment associated with large medial temporal lobe lesions (Murray and Mishkin 1984). Subsequent work showed that monkeys with virtually complete lesions of the amygdala performed as well as normal monkeys on four different memory tasks, including delayed nonmatching-to-sample task (Zola-Morgan et al. 1989). Other experiments with rats and mon-

keys suggest that the amygdala is important for other kinds of memory, including the development of conditioned fear and other forms of affective memory (see EMOTION AND THE ANIMAL BRAIN). These and other findings (Murray 1992) focused attention away from the amygdala toward the cortical structures of the medial temporal lobe, that is, the perirhinal, entorhinal, and parahippocampal cortices, in addition to the hippocampal region itself.

Direct evidence for the importance of the cortical regions has come from studies in which circumscribed damage has been done to the perirhinal, entorhinal, or parahippocampal cortices, either separately or in combination (Moss, Mahut, and Zola-Morgan 1981; Zola-Morgan et al. 1989; Gaffan and Murray 1992; Meunier et al. 1993; Suzuki et al. 1993; Leonard et al. 1995). For example, monkeys with combined lesions of the perirhinal and parahippocampal cortices exhibited severe, multimodal, and long-lasting memory impairment (Zola-Morgan et al. 1989; Suzuki et al. 1993). More limited lesions of the cortical regions also produce memory impairment. For example, several studies found that monkeys with bilateral lesions limited to the perirhinal cortex exhibit long-lasting memory impairment (Meunier et al. 1993; Ramus, Zola-Morgan, and Squire 1994). Additionally, a large number of individual studies in monkeys and in rats with varying extents of damage to the medial temporal lobe, together with work in humans, has led to the idea that the severity of memory impairment increases as more components of the medial temporal lobe memory system are damaged.

A long-standing and controversial issue in work on memory has been whether the hippocampal region is disproportionately involved in spatial memory, or whether spatial memory is simply a good example of a broader category of memory that requires the hippocampal region. One view of the matter comes from earlier work with monkeys (Parkinson, Murray, and Mishkin 1988). Monkeys with lesions that involved the hippocampal formation (hippocampus plus underlying posterior entorhinal cortex and parahippocampal cortex) were severely impaired in acquiring an object-place association task, whereas lesions that involved the amygdala plus underlying anterior entorhinal cortex and perirhinal cortex were only mildly impaired. The authors suggested that the hippocampus has an especially important role in spatial memory, an idea developed originally by O'Keefe and Nadel (1978), based mostly on rat work. It was unclear from this monkey study, however, whether the observed spatial deficit was due to hippocampal damage, the adjacent cortical damage, or both. Additional work from both humans and animals suggests another view. In one formal study (Cave and Squire 1991), spatial memory was found to be proportionately impaired in amnesiac patients relative to object recognition memory and object recall memory. The same (nonspatial) view of hippocampal function has also been proposed for the rat, based, for example, on demonstrated deficits in odor memory tasks after ibotenate hippocampal lesions (Bunsey and Eichenbaum 1996). The role of the hippocampus in spatial memory remains unclear. Recent commentaries on the issue of the hippocampus and spatial memory can be found under Further Reading.

Uncertainty about the function of the hippocampus has been due, in part, to the inability until recently to make circumscribed lesions limited to the hippocampal region in experimental animals. Studies in which selective lesions of the hippocampal region could be accomplished became possible only with the development of (a) a technique for producing restricted ibotenate lesions of the hippocampus in the rat and (b) a technique that uses MAGNETIC RESONANCE IMAGING to guide the placement of radiofrequency or ibotenic acid stereotaxic lesions of the hippocampal region in the monkey. Monkeys with bilateral, radiofrequency lesions of the hippocampal region, which spared almost entirely the perirhinal, entorhinal, and parahippocampal cortices, exhibited impaired performance at long delays (ten minutes and forty minutes) on the delayed nonmatching-to-sample task (Alvarez, Zola-Morgan, and Squire 1995).

Ibotenic acid lesions cause cell death but, unlike radiofrequency lesions, spare afferent and efferent white matter fibers within the region of the lesion. If it should turn out, after systematic study, that ibotenic acid lesions of the hippocampal region do not impair performance on the delayed nonmatching task, the interpretation of such studies should not be overstated. The results concern recognition memory, not memory in general, and only the kind of recognition memory measured by the nonmatching-to-sample task itself. The delayed nonmatching task has been extraordinarily useful for evaluating the effects on visual recognition memory of damage to the medial temporal lobe memory system and for measuring the severity of recognition memory impairment. However, in the case of human memory, recognition memory tests are known to be rather easy and not as sensitive to memory impairment as other tests, for instance, tests of recall or cued recall. The issue of task sensitivity is crucially important. Other kinds of recognition memory tasks, for example, the paired comparisons task (a task of spontaneous novelty preference; Bachevalier, Brickson, and Hagger 1993) and tasks that are thought to be more sensitive than tasks of simple recognition memory, for example the transverse patterning, the transitive inference, and naturalistic association tasks, have recently been developed to assess memory in animals.

An important question with respect to the components of the medial temporal lobe memory system is whether these structures all share similar functions as part of a common memory system, or do they have distinct and dissociable functions? In this regard, one must consider the neuroanatomy of the medial temporal lobe system and its pattern of connectivity with association cortex. An extensive anatomical investigation by Suzuki and Amaral (1994) showed that different areas of neocortex gain access to the medial temporal lobe memory system at different points. Visual information arrives preferentially to perirhinal cortex. Approximately 65 percent of the input reaching the perirhinal cortex is unimodal visual information, mostly from TE and TEO. By contrast, about 40 percent of the input reaching parahippocampal cortex is visual, mostly from area V4. Cortical areas that are believed to be important for processing spatial information project preferentially to parahippocampal cortex. Approximately 8 percent of the input to parahippocampal cortex originates in the parietal cortex, whereas virtually none of the input to perirhinal cortex originates in the parietal cortex. These anatomical considerations lead to the expectation that perirhinal cortical lesions might impair visual memory more than spatial memory and that the reverse might be true for parahippocampal cortex. Furthermore, because both the perirhinal and the parahippocampal cortices project to the hippocampus, one might expect that hippocampal damage will similarly impair visual memory and spatial memory. The establishment of new, more sensitive behavioral tests and the development of new techniques for producing selective brain lesions have now made it possible to address these possibilities and to systematically clarify the separate contributions to memory of structures in the medial temporal lobe and the diencephalon.

Memory, Human Neuropsychology

LEARNING is the process by which new knowledge is acquired about the world. MEMORY is the process by which what is learned can be retained in storage with the possibility of drawing on it later. Most of what humans know about the world is not built into the brain at the time of birth but is acquired through experience. It is learned, stored in the brain as memory, and is available later to be retrieved.

Memory is localized in the brain as physical changes produced by experience. Memory is thought to be stored as changes in synaptic connectivity within large ensembles of neurons. New synaptic connections may be formed, and there are changes as well in the strength of existing synapses. What makes a memory is not the manufacture of some chemical code, but rather increases and decreases in the strength of already existing neural connections and formation of new connections. What makes the memory specific (memory of a trip to England instead of memory of a drive to the hardware store) is not the kind of cellular and molecular event that occurs in the brain, but where in the nervous system the changes occur and along which pathways.

The brain is highly specialized and differentiated, organized so that different regions of neocortex simultaneously carry out computations on separate features of the external world (e.g., the analysis of form, color, and movement). Memory of a specific event, or even memory of something so apparently simple as a single object, is thought to be stored in a distributed fashion, essentially in component parts. These components are stored in the same neural systems in neocortex that ordinarily participate in the processing and analysis of what is to be remembered. In one sense, memory is the persistence of perception. It is stored as outcomes of perceptual operations and in the same cortical regions that are ordinarily involved in the processing of the items and events that are to be remembered.

It has long been appreciated that severe memory impairment can occur against a background of otherwise normal intellectual function. This dissociation shows that the brain has to some extent separated its intellectual and perceptual functions from its capacity for laying down in memory the records that ordinarily result from intellectual and perceptual work. Specifically, the medial temporal lobe and the midline diencephalon of the brain have specific memory functions, and bilateral damage to these regions causes an amnesic syndrome. The amnesic syndrome is characterized by profound forgetfulness for new material (anterograde amnesia), regardless of the sensory modality through which the material is presented and regardless of the kind of material that is presented (faces, names, stories, musical passages, or shapes). Immediate memory, as measured by digit span, is intact. However, a memory deficit is easily detected with conventional memory tests that ask subjects to learn and remember an amount of information that exceeds what can be held in immediate memory or with memory tests that ask subjects to learn even a small amount of information and then hold onto it for several minutes in the face of distraction. The impairment appears whether memory is tested by unaided (free) recall, by recognition, or by cued recall. As assessed by these various instruments, the deficit in amnesic patients is proportional to the sensitivity with which these tests measure memory in intact subjects. Recognition is easier than recall for all subjects, amnesic patients and normal subjects alike.

The same brain lesions that cause difficulties in new learning also cause retrograde amnesia, difficulty in recollecting events that occurred prior to the onset of amnesia. Typically, retrograde amnesia is temporally graded such that very old (remote) memory is affected less than recent memory. Retrograde amnesia can cover as much as a decade or two prior to the onset of amnesia. These observations show that the structures damaged in amnesia are not the repositories of long-term memory. Rather, these structures are essential, beginning at the time of learning, and they are thought to drive a gradual process of memory consolidation in neocortex. As the result of this process, memory storage in neocortex comes to be independent of the medial temporal lobe and diencephalic structures that are damaged in amnesia.

Information about what specific structures are important for human memory comes from carefully studied cases of amnesia, which provide both neuropsychological and neurohistological information, and from the study of an animal model of human amnesia in the monkey. The available human cases make several points. First, damage limited bilaterally to the CA1 region of the HIPPOCAMPUS is sufficient to cause a moderately severe anterograde amnesia. Second, when more damage occurs in the hippocampal formation, (e.g., damage to the CA fields, dentate gyrus, subicular complex, and some cell loss in entorhinal cortex), the anterograde amnesia becomes more severe. Third, damage limited bilaterally to the hippocampal formation is sufficient to produce temporally limited retrograde amnesia covering more than 10 years.

Systematic and cumulative work in monkeys has further demonstrated that the full medial temporal lobe memory system consists of the hippocampus and adjacent, anatomically related structures: entorhinal cortex, perirhinal cortex, and parahippocampal cortex. The critical regions of the medial diencephalon important for memory appear to be the mediodorsal thalamic nucleus, the anterior nucleus, the mammillary nuclei, and the structures within and interconnected by the internal medullary lamina.

One fundamental distinction in the neuropsychology of memory separates immediate memory from long-term memory. Indeed, this is the distinction that is revealed by the facts of human amnesia. In addition, a number of distinctions can be made within long-term memory. Memory is not a unitary mental faculty but depends on the operation of several separate systems that operate in parallel to record the effects of experience. The major distinction is between the capacity for conscious recollection about facts and events (so-called declarative or explicit memory) and a collection of nonconscious memory abilities (so-called nondeclarative or implicit memory), whereby memory is expressed through performance without any necessary conscious memory content or even the experience that memory is being used.

Declarative memory is the kind of memory that is impaired in amnesia. Declarative memory is a brain-systems construct. It is the kind of memory that depends on the integrity of the medial temporal lobe–diencephalic brain structures damaged in amnesia. Declarative memory is involved in modeling the external world, in storing representations of objects, episodes, and facts. It is fast, specialized for one-trial learning, and for making arbitrary associations or conjunctions between stimuli. The acquired representations are flexible and available to multiple response systems. Nondeclarative memory is not itself a brain-systems construct, but rather an umbrella term for several kinds of memory, each of which has its own brain organization. Nondeclarative memory underlies changes in skilled behavior, the development through repetition of appropriate ways to respond to stimuli, and it underlies the phenomenon of priming—a temporary change in the ability to identify or detect perceptual objects. In these cases, performance changes as the result of experience and therefore deserves the name memory, but like drug tolerance or immunological memory, performance changes without providing a record of the particular episodes that led to the change in performance. What

is learned tends to be encapsulated and inflexible, available most readily to the same response systems that were involved in the original learning.

Among the prominent kinds of nondeclarative memory are procedural memory (memory for skills and habits), simple classical CONDITIONING, and the phenomenon of priming. Skill and habit memory depends importantly on the dorsal striatum, even when motor activity is not an important part of the task. Thus, nondemented patients with Parkinson's disease, who have dorsal striatal damage, are impaired at learning a two-choice discrimination task where the correct answer on each trial is determined probabilistically. In this task, normal subjects learn gradually, not by memorizing the cues and their outcomes, but by gradually developing a disposition to respond differentially to the cues that are presented. Classical conditioning of skeletal musculature (e.g., eyeblink conditioning) depends on cerebellar and brain stem pathways. Emotional learning, including fear conditioning, depends on the amygdaloid complex. In the case of fear conditioning, subjects will often remember the unpleasant, aversive event. This component of memory is declarative and depends on the medial temporal lobe and diencephalon. But subjects may also develop a negative feeling about the stimulus object, perhaps even a phobia, and this component of remembering depends on the amygdala. The AMYGDALA also appears to be an important modulator of both declarative and nondeclarative forms of memory. For example, activity originating in the amygdala appears to underlie the observation that emotional events are typically remembered better than neutral events. Finally, the phenomenon of priming appears to depend on the neocortical pathways that are involved in processing the material that is primed. Neuroimaging studies have described reductions in activity in posterior neocortex in correspondence with perceptual priming.

Information is still accumulating about how memory is organized, what structures and connections are involved, and what jobs they do. The disciplines of both psychology and neuroscience contribute to this enterprise.

Memory Storage, Modulation of

The formation of lasting, long-term memory occurs gradually, over time, following learning. A century ago Mueller and Pilzecker (1900) proposed that the neural processes underlying new memories persist in a short-lasting modifiable state and then, with time, become consolidated into a relatively long-lasting state. Later, HEBB (1949) proposed that the first stage of the "dual-trace" memory system is based on reverberating neural circuits and that such neural activity induces lasting changes in synaptic connections that provide the basis for long-term memory.

Clinical and experimental evidence strongly supports the hypothesis that memory storage is time-dependent. Disruption of brain activity shortly after learning impairs long-term memory. In humans, acute brain trauma produces retrograde amnesia, a selective loss of memory for recent experiences (Burnham 1903; Russell and Nathan 1946) and in animals retrograde amnesia is induced by many treatments that impair brain functioning, including electrical brain stimulation and drugs (McGaugh and Herz 1972). Additionally, and more importantly, in humans as well as animals (Soetens et al. 1995), stimulant drugs administered shortly after learning enhance memory. Drugs affecting many neurotransmitter and hormonal systems improve long-term memory when they are administered within a few minutes or hours after training (McGaugh 1973, 1983). Extensive evidence indicates that the drugs enhance the consolidation of long-term memory.

Our memories of experiences vary greatly in strength. Some memories fade quickly and completely, whereas others last a lifetime. Generally, remembrance of experiences varies with their significance; emotionally arousing events are better remembered (Christianson 1992). William JAMES observed that, "An experience may be so exciting emotionally as almost to leave a scar on the cerebral tissue" (James 1890). Studies of retrograde amnesia and memory enhancement provide important clues to the physiological systems underlying variations in memory strength. In particular, the finding that drugs enhance memory consolidation suggests that hormonal systems activated by emotional arousal may influence consolidation (Cahill and McGaugh 1996).

Emotionally exciting experiences induce the release of adrenal hormones, including the adrenal medullary hormone epinephrine (Adrenaline) and the adrenal cortex hormone corticosterone (in humans, cortisol). Experiments with animal and human subjects indicate that these hormones, as well as other hormones released by learning experiences, play an important role in regulating memory storage (Izquierdo and Diaz 1983; McGaugh and Gold 1989). Administration of epinephrine to rats or mice shortly after training enhances their long-term memory of the training (Gold, McCarty, and Sternberg 1982). β-adrenergic antagonists such as propranolol block the memory enhancement induced by epinephrine. Comparable findings have been obtained in studies with human subjects. The finding that β-adrenergic antagonists block the enhancing effects of emotional arousal on long-term memory formation in humans supports the hypothesis that β-adrenergic agonists,

including epinephrine, modulate memory storage (Cahill et al. 1994). Additionally, studies of the effects of corticosterone, as well as synthetic glucocorticoid receptor agonists and antagonists, indicate that memory storage is enhanced by glucocorticoid agonists and impaired by antagonists. Furthermore, hormones of the adrenal medulla and adrenal cortex interact in modulating memory storage: metyrapone, a drug that impairs the synthesis and release of corticosterone, blocks the effects of epinephrine on memory consolidation (Sandi and Rose 1994; De Kloet 1991; Roozendaal, Cahill, and McGaugh 1996).

Recent research has revealed brain regions mediating drug and hormone influences on memory storage. Considerable evidence indicates that many drugs and hormones modulate memory through influences involving the amygdaloid complex. It is well established that electrical stimulation of the AMYGDALA modulates memory storage and that the effect is influenced by adrenal hormones (Liang, Bennett, and McGaugh 1985). Lesions of the stria terminalis (a major amygdala pathway that connects the amygdala with many brain regions) block the memory-modulating effects of many drugs and hormones, including those of adrenal hormones. Furthermore, lesions of the amygdala and, more specifically, lesions of the basolateral amygdala nucleus, also block the effects of adrenal hormones on memory storage (McGaugh, Cahill, and Roozendaal 1996).

In humans, amygdala lesions block the effects of emotional arousal on long-term memory (Cahill et al. 1995). In animals, infusions of β-adrenergic and glucocorticoid antagonists into the amygdala impair memory, whereas infusions of β-adrenergic agonists (e.g., norepinephrine) and glucocorticoid receptor agonists into the amygdala after training enhance memory. As was found with lesions, the critical site for infusions is the basolateral amygdala nucleus (Gallagher et al. 1981; Liang, Juler, and McGaugh 1986; McGaugh et al. 1996). Findings such as these indicate that the basolateral amygdala nucleus is an important and perhaps critical brain region mediating arousal-induced neuromodulatory influences on memory storage.

Thus, there is extensive evidence from human and animal studies that the amygdala is critically involved in modulating memory consolidation. However, it is also clear from the findings of many studies that the amygdala is not the neural locus of long-term memory. Lesions of the amygdala induced after training do not block retention of the memory of the training (Parent, West, and McGaugh 1994). Additionally, the amygdala is not the locus of neural changes underlying the enhanced memory induced by infusing drugs into the amygdala immediately after training. Drug infusions administered into the amygdala post training enhance long-term memory for training in many types of tasks, including tasks known to involve the HIPPOCAMPUS or caudate nucleus. Furthermore, inactivation of the amygdala with lidocaine infusions prior to retention testing does not block the enhanced memory (Packard, Cahill, and McGaugh 1994).

Research with humans has provided additional evidence that amygdala activation is involved in modulating the consolidation of long-term memory. In subjects tested several weeks after viewing emotionally arousing film clips, memory of the content of the film clips correlated very highly with activation of the amygdala when viewing the film clips, as indicated by POSITRON EMISSION TOMOGRAPHY (PET) brain scans (Cahill et al. 1996).

The formation of new long-term memory must, of course, involve the formation of lasting neural changes. Additionally, the strength of the induced neural changes, as subsequently reflected in long-term memory, is modulated by the actions of specific hormonal and brain systems activated by learning experiences. Such modulation serves to ensure that the significance of experiences will influence their remembrance. Investigations of the processes and systems underlying the modulation of memory storage are providing new insights into how memories are created and sustained.

Mental Causation

The problem of mental causation is the most recent incarnation of the venerable MIND-BODY PROBLEM, Schopenhauer's "world knot". DESCARTES held that mind and body were distinct kinds of entity that interact causally, but waffled over the question how this was possible. Mind-body dualism of the Cartesian sort is no longer popular, but variants of the Cartesian problem remain, and waffling is still in fashion. Current worries about mental causation stem from two sources: (1) "nonreductive" conceptions of the mental; and (2) externalism (or anti-INDIVIDUALISM) about mental "content."

Although most theorists have left dualism behind, many remain wedded to the Cartesian idea that the mental and the physical are fundamentally distinct. Mental properties, though properties of physical systems, are "higher-level" properties not reducible to or identifiable with "lower-level" properties of those systems. Most functionalist accounts of the mind embrace this picture, endorsing the slogan that mental properties are "multiply realizable." Take the property of being in pain. This property, like the property of being an eye, is said to be a functional, "second-order" property, one that a creature possesses by virtue of possessing some first-order "realizer"—a particular physical configuration or process, for instance. Pains are capable of endless "realizations" in the human nervous system, in the very different nervous system of a cephalopod, and perhaps

in silicon-based systems of Alpha Centaurians—or appropriately programmed computing machines. There is, then, no prospect of locating a unique physical property to identify with pain.

When, however, we try to reconcile "multiple realizability" with the idea that the physical realm is causally self-contained, trouble arises. Consider your body, a complex physical system composed of microparticles interacting in accord with fundamental physical laws. The behavior of those particles, hence the behavior of your body, is completely determined (albeit probabilistically) by those laws. Now suppose you step on a tack, experience a pain, and quickly withdraw your foot. Common sense tells us that your pain played a causal role in your foot's moving. But can this be right? Your experiencing a pain is a matter of your possessing a "higher-level" property, a property thought to be distinct from any of the properties possessed by your "lower-level" physical constituents. It appears, however, that your behavior is entirely determined by "lower-level" nonmental goings-on. In what sense, then, is your experience of pain "causally relevant" to the movement of your foot?

Some philosophers have responded to this difficulty by adopting a deflationary view of CAUSATION. As they see it, causation is just counterfactual dependence: roughly, if E would not have occurred unless C had, then C causes E (LePore and Loewer 1987). Others, appealing to scientific practice, have suggested that we replace metaphysically loaded references to causes with talk of causal explanation (Wilson 1995). Still others argue that the causal relevance of "higher-level" properties requires reduction: "Higher-level" mental properties must be identified with "lower-level" properties (Kim 1989). This strategy resolves one problem of mental causation, but at a cost few philosophers seem willing to pay.

Lack of enthusiasm for reduction is due in part to the widespread belief that mental properties are "multiply realizable," hence distinct from their physical realizers, and in part to a no less widespread commitment to externalism. Externalists hold that the "contents" of states of mind depend on agents' contexts. Wayne, for example, believes that water is wet. Wayne's belief concerns water, and the "content" of his belief is that water is wet. Imagine an exact duplicate of Wayne, Dwayne, who inhabits a distant planet, TWIN EARTH, an exact duplicate of Earth with one important difference: the colorless, tasteless, transparent liquid that fills rivers and bathtubs on Twin Earth differs in its molecular constitution from water. Water is H_2O. The substance on Twin Earth that Dwayne and his fellows call "water" is XYZ. Now, so the story goes, although Wayne and Dwayne are alike intrinsically, their thoughts differ. Wayne believes that water is wet; whereas Dwayne's beliefs concern, not water, but what we might call "twin water" (see Putnam 1975).

Thought experiments of this sort have convinced many philosophers that the contents of thoughts depend, at least in part, on thinkers' surroundings and causal histories (see Burge 1986; Davidson 1987; Baker 1987). A contextualism of this sort introduces a new twist on the problem of mental causation, and simultaneously renders REDUCTIONISM even

less attractive. Surely the contents of your thoughts are relevant to what those thoughts lead you to do. You flee because you believe the creature on the path in front of you is a skunk. Had you believed instead that the creature was a cat, you would have behaved differently. If the content of your belief—its being a belief about a skunk—depends on your causal history, however, how could it make a here-and-now physical difference to the way you move your body?

A molecule, a billiard ball, a planet, or a brain behaves as it does and reacts to incoming stimuli because of its intrinsic physical makeup. But if everything you do is a function of your intrinsic physical properties, and if the contents of your thoughts depend on relations you bear to other things, then it is hard to see how the contents of your thoughts could make any difference at all to what you do.

Again, some philosophers have sought to accommodate externalism and mental causation via deflationary accounts of causation or appeals to explanatory norms. Others have defended a notion of "narrow content," mental content that depends only on agents' intrinsic composition (Fodor 1987). Wayne and Dwayne, for instance, are said to entertain thoughts that have the same "narrow content" but differ in their "broad content." Externalists have been unenthusiastic about "narrow content." And, in any case, even if we embrace "narrow content," so long as we assume that mental properties are irreducible "higher-level" properties of physical systems, we are left with our initial worry about the causal irrelevance of "higher-level" properties.

Externalism aside, perhaps we could make progress by distinguishing predicates and properties. Predicates apply to objects by virtue of properties those objects possess, but not every predicate designates a property. The predicate "is a tree" applies to objects by virtue of their properties, but there is no property of being a tree common to all trees. Perhaps mental predicates are like this. The predicate "pain," for instance, might apply to many different kinds of object, not because these objects share some single property, but because they are similar in important ways: they possess distinct, though similar, first-order physical properties (which have uncontroversial causal roles). A view of this sort allows that "pain" applies truly to creatures in distress, although it obliges us to abandon the philosopher's conceit that the predicate "pain" thereby designates a property shared by every creature to whom "pain" is truly predicable.

Whether these remarks are on the right track, they suggest that the philosophy of mind would benefit from an infusion of good old-fashioned metaphysics. Until we are clear on the nature of properties, for instance, or the character of "multiple realizability," we shall not be in a position to make headway on the problem of mental causation.

Mental Models

As psychological representations of real, hypothetical, or imaginary situations, mental models were first postulated by the Scottish psychologist Kenneth Craik (1943), who wrote that the mind constructs "small-scale models" of reality to anticipate events, to reason, and to underlie EXPLANATION. The models are constructed in working memory as a result of perception, the comprehension of discourse, or imagination (see MARR 1982; Johnson-Laird 1983). A crucial feature is that their structure corresponds to the structure of what they represent. Mental models are accordingly akin to architects' models of buildings and to chemists' models of complex molecules.

The structure of a mental model contrasts with another sort of MENTAL REPRESENTATION. Consider the assertion

The triangle is on the right of the circle.

Its meaning can be encoded in the mind in a *propositional representation,* for example:

(right-of triangle circle)

The structure of this representation is syntactic, depending on the conventions governing the LANGUAGE OF THOUGHT: The predicate "right-of" precedes its subject "triangle" and its object "circle." In contrast, the situation described by the assertion can be represented in a mental model:

The structure of this representation is spatial: it is isomorphic to the actual spatial relation between the two objects. The model captures what is common to any situation where a triangle is on the right of a circle. Although it represents nothing about their distance apart or other such matters, the shape and size of the tokens can be revised to take into account subsequent information. Mental models appear to underlie visual IMAGERY. Unlike images, however, they can represent three dimensions (see MENTAL ROTATION), negation, and other abstract notions. The construction of models from propositional representations of discourse is part of the

process of comprehension and of establishing that different expressions refer to the same entity. How this process occurs has been investigated in detail (e.g., Garnham and Oakhill 1996).

If mental models are the end result of perception and comprehension, they can underlie reasoning. Individuals use them to formulate conclusions, and test the strength of these conclusions by checking whether other models of the premises refute them (Johnson-Laird and Byrne 1991). This theory is an alternative to the view that DEDUCTIVE REASONING depends on formal rules of inference akin to those of a logical calculus. The distinction between the two theories parallels the one in LOGIC between proof-theoretic methods based on formal rules and model-theoretic methods based, say, on truth tables. Which psychological theory provides a better account of human reasoning is controversial, but mental models have a number of advantages. They provide a unified account of deductive, probabilistic, and modal reasoning. People infer that a conclusion is necessary —it *must* be true—if it holds in all of their models of the premises; that it is probable—it is *likely* to be true—if it holds in most of their models of the premises; and that it is possible—it *may* be true—if it holds in at least one of their models of the premises. Thus an assertion such as

There is a circle or there is a triangle, or both

yields three models, each of which corresponds to a *true* possibility, shown here on separate lines:

<div align="center">

O

Δ

O   Δ

</div>

The modal conclusion

It is possible that there is both a circle and a triangle

follows from the assertion, because it is supported by the third model. Experiments show that the more models needed for an inference, the longer the inference takes and the more likely an error is to occur (Johnson-Laird and Byrne 1991). Models also have the advantage that they can serve as counterexamples to putative conclusions—an advantage over formal rules of inference that researchers in artificial intelligence exploit in LOGICAL REASONING SYSTEMS (e.g., Halpern and Vardi 1991).

Mental models represent explicitly what is true, but not what is false (see the models of the disjunction above). An unexpected consequence of this principle is the existence of "illusory inferences" to which nearly everyone succumbs (Johnson-Laird and Savary 1996). Consider the following problem:

Only one assertion is true about a particular hand of cards:

There is a king in the hand or there is an ace, or both.
There is a queen in the hand or there is an ace, or both.
There is a jack in the hand or there is a ten, or both.

Is it possible that there is an ace in the hand?

Nearly everyone responds "yes" (Johnson-Laird and Goldvarg 1997). Yet the response is a fallacy. If there were an ace in the hand, then two of the assertions would be true, contrary to the rubric that only one of them is true. The illusion arises because individuals' mental models represent what is true for each premise, but not what is false concomitantly for the other two premises. A variety of such illusions occur in all the main domains of reasoning. They can be reduced by making what is false more salient.

The term *mental model* is sometimes used to refer to the representation of a body of knowledge in long-term memory, which may have the same sort of structure as the models used in reasoning. Psychologists have investigated mental models of such physical systems as handheld calculators, the solar system, and the flow of electricity (Gentner and Stevens 1983). They have studied how children develop such models (Halford 1993), how to design artifacts and computer systems for which it is easy to acquire models (Ehrlich 1996), and how models of one domain may serve as an ANALOGY for another domain. Researchers in artificial intelligence have similarly developed qualitative models of physical systems that make possible "commonsense" inferences (e.g., Kuipers 1994). To understand phenomena as a result either of short-term processes such as vision and inference or of long-term experience appears to depend on the construction of mental models. The embedding of one model within another may play a critical role in METAREPRESENTATION and CONSCIOUSNESS.

Mental Representation

To understand the nature of mental representation posited by cognitive scientists to account for various aspects of human and animal cognition (see Von Eckardt 1993 for a more detailed account), it is useful to first consider representation in general. Following Peirce (Hartshorne, Weiss, and Burks 1931–1958), we can say that any representation has four essential aspects: (1) it is realized by a representation bearer; (2) it has content or represents one or more objects; (3) its representation relations are somehow "grounded"; and (4) it can be interpreted by (will function as a representation for) some interpreter.

If we take one of the foundational assumptions of cognitive science to be that the mind/brain is a computational device (see COMPUTATIONAL THEORY OF MIND), the mental representation bearers will be computational structures or states. The specific nature of these structures or states depends on what kind of computer the mind/brain is hypothesized to be. To date, cognitive science research has focused on two kinds: conventional (von Neumann, symbolic, or rule-based) computers and connectionist (parallel distributed processing) computers (see COGNITIVE MODELING, SYMBOLIC and COGNITIVE MODELING, CONNECTIONIST). If the mind/brain is a conventional computer, then the mental representation bearers will be data structures. Kosslyn's (1980) work on mental IMAGERY provides a nice illustration. If the mind/brain is a connectionist computer, then the representation bearers of occurrent mental states will be activation states of connectionist nodes or sets of nodes. In the first case, representation is considered to be "local"; in the second, "distributed" (see DISTRIBUTED VS. LOCAL REPRESENTATION and McClelland, Rumelhart, and Hinton 1986). There may also be implicit representation (storage of information) in the connections themselves, a form of representation appropriate for dispositional mental states.

While individual claims about what our representations are about are frequently made in the cognitive science literature, we do not know enough to theorize about the semantics of our mental representation system in the sense that linguistics provides us with the formal SEMANTICS of natural language (see also POSSIBLE WORLDS SEMANTICS and DYNAMIC SEMANTICS). However, if we reflect on what our mental representations are hypothesized to explain—namely, certain features of our cognitive capacities—we can plausibly infer that the semantics of our mental representation system must have certain characteristics. Pretheoretically, human cognitive capacities have the following three properties: (1) each capacity is intentional, that is, it involves states that have content or are "about" something; (2) virtually all of the capacities can be pragmatically evaluated, that is, they can be exercised with varying degrees of success; and (3) most of the capacities are productive, that is, once a person has the capacity in question, he or she is typically in a position to manifest it in a practically unlimited number of novel ways. To account for these features, we must posit mental representations that can represent specific objects; that can represent many different kinds of objects—concrete objects, sets, properties, events, and states of affairs in this world, in possible worlds, and in fictional worlds as well as abstract objects such as universals and numbers; that can represent both an object (in and of itself) and an aspect of that object (or both extension and intension); and that can represent both correctly and incorrectly. In addition, if we take the productivity of our cognitive capacities seriously, we must posit representations with constituent structure and a compositional semantics. (Fodor and Pylyshyn 1988 use this fact to argue that our mental representation system cannot be connectionist; see CONNECTIONISM, PHILOSOPHICAL ISSUES.)

Cognitive scientists are interested not only in the content of mental representations, but also in where this content comes from, that is, in what makes a mental representation of a tree have the content of being about a tree. Theories of what determines content are often referred to as this-or-that kind of "semantics." Note, however, that it is important to

distinguish such "theories of content determination" (Von Eckardt 1993) from the kind of semantics that systematically describes the content being determined (i.e., the kind referred to in the previous paragraph).

There are currently five principal accounts of how mental representational content is grounded. Two are discussed elsewhere (see FUNCTIONAL ROLE SEMANTICS and INFORMATIONAL SEMANTICS). The remaining three are characterized below.

1. *Structural isomorphism.* A representation is understood to be "some sort of model of the thing (or things) it represents" (Palmer 1978). The representation (or more precisely, the representation bearer) represents aspects of the represented object by means of aspects of itself. Palmer (1978) treats both the representation bearer and the represented object as relational systems, that is, as sets of constituent objects and sets of relations defined over these objects. A representation bearer then represents a represented object under some aspect if there exists a set G of relations constituting the representation bearer and a set D of relations constituting the object such that G is isomorphic to D.

2. *Causal historical.* (Devitt 1981; Sterelny 1990) Intended to apply only to the mental analogues of designational expressions, this account holds that a token designational "expression" in the LANGUAGE OF THOUGHT designates an object if there is a certain sort of causal chain connecting the representation bearer with the object. Such causal chains include perceiving the object, designating the object in natural language, and borrowing a designating expression from another person (see REFERENCE, THEORIES OF).

3. *Biological function.* In this account (Millikan 1984), mental representations, like animal communication signals, are "intentional icons," a form of representation that is "articulate" (has constituent structure and a compositional semantics) and mediates between producer mechanisms and interpreter mechanisms. The content of any given representation bearer will be determined by two things—the systematic natural associations that exist between the family of intentional icons to which the representation bearer belongs and some set of representational objects, and the biological functions of the interpreter device. More specifically, a representation bearer will represent an object if the existence of a mapping from the representation bearer family to the object family is a condition of the interpreter device successfully performing its biological functions. Take the association between bee dances and the location of nectar relative to the hive. The interpreter device for bee dances consists of the gatherer bees, among whose biological functions are those adapted to specific bee dances, for example, finding nectar 120 feet to the north of the hive in response to, say, bee dance 23. The interpreter function can successfully perform its function, however, only if bee dance 23 is in fact associated with the nectar's being at that location.

It can be argued that for a mental entity or state to be a representation, it must not only have content, it must also be significant for the subject who has it. According to Peirce, a representation having such significance can produce an "interpretant" state or process in the subject, and this state or process is related to both the representation and the subject in such a way that, by means of the interpretant, what the representation represents can make a difference to the internal states and behavior of the subject. This aspect of mental representation has received little explicit attention; indeed, its importance and even its existence have been disputed by some. Nevertheless, many cognitive scientists hold that the interpretant of a mental representation, for a given subject, consists of all the possible (token) computational consequences, including both the processes and the results of these processes, contingent on the subject's actively "entertaining" that representation.

Cognitive scientists engaged in the process of modeling or devising empirical theories of specific cognitive capacities (or specific features of those capacities) often posit particular kinds of mental representations. For pedagogical purposes, Thagard (1995) categorizes representations into six main kinds, each of which is typically associated with certain types of computational processes: sentences or well-formed formulas of a logical system (see LOGICAL REASONING SYSTEMS); rules (see PRODUCTION SYSTEMS and NEWELL); representations of concepts such as frames; SCHEMATA; scripts (see CATEGORIZATION), analogies (see ANALOGY), images; and connectionist representations. Another popular distinction is between symbolic representation (found in "conventional" computational devices) and subsymbolic representation (found in connectionist devices). There is unfortunately no conceptually tidy taxonomy of representational kinds. Sometimes such kinds are distinguished by their computational or formal characteristics—for example, local versus distributed representation in connectionist systems. Sometimes they are distinguished in terms of what they represent—for example, phonological, lexical, syntactic, and semantic representation in linguistics and psycholinguistics. And sometimes both form and content play a role. Paivio's (1986) dual-coding theory claims that there are two basic modes of representation— imagistic and propositional. According to Eysenck and Keane (1995), imagistic representations are modality-specific, nondiscrete, implicit, and involve loose combination rules, whereas propositional representations are amodal, discrete, explicit, and involve strong combination rules. The first contrast, modality-specific versus amodal, refers to the aspect under which the object is represented, hence to content; the other three contrasts all concern form.

Not all philosophers interested in cognitive science regard the positing of mental representations as being necessary or even unproblematic. Stich (1983) argues that if one compares a "syntactic theory of mind" (STM), which treats mental states as relations to purely syntactic mental sentence tokens and which frames generalizations in purely formal or computational terms, with representational approaches, STM will win. Representational approaches, in his view, necessarily encounter difficulties explaining the cognition of young children, "primitive" folk, and the mentally and neurally impaired. STM does not. Nor is it clear that cognitive science ought to aim at explaining the sorts of intentional phenomena (capacities or behavior) that mental representations are typically posited to explain.

Even more damning critiques of mental representation can be found in Judge (1985) and Horst (1996). Judge accepts the Peircean tripartite conception of representation

according to which a representation involves a representation bearer R, an object represented O, and an interpretant I, but takes the interpretant to require an agent performing an intentional act such as understanding R to represent O, which causes problems for mental representation, in her view. Understanding R to represent O itself necessitates that the agent have nonmediated access to O. But, if we assume that all cognition is mediated by mental representation, this is impossible. (Another problem with this view of the interpretant, not discussed by Judge, is that it leads to an infinite regress of mental representations.)

Horst (1996) also believes that cognitive science's attempt to explain INTENTIONALITY by positing mental representations is fundamentally confused. Mental representations are usually taken to be symbols. But a symbol, in the standard semantic sense, involves conventions, both with respect to its meaning and with respect to its syntactic type. And because conventions themselves involve intentionality, intentionality cannot be explained by positing mental representations. An alternative is to treat "mental symbol" as a technical term. But Horst argues that, viewed in this technical way, the positing of mental representations also fails to be explanatory. Furthermore, even if such an alternative approach were to work, cognitive science would still be saddled with the conventionality of mental syntax.

Mental Retardation

Definitions of mental retardation characteristically include three criteria: (1) significantly subaverage INTELLIGENCE

accompanied by (2) significant limitations in adaptive skills with (3) an onset during the developmental period. Thus, according to the DSM-IV (American Psychiatric Association 1994), individuals are considered to have mental retardation if (1) they have a current IQ, based on an individually administered test, of approximately two or more standard deviations below the mean (e.g., ~70); (2) they have significant limitations (relative to those expected for chronological age and sociocultural background) in two or more of the following domains: communication, social/interpersonal skills, self-care, home living, self-direction, leisure, functional academic skills, use of community resources, work, health, and safety; and (3) these difficulties were first evidenced prior to age 18 years. Each of the other major organizations involved in the treatment of individuals with mental retardation—the American Association on Mental Retardation (AAMR), the American Psychological Association (APA), and the World Health Organization (WHO)—accepts the same three criteria, but implements them in slightly different ways (see Luckasson et al. 1992; American Psychological Association 1996; World Health Organization 1996). The DSM-IV, APA, and WHO ICD-10 definitions further divide mental retardation into four levels: mild (IQ between 50–55 and approximately 70); moderate (IQ between 35–40 and 50–55); severe (IQ between 20–25 and 35–40); and profound (IQ below 20). The AAMR definition also recognizes four levels of mental retardation, based on the intensity of support needed to enhance independence, productivity, and community integration: intermittent, limited, extensive, and pervasive.

Epidemiological research indicates a prevalence of mental retardation at between 0.8 and 1.2 percent. Per 1,000 individuals, approximately 3–6 have mild mental retardation, 2 have moderate mental retardation, 1.3 have severe mental retardation, and 0.4 have profound mental retardation. The cause of mental retardation is known for approximately 33–52 percent of individuals with IQs between 50 and 69: chromosomal: 4–8 percent; prenatal (multifactorial or environmental): 11–23 percent; perinatal or postnatal: 21 percent. For individuals with IQs below 50, the cause of mental retardation is known for 60–75 percent: chromosomal: 20–40 percent; prenatal: 20–30 percent; perinatal or postnatal: less than 20 percent (Pulsifer 1996). The most common known causes of mental retardation are fetal alcohol syndrome, Down's syndrome, and fragile X syndrome. Individuals with mental retardation often have additional disabilities (Batshaw and Shapiro 1997). Seizure disorders and cerebral palsy are present in about 10 percent of individuals with mild mental retardation and more than 20 percent of individuals with severe mental retardation. Individuals with mental retardation are three or four times more likely than the general population to have a psychiatric disorder (Kymissis and Leven 1994), with the likelihood of comorbid psychiatric disorder increasing as a function of severity of mental retardation (mild mental retardation: 25 percent, severe: 50 percent). Sensory impairments are also frequent (mild mental retardation: 24 percent, severe: 55 percent).

Historically, psychologists and educators have focused on level of mental retardation rather than cause (etiology), both for research purposes and for educational intervention (Goodman 1990; Hodapp 1997). Extensive characterizations are provided in the *Manual of Diagnosis and Professional Practice in Mental Retardation* (American Psychological Association 1996). Individuals with mild mental retardation are expected to attain a mental age of between 8 and 12 years. Many individuals acquire fluent language by adolescence; READING and arithmetic skills are usually between the first and sixth grade levels. Independence in both employment and daily living is typically attained. Individuals with moderate mental retardation are expected to attain a mental age of between 6 and 8 years, to acquire functional language abilities, but not functional reading or arithmetic skills, and to require supervision during adulthood. Individuals with severe mental retardation are expected to attain a mental age of between 4 and 6 years, although language abilities will be at a lower level. During adulthood, assistance is required for self-care skills. Individuals with profound mental retardation attain a mental age of between birth and 4 years. Many of these individuals are medically fragile, with a very high early mortality rate. During adulthood, some individuals will be able to walk and to produce single words. Pervasive supervision is required throughout the life span.

More recently, some researchers have begun to emphasize the importance of etiology. There are more than 500 known genetic causes of mental retardation (Flint and Wilkie 1996), in addition to a wide range of teratogenic causes (e.g., prenatal alcohol exposure). Each of these may be expected to affect brain structure and function. The particular areas and functions impacted will vary due to differences in which genes are affected and the roles the particular genes play in development, or which aspects of the brain were developing most rapidly at the time of exposure to a particular teratogen. It is likely that some aspects of cognition will be more severely impacted than others, and that areas of severe impact will vary from syndrome to syndrome. If so, the overall mental age attributed to a given individual (which is used to indicate level of mental retardation) may not accurately reflect his or her abilities in specific domains. For example, consider Williams syndrome, which is caused by a hemizygous microdeletion of chromosome 7q11.23, encompassing at least fifteen genes. Full-scale IQs range from less than 40 to about 90, with a mean of 55–60. Despite the fact that this mean IQ is in the range of mild mental retardation, individuals with Williams syndrome evidence a wide range of ability levels, as a function of domain. Their auditory rote memory ability is typically within the normal range (greater than second percentile), and about half have vocabulary or grammatical abilities, or both, within the normal range. In contrast, levels of visual-spatial constructive ability typically fall within the moderate to severe range of mental retardation (Mervis et al. forthcoming; see also Bellugi, Wang, and Jernigan 1994). In addition, unlike the typical characterization of individuals with mild mental retardation, most individuals with Williams syndrome evidence additional psychopathology: attention deficit hyperactivity disorder, anxiety disorder, or both (e.g., Dykens and Hodapp 1997). Perhaps because of these problems, individuals with Williams syndrome also differ from

the typical characterization of individuals with mild mental retardation, by seldom being able to live independently.

As evidenced by the example of Williams syndrome, summary test scores often do not represent well the level of ability within individual domains. Thus it is crucial to take into account etiology when planning either basic research or intervention. At the same time, it is important to remember that there is within-syndrome variability, both in overall IQ and fit to the behavioral phenotype associated with the syndrome. Explication of both within- and between-syndrome variability depends on coordination of research efforts among researchers studying cognition, personality, brain structure and development, and genetics. Such interdisciplinary efforts should lead to a deeper understanding of basic processes and their relation to intelligence and adaptive functioning, whether the goal is to explain more fully a specific etiology or to elucidate processes relevant to mental retardation as a whole.

Mental Rotation

In Douglas Adams's (1988) novel *Dirk Gently's Holistic Detective Agency,* a sofa gets stuck on a stairway landing. Throughout the remainder of the novel, Dirk Gently ponders how to get it unstuck by imagining the sofa rotating into various positions (he eventually solves the problem using a time machine). The well-known psychologist Roger Shepard once had a somewhat similar experience, awakening one morning to "a spontaneous kinetic image of three-dimensional structures majestically turning in space" (Shepard and Cooper 1982, 7). That experience inspired Shepard and his student Jacqueline Metzler to run what has become a seminal experiment in cognitive science—one that both defines and operationalizes mental rotation.

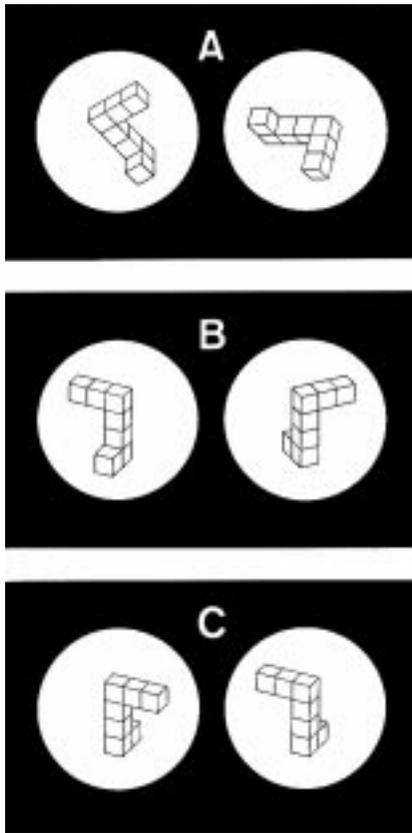
Shepard and Metzler (1971) presented subjects with images of novel three-dimensional (3-D) objects at various orientations—on each trial a pair of images appeared side-by-side and subjects decided whether the two images depicted the same (figures 1a and 1b) or different objects (figure 1c) regardless of any difference in orientation. A given 3-D object had two "handedness" versions: its "standard" version and a mirror-reflected version (equivalent to the relationship between left- and right-handed gloves).


Figure 1. Illustrative pairs of perspective views, including a pair differing by an 80-degree rotation in the picture plane (a), a pair differing by an 80-degree rotation in depth (b), and a pair differing by a reflection as well as a rotation (c).

Different objects were always mirror reflections of one another, so objects could never be discriminated using distinctive local features. Shepard and Metzler measured the time it took subjects to make same/different discriminations as a function of the angular difference between them. What they found was a remarkably consistent pattern across both picture plane and depth rotations—mean response times increased linearly with increasing angular separation. This outcome provides evidence that subjects mentally rotate one or both objects until they are (mentally) aligned with one another. Shepard and Metzler suggest that the mental rotation process is an internal analogue of physical rotation, that is, a continuous shortest path 3-D rotation that would bring the objects into alignment.

A variation on Shepard and Metzler's experiment demonstrated that mental rotation is also used when subjects judge the handedness of familiar objects. Another student of Shepard's, Lynn Cooper, presented subjects with single English letters or digits (Cooper and Shepard 1973). On each trial a standard (e.g., "R") or a mirror-reflected version (e.g., "Я") of a letter or digit was shown at some misorientation in the picture plane. Because subjects had to judge whether the misoriented character was of standard or mirror handedness they could not use local distinguishing features

to make the discrimination. Moreover, because handedness is only defined relative to the viewer, subjects presumably needed to align each test character with their egocentric reference frame in which left and right are defined. The results, quite similar to those obtained with 3-D objects, confirmed this assumption—mean response times for judging handedness increased monotonically as the test characters were misoriented farther and farther from their canonical upright orientations. Response times turned out to be symmetric around 180 degrees—the point at which the characters were exactly upside down. Thus subjects were apparently mentally rotating the characters in the shortest direction to the upright regardless of whether this rotation was clockwise or counterclockwise.

Why are these findings so important? Much of the theorizing about COGNITIVE ARCHITECTURE during the 1960s assumed a symbolic substrate (e.g., PRODUCTION SYSTEMS) in which all mental representations were thought to have a common amodal format. Shepard's results demonstrated that at least some cognitive processes were modal, and, in particular, tied to visual perception. The hypothesis that mental rotation is a continuous process akin to a real-world rotation also has implications for the nature of IMAGERY, namely, that humans have the capacity to make judgments using inherently spatial representations and that such representations are sophisticated enough to support PROBLEM SOLVING, spatial reasoning, and SHAPE PERCEPTION. Not surprisingly, this claim evoked a great deal of skepticism.

In response, Shepard and Cooper went on to meticulously demonstrate that mental rotation indeed involved a continuous mental transformation. Three critical results provide converging evidence for this conclusion. First, Cooper and Shepard (1973) ran a variant of their familiar characters experiment in which they preceded each letter or digit with a cue to the test character's orientation, identity, or both. They found that neither orientation nor identity alone was sufficient to diminish the effect of stimulus orientation on response times. In contrast, providing both, along with sufficient time for the subject to prepare, removed almost all effects of orientation. Thus it appears that mental rotation operates on a representation that depicts a particular shape at a particular position in space—properties associated with an image.

Second, Cooper and Shepard (1973; see also Cooper 1976) ran an experiment in which they controlled an individual subject's putative rate of rotation across a series of trials. Given this information, for a misoriented test letter or digit, they could predict the instantaneous orientation of the rotating mental image of that character. On each trial, a test character was presented, followed at some point by a probe character. The task was to begin rotating the test character, but then to judge the handedness of the probe. Under these conditions, response times were essentially unrelated to the absolute orientation of the probe, but increased monotonically with increasing angular distance from the presumed orientation of the rotating mental image of the test character. For example, when the predicted orientation of the test character image and the visible probe corresponded, response times were independent of the actual orientation of the probe. Thus the changing image actually passes through all

of the intermediate orientations—a property expected for a truly analog transformation mechanism.

Third, Cooper and Shepard ran an experiment in which subjects were given extensive practice judging the handedness of characters mentally rotated in only one direction, for example, 0 degrees to 180 degrees counterclockwise. When these subjects were tested with characters misoriented slightly past 180 degrees, say 190 degrees, the distribution of response times had two peaks—one corresponding to mentally rotating the short way around (clockwise) and one corresponding to mentally rotating the long way around (counterclockwise and consistent with the practice subjects had received). Thus it was the actual angular distance traversed by a rotation that determined the time consumed—again consistent with an analog mechanism.

In summary, there is compelling evidence for the use of a continuous mental rotation process that brings images of two objects into correspondence or the image of a single object into alignment with an internal representation. The existence of such a mechanism suggests that models of cognitive architecture should include modality-specific mechanisms that can support mental imagery. Mental rotation may also play a role in HIGH-LEVEL VISION, for example, in shape perception (Rock and Di Vita 1987), FACE RECOGNITION (Hill, Schyns, and Akamatsu 1997; Troje and Bülthoff 1996), and OBJECT RECOGNITION (Jolicoeur 1985; Tarr 1995; Tarr and Pinker 1989).

Metacognition

Broadly defined, *metacognition* is any knowledge or cognitive process that refers to, monitors, or controls any aspect of cognition. Although its historical roots are deep (e.g., James 1890), the study of metacognition first achieved widespread prominence in the 1970s through the work of Flavell (1979) and others on developmental changes in children's cognition about MEMORY ("metamemory"), understanding ("metacomprehension"), and communication ("metacommunication"). Metacognition is now seen as a central contributor to many aspects of cognition, including memory, ATTENTION, communication, PROBLEM SOLVING, and INTELLIGENCE, with important applications to areas like EDUCATION, aging, neuropsychology, and eyewitness testimony (Flavell, Miller, and Miller 1993; Metcalfe and Shimamura 1994). In this sense at least, metacognition is a domain-general facet of cognition.

Although theorists differ in how to characterize some aspects of metacognition (see Schneider and Pressley 1989), most make a rough distinction between metacognitive knowledge and metacognitive regulation. *Metacognitive knowledge* refers to information that individuals possess about their own cognition or cognition in general. Flavell (1979) further divides metacognitive knowledge into knowledge about persons (e.g., knowing that one has a very good memory), tasks (e.g., knowing that categorizable items are typically easier to recall than noncategorizable items), strategies (e.g., knowledge of mnemonic strategies such as rehearsal or organization), and their interactions (e.g., knowing that organization

is usually superior to rehearsal if the task involves categorizable items). Although even preschool children have some metacognitive knowledge, marked developmental progress occurs in all these areas and, indeed, continues to be made in adolescence and beyond (e.g., Brown et al. 1983; Schneider and Pressley 1989).

Metacognitive regulation includes a variety of executive functions such as planning, resource allocation, monitoring, checking, and error detection and correction (Brown et al. 1983). Nelson and Narens (1990) divide metacognitive regulation into monitoring and control processes, defined in terms of whether information is flowing to or from the "meta-level." In monitoring (e.g., tracking one's comprehension of material while READING), the meta-level receives information from ongoing, "object-level" cognition, whereas in control (e.g., allocating effort and attention to important rather than trivial material), the meta-level modifies cognition. Again, important developmental advances occur in both these metacognitive processes (e.g., Garner 1987).

Although monitoring may occur without explicit awareness, it often produces, and is in turn affected by, conscious metacognitive experiences (Flavell 1979): for example, the feeling of knowing something but being unable to recall it. Even two-year-olds may have some metacognitive experiences, although older children and adults appear to be much better at interpreting and taking advantage of them (Flavell 1987). An important question concerns whether metacognitive experiences such as feelings of knowing are actually veridical indicators of underlying cognition. This issue has received close attention in recent years in the field of adult cognition (e.g., Metcalfe and Shimamura 1994; Nelson 1992). The findings suggest that the presence or absence of feelings of knowing does predict later recognition memory (see Hart 1965 for the seminal finding). However, although the accuracy of such feelings is typically above chance, it is far from perfect and appears to be somewhat task-dependent. Moreover, the mechanisms underlying feelings of knowing are not yet fully clear: Individuals may have partial access to the unrecalled item, or alternatively, they may simply infer the likelihood of knowing from other related information that is accessible (Nelson 1992).

Metacognitive knowledge and regulation are often closely intertwined. For example, knowing that a task is difficult can lead an individual to monitor cognitive progress very carefully. Conversely, successful cognitive monitoring can lead to knowledge of which tasks are easy and which difficult.

Precisely how metacognitive abilities are acquired is not known, but the process is almost certainly multifaceted. Likely contributors include general advances in self-regulation and reflective thinking, the demands of formal schooling, and the modeling of metacognitive activity by parents, teachers, and peers (see Flavell 1987). A critical precursor to the development of metacognition is the acquisition of initial knowledge about the existence of the mind and mental states (i.e., the development of a THEORY OF MIND). Well established by the end of the preschool years, such knowledge continues to develop in tandem with metacognition throughout middle childhood and adolescence (Moses and Chandler 1992). Somewhat curiously, theory of mind and metacognition are often thought of as separate research domains. Certainly, the two areas of inquiry tend to have different foci: Prototypical theory of mind studies assess younger children's appreciation of the role of mental states in the prediction and explanation of other people's behavior, whereas classical metacognitive studies examine older children's knowledge of mental processes in the self, often in an academic context. Still, no absolute distinction between the two areas should be drawn: Both are centrally concerned with the study of cognition about cognition.

Metacognitive impairments are not limited to very young children. Poor metacognitive skills can also be found in learning disabled and mentally retarded individuals. Conversely, gifted individuals often have excellent metacognitive abilities (Jarman, Vavrik, and Walton 1995) which may be especially evident in domains where they have special expertise (Alexander, Carr, and Schwanenflugel 1995). Some aspects of metacognition may also be deficient in the aged, although whether the impairments are a function of aging or some other factor (e.g., lack of college experience) is not always clear (Nelson 1992). Finally, individuals with frontal lobe damage frequently show metacognitive deficits, whereas those with damage to other parts of the cortex typically do not (Shimamura 1996). For example, frontal lobe patients are often unaware of their cognitive deficits, they lack knowledge of and are impaired in their use of metacognitive strategies, and the accuracy of their feelings of knowing is poor. That the locus of metacognition in the brain might be the frontal lobes should come as no surprise, given the extensive overlap between metacognitive regulation and executive functioning, an aspect of cognition long associated with the prefrontal cortex.

Much of the interest in metacognition derives from the belief that metacognitive skills significantly influence cognitive performance. Of course, many factors are likely to affect behavior in a specific cognitive situation (Flavell, Miller, and Miller 1993), including implicit processes of which the individual is unaware (Reder 1996). Nevertheless, in the case of memory (where the issue has been examined most thoroughly), a moderately high correlation is often found between metamemory and task performance (Schneider and Pressley 1989). The association tends to be stronger for older children, for more difficult tasks, and for certain types of metamemory (e.g., memory monitoring). Not surprisingly, the correlation between metamemory (e.g., strategy knowledge) and strategy use is typically higher than that between metamemory and performance, confirming that the links between metacognition and task success are indeed complex.

Given that metacognitive abilities actually do enhance cognitive performance, their acquisition should have far-reaching educational implications. In this respect, it is encouraging that metacognitive strategies can sometimes be successfully taught (e.g., Brown and Campione 1990). The teaching is most effective if individuals are explicitly taught how a strategy works and the conditions under which to use it, and if they attribute performance gains to the strategy (e.g., Schneider and Pressley 1989). Importantly, it is under these teaching conditions that individuals are most likely to maintain and generalize their newly acquired metacognitive skills.

Metaphor

Metaphor, from the Greek for "transference," is the use of language that designates one thing to designate another in order to characterize the latter in terms of the former. *Nominal metaphors* use nouns in this way, as in "My daughter is an *angel.*" *Predicative metaphors* use verbs, as in "The dog *flew* across the back yard." In addition to single words being used metaphorically, phrases, sentences, and more extended texts can also function as metaphors, as in the assertion "Bravely the troops carried on" to refer to telephone operators who continued to work during a natural

disaster. Sometimes a metaphor can be recognized because it is literally false. When a proud father says, "My daughter is an angel," no one believes that she has wings. But a metaphor need not be literally false. The opposite assertion—that one's daughter is no angel—is literally true; she does not have wings. Yet this is not likely to be the speaker's intended meaning, nor is it likely to be a hearer's interpretation. In each of these two cases, hearers must go beyond the literal meaning to arrive at the speaker's intention—what the hearer is intended to understand (see PSYCHOLINGUISTICS and PRAGMATICS).

Does the need to go beyond literal meanings imply that literal meanings have unconditional priority? The standard pragmatic theory of metaphor assumes that literal meanings are always computed first, and only when a literal meaning makes no sense in context are alternative, metaphorical meanings derived (Searle 1979). If this is so, then metaphorical meaning should be ignored whenever a literal meaning makes sense. However, people cannot ignore metaphors. Whenever metaphorical meanings are available, they are automatically processed, even when there is no apparent need to do so (Glucksberg, Gildea, and Bookin 1982). Furthermore, metaphors are no more difficult to understand than comparable literal expressions (Ortony et al. 1978), suggesting that literal meanings do not have priority.

Metaphors have traditionally been viewed as implicit comparisons. According to this view, metaphors of the form *X is a Y* are understood by converting them into simile form, X is *like* a Y. The simile is then understood by comparing the properties of X and Y. This view has been challenged on both theoretical and empirical grounds. One finding is particularly telling. Metaphors in class inclusion form, such as "My lawyer is a shark" take less time to understand than when in simile form, such as "My lawyer is *like* a shark" (Johnson 1996).

That metaphors can be understood more easily than similes argues that metaphors are exactly what they seem to be, namely, class inclusion assertions (Glucksberg and Keysar 1990). In such assertions, the metaphor vehicle (e.g., *shark*) is used to refer to the category of predatory creatures in general, not to the marine creature that is also named "shark." This dual reference function of metaphor vehicles is clear in metaphors such as "Cambodia was Vietnam's Vietnam." Here, the first mention of *Vietnam* refers to the nation of Vietnam. In contrast, the second mention of *Vietnam* does not refer to that nation, but instead to the American involvement in Vietnam, which has come to epitomize the category of disastrous military interventions. That intervention has become a metaphor for such disasters, and so the word *Vietnam* can be used as a metaphor vehicle to characterize other ill-fated military actions, such as Vietnam's invasion of Cambodia. More generally, metaphor vehicles such as *Vietnam* can be used as names for categories that have no names of their own (Brown 1958). With continued use, once-novel metaphors become frozen, their original metaphorical meanings become literal, and their senses become dictionary entries. The word "butcher" is a case in point: It can be taken to mean a meat purveyor, a bungler, or a vicious murderer, depending on the context.

Thus, while metaphors can suggest a comparison, they are primarily attributive assertions, not merely comparisons. To say that someone's job is a jail is to attribute (i.e., *transfer,* in the original Greek sense) salient properties of the category *jail* to a particular job (Ortony 1979). That particular job is now included in the general, abstract category of *jail*, and as a consequence of that categorization is now similar in relevant respects to literal jails (Glucksberg, McGlone, and Manfredi 1997). Predicative metaphors, in which verbs are used figuratively, function similarly. The verb *to fly* literally entails movement in air. Because flying through the air epitomizes speed, expressions such as "He hopped on his bike and flew home" are readily understood, just as nominal metaphors, such as "His bike was an arrow," are readily understood. Arrows are prototypical members of the category of speeding things; flying is a prototypical member of the category of fast travel. For both nominal and predicative metaphors, prototypical members of categories can be used as metaphors to attribute properties to topics of interest.

Why are metaphors used instead of comparable literal expressions? Often there are no comparable literal expressions (Black 1962), particularly when metaphor is used systematically to describe one domain in terms of another. Perceptual metaphors enable us to describe experiences in one sense modality in terms of another, as in *bright sound.* Theories can be described in terms of structures, with correspondences between the blueprints and foundations of a structure on the one hand, and those of a theory on the other. Once a target domain (e.g., theories) has been described in terms of a source domain (e.g., buildings), then new correspondences can be introduced, as in "The theory's superstructure is collapsing of its own weight." Whether such systematic correspondences constitute conceptual knowledge per se or are primarily a means of describing and transmitting such knowledge remains an unresolved issue (see COGNITIVE LINGUISTICS and METAPHOR AND CULTURE; Lakoff and Johnson 1980; McGlone 1996; Murphy 1996; Quinn 1991).

Domains for which metaphors seem particularly apt include science, emotions, personality characteristics, and politics (Cacciari forthcoming). Indeed, any domain can be effectively framed by choice of metaphor. Immigration, for example, can be viewed either as an invigorating process ("New blood has been pumped into the city's economy") or as a threat ("The tide of refugees will soon drown us"). Similarly, different interpretations of feelings and interpersonal relations can be effectively revealed and communicated via metaphor in clinical settings (Rothenberg 1984).

Given the importance and ubiquity of metaphor, it is not surprising that the beginnings of metaphorical thought and language appear early in children's cognitive and linguistic development. Infants as young as two months can detect intermodal correspondences (Starkey, Spelke, and Gelman 1983). Such correspondences represent a rudimentary form of metaphorical conceptualization (Marks 1982). Children as young as two years use and understand more abstract metaphorical correspondences, such as between the shoulders of a person and those of a mountain, although sophisticated use of metaphors comes only with complex knowledge of relations among CONCEPTS and facility in

analogical reasoning (Gentner and Markman 1977). As children learn to distinguish between figurative and literal language, they use the same "psychological mechanisms" to understand the one as they do the other (Miller 1979; 248). Literal and nonliteral understanding develop hand in hand.

Metaphor and Culture

How culture might figure in the conceptual domain-to-domain mappings that characterize METAPHOR has gone largely unaddressed. On the one hand, this is because anthropologists who study metaphor, and who belong to the interpretivist school and its offshoots, take the position that culture resides in metaphors, as it does in other symbols—and not in the use and sense people make of these. These scholars draw on literary criticism, semiotics, structuralism, and the like to interpret metaphors and other tropes (Linger 1994).

On the other hand, the role of culture in the production and comprehension of metaphor tends to be crowded out of systematic consideration by linguists, many of whom, perhaps understandably, have treated the metaphors occurring in language as direct reflections of deeper conceptual structures. On grounds of the ubiquity and automaticity of metaphor in speech, Lakoff and his colleagues (e.g., Lakoff and Johnson 1980) have made broad claims for the indispensable role of what they call "conceptual metaphors" in comprehension. In a characteristic assertion of this position, Lakoff and Turner (1989, xi) propose that "metaphor allows us to understand our selves and our world in ways that no other modes of thought can." One challenge to this view, from COGNITIVE ANTHROPOLOGY (Quinn 1991; 1997), holds that the metaphors expressed in language are underlain by cultural understandings, which cannot be read directly from linguistic metaphors but must be investigated independently.

Cultural understandings govern metaphor use in two ways. Sometimes a given domain of experience is understood by analogy to another domain. Such an analogy and

the extensive metaphorical language it provides may be culturally and historically quite distinctive. Yet the analogy may be so well established that it is naturalized in thinking, and the metaphors it provides have become standard parts of language, making it, not impossible, but difficult, for those who have learned to conceptualize the world in this way to think and talk in any other terms (Reddy 1979). Perhaps the most famous case is that of the "conduit" metaphor (Reddy 1979) for talking in English about meanings as transmitted in words—as in "Did I get my point across?" Various authors have pointed to the force of the conduit model and its metaphorical language, arguing that it has seriously constrained mathematical information theory (Reddy 1979); led the aforementioned interpretive anthropologists to mistakenly locate culture in symbols (Linger 1994); and bedeviled linguists themselves (Langacker 1991), possibly including those who study metaphor.

Cultural understandings enter the use of metaphors in a second way, one that depends on their intentional selection. Metaphors are commonly employed in ordinary speech to clarify to their audiences points that speakers are trying to convey. This communication task depends on knowledge that the audience can be counted on to share intersubjectively with the speaker. Cultural knowledge is reliably so shared. A common misconception has been that metaphoric target domains are less well understood, perhaps because they are abstract or intangible or unseen or unfamiliar, and that metaphoric source domains are better understood (e.g., Lakoff and Turner 1989), perhaps because they are physical in nature or otherwise concretely experienced. Rather, metaphors intended for clarification are typically selected from among cultural exemplars of that feature of the target domain under discussion (Glucksberg 1991; Quinn 1997). Indeed, this is how metaphors do their work of clarifying, by introducing an outstanding and unambiguous instance of the point being made.

Thus marriage, in the following example, is no more concrete, tangible, knowable, familiar, or well understood to the speaker than baseball. In a newspaper story on his retirement, Kansas City Royals third baseman George Brett was quoted as saying, "I compare it to a marriage. We've had our problems, but overall, we have had a good relationship. I never, ever want to put on another uniform" (*USA Today*, Wednesday, May 5, 1993). What is the case is that marriage is exemplary, for Brett and his American audience, of a relationship that is meant to endure and that does so (when it does so) because it is rewarding despite its difficulties. This is why his metaphor gives readers a surer sense of the complex idea Brett wants to convey about his relationship with the Royals.

When metaphors serve in this way to clarify what we mean to say, the cultural understandings that underlie what we mean may lend considerable regularity to the metaphors chosen. Thus, for example, in Americans' DISCOURSE, metaphors for marriage all fall into eight classes that reflect an underlying cultural model of marriage. For instance, marriage is seen as an ongoing journey ("Once the marriage was formalized it was an unalterable course"), a durable material ("You really have to start out with something strong if it's going to last"), and a firmly held possession ("I think we got

it!"). Each metaphor exemplifies a different kind of lasting thing, and all convey the expectation that marriage is lasting—a key piece of Americans' model of it. That different metaphors are used to capture the same shared understanding is strong evidence that a speaker must have had this point already in mind and selected the metaphor to match it. Indeed, speakers will occasionally concatenate two or three different metaphors to emphasize a point and also readily convey the same understanding nonmetaphorically. Far from following the entailments of a chosen metaphor, reasoning in discourse on marriage commonly follows the idealized cultural model of marriage, and employs different metaphors or no metaphor at all, or at times switches from one metaphor to another in midstream to reach the conclusion being reasoned to (Quinn 1991).

Cultural exemplars such as being married in the Brett quote, or ongoing journeys, durable materials, and firmly held possessions in the examples from discourse about marriage, can usefully be viewed as COGNITIVE ARTIFACTS, though wholly internalized ones. That is to say, they mediate performance of a commonplace cognitive task—in this case, the task of communicating accurately and efficiently. The psychological processing required for this task lends itself to a straightforward connectionist interpretation. Connections built up from experience between properties of the world and their known exemplars permit rapid, automatic identification of apposite metaphors. Of course, for metaphors to do their work of clarification, members of a speech community must, and do, share a large stock of such cultural exemplars. Knowledge of these is accumulated from a variety of experience, both first- and secondhand. Crucial is the ongoing experience of hearing and using metaphors in speech, not only because it presents individuals with many more exemplars than could possibly be encountered otherwise, but also because it weeds out more idiosyncratic choices that would be ill understood by audiences, in favor of more widely agreed upon cultural exemplars that communicate well. Through their repeated use as metaphors, these more readily understood examplars gain even wider acceptance, sometimes becoming wholly conventional.

Metareasoning

Metareasoning is reasoning about reasoning—in its broadest sense, any computational process concerned with the operation of some other computational process within the same entity. The term relies on a conceptual distinction between *object-level* deliberation about *external* entities, for example, considering the merits of various opening moves one might make in a game of chess, and *metalevel* deliberation about internal entities (computations, beliefs, and so on), for example, deciding that it is not worth spending much time deliberating about which opening move to make. Genesereth and Nilsson (1987) provide formal definitions along these lines. Smith (1986) makes a further distinction between INTROSPECTION about purely internal entities and *reflection* relating internal and external entities. In this view, a proposition such as "If I open the window I will know if the birds are singing" is reflective, because it relates a physical action to a future state of knowledge.

The capacity for metareasoning serves several purposes in an intelligent agent. First, it allows the agent to *control* its object-level deliberations—to decide which ones to undertake and when to stop deliberating and act. This is essential, given the pervasive problem of COMPUTATIONAL COMPLEXITY in decision making, and the consequent need for BOUNDED RATIONALITY. In GAME-PLAYING SYSTEMS, for example, the *alpha-beta* ALGORITHM makes a simple metalevel decision to avoid certain lines of deliberation about future moves, taking advantage of a metalevel theorem to the effect that these lines cannot affect the ultimate object-level decision. Second, metareasoning allows the agent to *generate* computational and physical behaviors, such as planning to obtain information, that require introspective or reflective reasoning. Third, it allows the agent to recover from errors or impasses in its object-level deliberations.

Most early work on metareasoning focused on designing an INTELLIGENT AGENT ARCHITECTURE (see also COGNITIVE ARCHITECTURE) that could support introspection and reflection. The use of metareasoning to control deduction seems to have been proposed first by Hayes (1973), although the first implementation was in the TEIRESIAS system (Davis 1980), which used metarules to control deliberation within a rule-based expert system. The Metalevel Representation System, or MRS, (Genesereth and Smith 1981) used LOGIC PROGRAMMING for both object and metalevel inference and provided a very flexible interface between the two. Because MRS allowed reasoning about which procedure to use for each object-level inference, and about which representation to use for each object-level fact, it enabled many different representations and reasoning methods to operate together seamlessly. By far the most ambitious metalevel architecture is Soar (Laird, Newell, and Rosenbloom 1987), whose fundamental mode of computation is based on PROBLEM SOLVING. Whenever Soar does not have an unambiguous rule telling it which problem-solving step to take next, it invokes *universal subgoaling* to set up a metalevel problem space that will resolve the issue. As might be imagined from these examples, designers of such systems must take care to avoid an *infinite regress* of metameta . . . reasoning.

Does metareasoning differ from "ordinary" reasoning? In all metalevel architectures, the metalevel is given direct access to object-level data structures. Thus metareasoning (at least in computers) can assume a completely and perfectly observable object-level state—which is seldom the case with ordinary reasoning about the external world. Furthermore, it is possible to represent fully and exactly the nature of the available object-level computations. Thus it is possible for the metalevel to simulate completely the object-level computations under consideration (as is done in Soar). This would seem counterproductive, however, as a way of selecting among object-level computations because simulating a computation (and hence knowing its outcome) is just a very slow way of doing the computation itself—knowledge of the outcome of a computation *is* the outcome. For this reason, Soar always compiles the results of subgoaling into a new rule, thereby avoiding deliberation in similar cases in future. Compilation of metareasoning into more efficient forms is perhaps the principal way an agent's computational performance can improve over time.

In the research outlined thus far, the metareasoning consisted mostly of applying simple "IF-THEN" rules encoding the system designer's computational EXPERTISE; no standard of rationality for metareasoning was provided. The concept of *rational metareasoning* (Horvitz 1989; Russell and Wefald 1989) had its roots in early work by I. J. Good (1971) on "Type II rationality" and in *information value theory* (Howard 1966), which places a value on acquiring a piece of information based on the expected improvement in decision quality that results from its acquisition. A COMPUTATION can be viewed as the process of making explicit some information that was previously implicit, and therefore value can be placed on computations in the same way. That is, a computation can be viewed as an action whose benefit is that it may result in better external decisions, and whose cost is the delay it incurs. Thus, given a model of the effects of computations and information about object-level utility, the metalevel can infer the value of computations. It can decide which computations to do and when computation should give way to action.

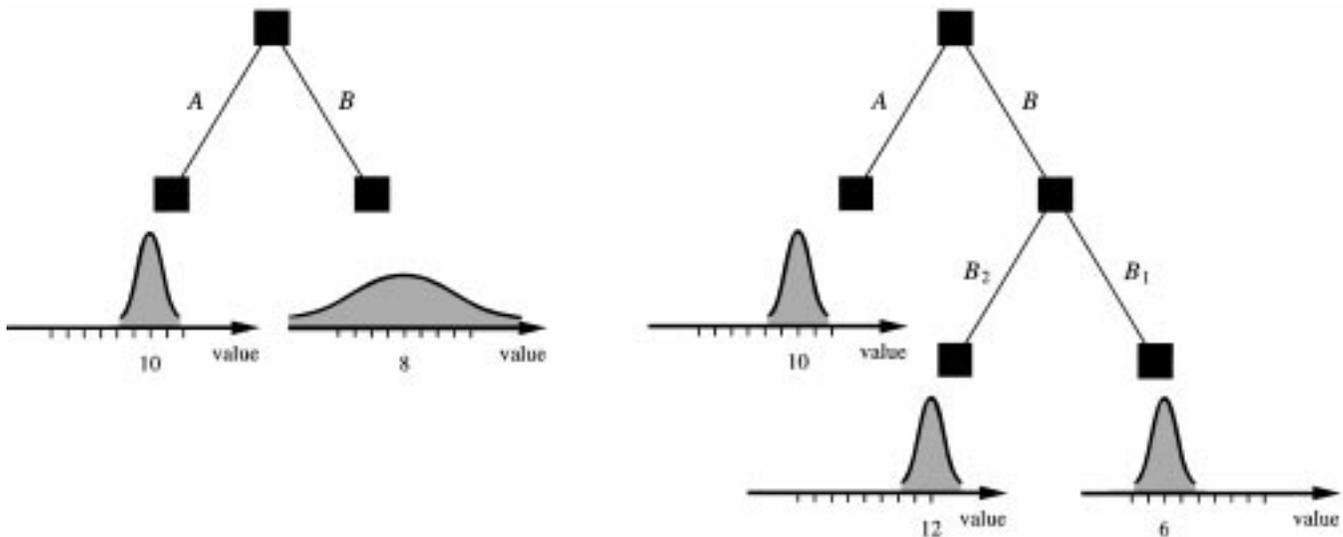
The simplest applications of rational metareasoning arise in the context of *anytime algorithms* (Horvitz 1987; Dean and Boddy 1988), that is, algorithms that can be interrupted at any time and whose output quality improves continuously with time. Each such algorithm has an associated *performance profile* describing its output quality as a function of time. The availability of the profile makes the metalevel decision problem—which algorithm to run and when to terminate—fairly trivial. The use of anytime algorithms devised for a wide variety of computational tasks has resulted in a widely applicable methodology for building complex, real-time decision-making systems (Zilberstein and Russell 1996).


Figure 1. The consequence of computation: Lookahead reveals that *B* may in fact be better than *A*.

A finer-grained approach to metareasoning can be obtained by evaluating individual computation steps within an algorithm. Consider the decision-making situation shown in figure 1a. An agent has two possible actions, *A* and *B*. Based on a quick assessment, the outcome of *A* appears to be worth 10 with a standard deviation of 1, whereas the outcome of *B* seems to be worth 8 with a standard deviation of 4. The agent can choose *A* immediately, or it can refine its estimates by looking further into the future. For example (figure 1b), it can consider the actions B_1 and B_2, with the outcomes shown. At this point, action *B* (followed by B_1) seems to lead to a state with value 12; thus the lookahead computation has changed the agent's decision, with an apparent benefit of 2. Obviously, this is a post hoc analysis, but, as shown by Russell and Wefald (1991), an expected value of computation can be computed efficiently—*prior* to performing the lookahead. In figure 1a, this value is 0.3 for lookahead from *A* and 0.82 for lookahead from *B*. If the initial estimated outcome of *A* were 12, however, these values would drop to 0.002 and 0.06, respectively. Hence, as one would expect, the value of computation depends strongly on whether a clear choice of action has already emerged. If, however, the initial estimates for *A* and *B* were both 10, with standard deviations of 0.1, then the value of computation becomes 0.03. Computation is worthless when it does not matter which action one eventually chooses.

Rational metareasoning can be applied to control deliberations in a wide variety of object-level algorithms including HEURISTIC SEARCH and game playing (Russell and Wefald 1991), LOGICAL REASONING SYSTEMS (Smith 1989), and MACHINE LEARNING (Rivest and Sloan 1988). An important insight to emerge from this work is that a metareasoning capability can, in principle, be *domain independent* (Russell and Wefald 1991; Ginsberg and Geddis 1991) because the necessary domain-specific information (such as the utility function) can be extracted from the object level. One can therefore view successful computational behavior as emerging not from carefully crafted, domain-specific algorithms

but from the interaction of a general capacity for rational metareasoning with object-level domain knowledge. More efficient, domain-specific computational behaviors might then result from processes of compilation and metalevel REINFORCEMENT LEARNING.

Metarepresentation

Cognitive systems are characterized by their ability to construct and process representations of objects and states of affairs. MENTAL REPRESENTATIONS and public representations such as linguistic utterances are themselves objects in the world, and therefore potential objects of second-order representations, or "metarepresentations." Under this or another name, (e.g., "higher-order representations"), metarepresentations are evoked in evolutionary approaches to INTELLIGENCE, in philosophical and developmental approaches to commonsense psychology, in pragmatic approaches to communication, in theories of consciousness, and in the study of reasoning.

It is assumed that the members of most animal species are incapable of recognizing in themselves or attributing to conspecifics mental representations such as beliefs or desires: they utterly lack metarepresentational abilities. Highly intelligent social animals such as primates, on the other hand, are believed to have evolved an ability to interpret and predict the behavior of others by recognizing their mental states. Indeed, Dennett (1987) has described some primates as "second-order intentional systems," capable of having "beliefs and desires about beliefs and desires." Second-order intentional systems are, for instance, capable of deliberate deception. In a population of second-order intentional systems, a third-order intentional system would be at a real advantage, if only because it would be able to see through deception. Similarly, in a population of third-order intentional systems, a fourth-order intentional system would be a greater advantage still, with greater abilities to deceive others and avoid being deceived itself, and so on. Hence the hypothesis, supported by some ethological evidence, that primates have developed a kind of strategic MACHIAVELLIAN INTELLIGENCE (Byrne and Whiten 1988) involving higher-order metarepresentational abilities. These evolutionary and ethological arguments have in part converged, in part con-flicted with experimental studies of primates' metarepresentational abilities that have started with Premack and Woodruff's pioneering article "Does the Chimpanzee Have a Theory of Mind?" (1978). Though the level of metarepresentational sophistication of other primates is still disputed, that of human beings is not. The human lineage may be the only one in which a true escalation of metarepresentational abilities has taken place.

Humans are all spontaneous psychologists. They have some understanding of cognitive functions such as perception and MEMORY (see METACOGNITION). They also attribute to one another PROPOSITIONAL ATTITUDES such as beliefs and desires, and do so as a matter of course. While philosophers have described the basic tenets of this commonsense or FOLK PSYCHOLOGY and discussed its empirical adequacy, psychologists have focused on the development of this cognitive ability, often described as a THEORY OF MIND. Philosophers and psychologists have been jointly involved in discussing the mechanism through which humans succeed in metarepresenting other people's thoughts and their own. This investigation has taken the form of a debate between those who believe attribution of mental states to others is done by simulation (e.g., Goldman 1993; Gordon 1986; Harris 1989), and those who believe it is done by inference from principles and evidence (e.g., Gopnik 1993; Leslie 1987; Perner 1991; Wellman 1990). In this debate (see SIMULATION VS. THEORY-THEORY), much attention has been paid to different degrees of metarepresentational competence that may be involved in attributing mental states to others. In particular, the ability to attribute *false* beliefs is seen as a sufficient, if not necessary, proof of basic metarepresentational competence. This metarepresentational competence can be impaired—the basis of a new, cognitive approach to AUTISM. Conversely, the study of autism has contributed to the development of a finer-grained understanding of metarepresentations (see Baron-Cohen 1995; Frith 1989).

Cognitive approaches have stressed the metarepresentational complexity of human communication. The very act of communicating involves, on the part of the communicator and addressee, mutual metarepresentations of each other's mental states. In ordinary circumstances, the addressee of a speech act is interested in the linguistic MEANING of the utterance only as a means of discovering the speaker's meaning. Speaker's meaning has been analyzed by the philosopher Paul GRICE (1989) in terms of several layers of metarepresentational intentions, in particular the basic metarepresentational intention to cause in the addressee a certain mental state (e.g., a belief), and the higher-order metarepresentational intention to have that basic intention recognized by the addressee. Grice's analysis of metarepresentational intentions involved in communication has been discussed and developed by numerous philosophers and linguists (e.g., Bach and Harnish 1979; Bennett 1976; Recanati 1986; Schiffer 1972; Searle 1969; Sperber and Wilson 1986).

It has long been observed that human languages have the semantic and syntactic resources to serve as metalanguages. In direct and indirect quotations, utterances and meanings are metarepresented. The study of such metalinguistic devices has been developed in semiotics (see SEMIOTICS AND COGNITION), in philosophy of language, and in PRAGMATICS. In particular, in the study of FIGURATIVE LANGUAGE, irony

has been described as a means of distancing oneself from some propositional attitude by metarepresenting it (see Gibbs 1994; Sperber and Wilson 1986).

The ability to metarepresent one's own mental states plays an important role in CONSCIOUSNESS, and may even be seen as defining it. For David Rosenthal (1986; 1997) in particular, a mental state is conscious if it is represented in a higher-order thought. When a thought itself is conscious, then the higher-order thought that represents it is a straightforward metarepresentation. These higher-order thoughts may themselves be the object of yet higher-order thoughts: The reflexive character of consciousness (i.e., that one can be conscious of being conscious) is then explained in terms of a hierarchy of metarepresentations. While many philosophers do not accept this "higher-order thought" theory of consciousness, the role of metarepresentations at least in aspects of consciousness and in related phenomena such as INTROSPECTION is hardly controversial.

Much of spontaneous human reasoning is about states of affairs and how they relate to one another. But some reasoning, especially deliberate reasoning as occurs in science or philosophy, is about hypotheses, theories, or claims—representations—and only indirectly about the state of affairs represented in these representations. In the psychology of DEDUCTIVE REASONING, growing attention has been paid to such metarepresentational reasoning, in particular by experimenting with liar and truth teller problems, either from the point of view of "mental logic" (Rips 1994) or from that of MENTAL MODELS (Johnson-Laird and Byrne 1991). In artificial intelligence, too, there is a growing interest in modeling such METAREASONING.

This rapid overview does not exhaust the areas of cognitive science where metarepresentation (whether so named or not) plays an important role. In a great variety of cognitive activities, humans exhibit unique metarepresentational virtuosity. This, together with the possession of language, may be their most distinctive cognitive trait.

Meter and Poetry

The fundamental formal distinction between poetry and all other forms of literary art is this: poems are made up of lines. But how long is a line? Lines of metrical verse are subject to measurement just as surely as if they were made of cloth and both poet and reader has a yardstick. In the case of cloth, you measure physical distance by counting in yards. What do you use to measure the length of a line of poetry? The simplest kinds of meters are measured in syllables. There are only so many in a line.

Such meters occur in the poetry of languages all over the world. Much of the poetry in the Romance languages counts syllables (Halle and Keyser 1980). Hebrew poetry of the Old Testament does as well (Halle 1997). So, too, do the Japanese verse forms known as *tanka* and *haiku* (Halle 1970). In the five-line *tanka,* lines are 5-7-5-7-7 syllables long. In the three-line *haiku,* the lines are 5-7-5 syllables long. As shown by the poems in (1) and (2), syllables with double vowels (i.e., long syllables) are counted as two units; all other syllables count as one.

(1) Haru tateba   5   When spring comes
    Kiyuru koori no   7   the ice melts away
    Nokori naku   5   without trace
    Kimi ga kokoro mo   7   your heart
    Ware ni tokenamu   7   melts into me
    (Kokinshuu)

(2) Kaki kueba   5   Eating persimmons
    Kanega narunari   7   the bell rings
    Hooryuu-ji   5   Hooryuuji
    (Masaoka)

Japanese poets and their readers both know what a syllable is. They also know the difference between a long syllable and a short one. This shared knowledge is what Japanese meter depends upon. Segmenting a word into syllables requires a great deal of sophisticated knowledge about such things as the difference between a vowel, a consonant, a liquid, and a glide. No modern computer can reliably segment a stretch of speech into syllables. Yet speakers of all languages do this constantly and unconsciously.

Much more complex linguistic machinery is involved in verse where line length is measured by counting feet rather than syllables. Foot-counting verse is encountered in a wide range of poetic traditions, among them Homer and much of the poetry of classical Greek and Latin antiquity, the Old Norse bards, English poetry from Chaucer to Frost, German poetry from Hans Sachs to Rilke, and Russian poetry from the eighteenth century to the present.

To illustrate the more complex machinery of foot-counting meters, we look at the so-called syllabo-tonic meters of English and, in particular, iambic pentameter. This meter is made up, as its name suggests, of five feet. An iambic foot is made up of two syllables followed by a boundary. There is a specific procedure that divides the line into iambic feet. Consider the opening line of Gray's "Elegy Written in a Country Churchyard":

(3) The curfew tolls the knell of parting day.
    *   * * *   *   * * *   *   *

We represent each syllable in the verse by an asterisk beneath the line. The procedure is: insert right parenthesis from left to right, starting at the left edge so as to group asterisks into pairs:

(4) The curfew tolls the knell of parting day.
)*   *)* *) *   *)* *)* *)

Although there are six parentheses in this line, there are only five feet because an iambic foot is defined as a sequence of two syllables followed by a parenthesis. The rule that inserts parentheses is:

(5) Insert a right parenthesis ")" at the beginning of the line and, proceeding rightward, after every other syllable (thus generating binary feet).

Readers familiar with iambic verse know that many lines of iambic pentameter verse are often longer than 10 syllables. These exhibit what the textbooks call "feminine rhymes." The following couplet from Byron's "Don Juan" (Canto 65) is illustrative:

(6) Yet he was jealous, though he did not show it,
    For jealousy dislikes the world to know it.

The line-final rhyming pair is *show it: know it.* Each member of the pair has a so-called extrametrical syllable— namely, *it.* Rule (5) automatically accounts for the possibility of such syllables in iambic verse:

(7) Yet he was jealous, though he did not show it.
)* *) * *)*   *) * *) *   *) *
    For jealousy dislikes the world to know it.
)* *)* *) * *)   * *) * *) *

As before, right parentheses are inserted, beginning at the left. Notice, however, that a right parenthesis cannot be inserted to the right of the final * in (7) because (5) requires that two syllables are skipped before a right parenthesis can be inserted. Here only a single * follows the last parenthesis. Therefore, no parenthesis is inserted line finally and the line is correctly scanned as containing only five iambic feet.

Just as readers familiar with poetry written in iambic pentameter recognize that some lines are longer than 10 syllables, they also know certain lines are not possible iambic pentameter lines, even though they may be composed of 10 syllables. For example, a line like (8) is not a possible iambic pentameter line.

(8) On cutting Lucretia Borgia's bright hair

This causes a problem for the account given so far because (5) scans the line without difficulty:

(9) On cutting Lucretia Borgia's bright hair
) * *) *   *) * *) * *)   *   *)

(5) must be modified in such a way that it will continue to scan lines like those in (4) and (7) while ruling out lines like (9).

It is well known that in foot-based meters not only does line length play a role but so does the placement of certain marked syllables. In the English iambic meters, these are the syllables that bear the main stress of the word. We mark such metrically important syllables by inserting a bracket before or after them. The marked syllables in stress-based verse are called stress maxima. A stress maximum is the main stressed syllable in a polysyllabic word. In the history of English, poets made use of slightly different definitions, extending the definition in some cases and restricting it in others. For present purposes, the stress maximum is defined as:

(10) The stressed syllable of a polysyllabic word that is preceded by a lesser stressed syllable is a stress maximum.

The stressed syllables in the following words are instances of stress maxima:

(11) Lucrétia   meándering
      autobiográphic   pellúcid

Rule (12) accounts for the placement of such syllables in an iambic pentameter line.

(12) In an iambic line, insert a right bracket after (to the right of) a stress maximum.

Let us see how rules (5) and (12) construct feet within a line like (13).

(13) The curfew tolls the knell of parting day.

The square brackets called for by stress maxima are inserted first. They are no different from parentheses, but we use them to help the reader keep track of which rule is responsible for a given boundary:

(14) The cúrfew tolls the knell of párting day.
        *   *] *   *   *   * * * *] *   *

Next come the parentheses inserted by (5):

(15) The curfew tolls the knell of parting day.
        *   *]) * *) *   *) * *]) * *)

The line is correctly divided into five feet and, significantly, where right parentheses and right brackets occur in the line, they coincide. Now consider how (5) and (12) assign boundaries to the unmetrical (8):

(16) On cutting Lucretia Borgia's bright hair
        *   *])*   *)*])* *]) *   *)   *

Unlike the metrical lines discussed thus far, this line contains two feet that end on consecutive syllables, namely:

(17) -ing Lucrétia
        *   *) *] *

This is not a well-formed configuration. We exclude it by means of prohibition (18):

(18) Feet may not end on consecutive syllables.

Rule (18) applies after the insertion of parentheses by (5) and (12). All scansions that conform to it are well-formed. Scansions that fail to do so are not.

The theory of meter proposed contains two rules, one output constraint, and a definition of stress maximum. The rules insert right foot boundaries, either to the right of stress maxima or else iteratively from left to right. The constraint rules out scansions with unary feet. The grammar is summarized in (19):

(19) Rule: a. Insert a right bracket "]" to the right of a stress maximum.
            b. Insert a right parenthesis ")" from left to right, skipping two consecutive syllables.
      Constraint: In iambic verse feet may not end on consecutive syllables.
      Stress Maximum: The stressed syllable of a polysyllabic word preceded by a lesser stressed syllable.

Just as two speakers of a language share a body of linguistic knowledge called a grammar, which enables them to speak to one another, so, too, do poets and their readers share a body of knowledge that enables the one to write metrically and the other to scan what has been put into meter. The rules in (19) are an attempt at illustrating what this body of shared metrical knowledge looks like.

Up to now, nothing has been said about the machinery used to scan iambic pentameter lines. That machinery is identical to that needed to account for the way ordinary speakers assign stress to the words of English (see STRESS, LINGUISTIC), and is part of the natural endowment of human beings that enables them to speak a language—what linguists have come to call Universal Grammar (UG). In other words, poets who write metrically do so using the same theoretical apparatus provided by UG that speakers use to assign stress to the words of their language. This convergence of the machinery of meter with the machinery of stress assignment is the essence of PROSODY.

Mid-Level Vision

Mid-level vision refers to a putative level of visual processing, situated between the analysis of the image (lower-level vision) and the recognition of specific objects and events (HIGH-LEVEL VISION). It is largely a viewer-centered process, seemingly concerned explicitly with real-world scenes, not simply images (see Nakayama, He, and Shimojo 1995). Yet, in distinction to high-level vision, mid-level vision represents the world only in a most general way, dealing primarily with surfaces and objects and the fact that they can appear at different orientations, can be variously illuminated, and can be partially occluded.

Vision as we understand it today is far more complicated than had been recognized even thirty to forty years ago. Despite the seeming unity of our visual experience, there is mounting evidence that vision is not a single function but is likely to be a conglomerate of functions, each acting with considerable autonomy (Goodale 1995; Ungerleider and Mishkin 1982). Along with this new appreciation of vision's complexity comes the striking fact that from a purely anatomical point of view, the portion of the brain devoted to vision is also much greater than previously supposed (Allman and Kaas 1975; Felleman and van Essen 1991). For example, about 50 percent of the CEREBRAL CORTEX of primates is devoted exclusively to visual processing, and the estimated territory for humans is nearly comparable. So vision by itself looms very large even when stacked up against all other conceivable functions of the brain. As such, subdivisions in vision, particularly principled ones that delineate qualitatively different processes, are sorely needed, and Marr's (1982) seminal argument for three levels provides the broad base for what we outline here.

Let us consider what processes might constitute mid-level vision, and then contrast them with low-level and high-level vision. Good examples of mid-level visual processing can be seen in the work of Kanizsa (1979). Compare figure 1a where we see many isolated fragments with figure 1b where the same fragments are accompanied by additional diagonal line segments. In figure 1b there is a dramatic shift in what is perceived. The isolated pieces seen in figure 1a now form a single larger figure, the familiar Necker cube.

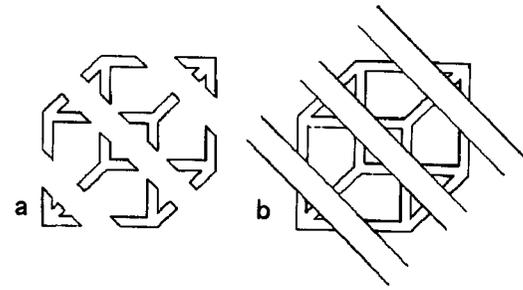
The phenomenon just described is characterized by several things, which all appear to be related to objects and surfaces and their boundaries. Furthermore, they are examples of occlusion, the partial covering of one surface by another. There is also the indication of inferences being made, enabling us to represent something that has been made invisible. We are thus aware of something continuing behind, which in turn enables us to see a single figure, not isolated fragments.


Figure 1.
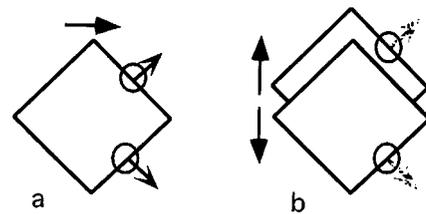

Figure 2.

These characteristics, while not delineating mid-level vision in its entirety, provide sufficient basis for characterizing it as qualitatively different from low- and high-level vision. Consider the "aperture" problem for motion and its solution, something that until recently has been considered as within the province of low-level vision. Since Wallach's work (1935/1997), it has been recognized that there is an inherent ambiguity of perception if motion is analyzed locally, as would be the case for directionally selective receptive fields (see circles in figure 2). Thus in the case of a rightward-moving diamond (figure 2a), the local motions of the edges are very different from the motion of the whole figure. Yet, we are unaware of these local motions and see unified motion to the right. Computational models based on local motion measurements alone can recover the horizontal motion of the single figure on the left, but they cannot account for the perceived motion of one figure moving differently from another on the right (figure 2b). Although the local motions here are essentially identical, our visual system sees the motion in each case to be very different. It sees rightward motion of a single object versus opposing vertical motion of two objects. Only by the explicit parsing of the moving scene into separate surfaces can the correct motion be recovered. Thus, directionally selective neurons by themselves cannot supply reliable information regarding the motion of objects. Mid-level vision, with its explicit encoding of distinct surfaces, is required.

How might we distinguish mid-level from high-level vision? Consider figure 3. Most obvious is the reversal of the duck and the rabbit. From the above discussion, it should be clear that this reversal cannot be happening at the level of mid-level vision, which concerns itself more generally with surfaces and objects, but at higher levels where specific objects, like rabbits and ducks, are represented. For mid-level vision there is *no* reversal. Here mid-level vision's

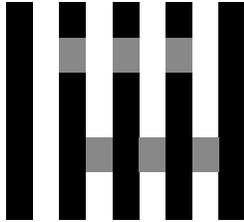
Figure 3.


Figure 4.

job is to make sure we see a single thing or surface, despite its division into four separate image fragments by the overlying occluder and despite the change in its identity (the rabbit vs. the duck).

Another job of mid-level vision is to cope effectively with the characteristics of reflected light as it plays across surfaces in natural scenes. Surfaces can appear in various guises in the image, the result of being illuminated from various angles, being shaded by themselves or other surfaces, and by being viewed through transparent media. It would thus seem natural that various visual mechanisms would have developed or evolved to deal with these issues of illumination just as they have for cases of occlusion. This view is strengthened by the existence of perceptual phenomena that provide at least some hint as to how such processes may be occurring, also demonstrating the existence of processing that cannot be explained by low-level vision, say by lateral interactions of neurons with various types of receptive fields. Consider White's illusion shown in figure 4 where the apparent difference in brightness of the gray squares (top vs. bottom row) is very large despite being of equal luminance. Each identical gray patch is bounded by identical amounts of black and white areas, thus ruling out any explanation based on simultaneous contrast or lateral inhibition. The major difference is the nature of the junction structure bounding the areas, properties very important in mid-level vision processing. Figure 5 suggests that mid-level vision's role is the processing of shadows, showing how specific are the requirements for a dark region to be categorized as shadow and how consequential this categorization is for higher-level recognition. On the left we see a 3-D figure, a face. On the right, it looks more 2-D, where the outline around the dark region diminishes the impression that the figure contains shadows.

Although phenomena related to mid-level vision have been well-known, starting with GESTALT PSYCHOLOGY and more recently with work by Kanizsa (1979), the scope and positioning of mid-level vision in the larger scheme of visual processing has been unclear. Recently, Nakayama et al. (1995) have suggested that mid-level vision, in the form

Figure 5.

of surface representation, is required for a range of processes more traditionally associated with early vision, including motion perception (see MOTION, PERCEPTION OF), forms of stereopsis, TEXTURE segregation and saliency coding. More speculatively, there has been a proposal that mid-level vision is the first level of processing, the results of which are available to conscious awareness (Jackendoff 1987; Nakayama, He, and Shimojo 1995), thus implying that mid-level vision is the earliest level to which ATTENTION can be deployed.

Mind-Body Problem

The *mind-body problem* is the problem of explaining how our mental states, events, and processes are related to the physical states, events, and processes in our bodies. A ques-

tion of the form "How is A related to B?" does not by itself pose a philosophical problem. To pose such a problem, there has to be something about A and B that makes the relation between them seem problematic. Many features of mind and body have been cited as responsible for our sense of the problem. Here I will concentrate on two: the apparent causal interaction of mind and body, and the distinctive features of CONSCIOUSNESS.

A long tradition in philosophy has held, with René DESCARTES, that the mind must be a nonbodily entity: a soul or mental substance. This thesis is called "substance dualism" or "Cartesian dualism" because it says that there are two kinds of substance in the world, mental and physical or material. Belief in such dualism is based on belief that the soul is immortal, and that we have free will, which seems to require that the mind be a nonphysical thing because all physical things are subject to the laws of nature.

To say that the mind (or soul) is a mental substance is not to say that the mind is made up of nonphysical "stuff" or material. Rather, the term *substance* is used in the traditional philosophical sense: a *substance* is an entity that has properties and that persists through change in its properties. A tiger, for instance, is a substance, whereas a hurricane is not. To say there are mental substances—individual minds or souls—is to say there are objects that are nonmaterial or nonphysical, and these objects can exist independently of physical objects, such as a person's body. These objects, if they exist, are not made of nonphysical "stuff"—they are not made of "stuff" at all.

But if there are such objects, then how do they interact with physical objects? Our thoughts and other mental states often seem to be caused by events in the world external to our minds, and our thoughts and intentions seem to make our bodies move. A perception of a glass of wine can be caused by the presence of a glass of wine in front of me, and my desire for some wine plus the belief that there is a glass of wine in front of me can cause me to reach toward the glass. But many think that all physical effects are brought about by purely physical causes: The physical states of my brain are enough to cause the physical event of my reaching toward the glass. So how can my mental states play any causal role in bringing about my actions?

Some dualists react to this by denying that such psychophysical causation really exists (this view is called EPIPHENOMENALISM). Some philosophers have thought that mental states are causally related only to other mental states, and physical states are causally related only to other physical states: The mental and physical realms operate independently. This "parallelist" view has been unpopular in the twentieth century, as have most dualist views. For if we find dualism unsatisfactory, there is another way to answer the question of psychophysical causation. We can say that mental states have effects in the physical world precisely because they are, contrary to appearances, physical states (see Lewis 1966). This is a *monist* view because it holds that there is only one kind of substance, physical or material substance. Therefore it is also known as PHYSICALISM or "materialism."

Physicalism comes in many forms. The strongest form is the form just mentioned, which holds that mental *states* or *properties* are identical with physical states or properties. Sometimes called the "type-identity theory," this view is considered an empirical hypothesis, awaiting confirmation by science. The model for such an identity theory is the identification of properties such as the heat of a gas with the mean kinetic energy of its constituent molecules. Because such an identification is often described as part of the *reduction* of thermodynamics to statistical mechanics, the parallel claim about the mental is often called a "reductive" theory of mind, or "reductive physicalism" (see Lewis 1994).

Because it seems committed to the implausible claim that all creatures who believe that grass is green have one physical property in common—the property identical to the belief that grass is green—many philosophers find reductive physicalism an excessively bold empirical speculation. For this reason (and others), some physicalists adopt a weaker version of physicalism, which holds that all particular objects and events are physical, but that there are mental properties not identical to physical properties. (Davidson 1970 is one inspiration for such views; see ANOMALOUS MONISM.) Such "non-reductive physicalism" is a kind of dualism because it holds there are two kinds of properties, mental and physical, but it is not *substance* dualism because it holds that all substances are physical substances.

Nonreductive physicalism is also sometimes called a "token identity theory" because it identifies mental and physical particulars or tokens, and it is invariably supplemented by the claim that mental properties *supervene* on physical properties. Though the notion can be refined in many ways, SUPERVENIENCE is essentially a claim about the dependence of the mental on the physical: There can be no difference in mental facts without a difference in some physical facts (see Kim 1993; Horgan 1993).

If the problem of psychophysical causation was the whole of the mind-body problem, then it might seem that physicalism is a straightforward solution to that problem. If the only question is, How do mental states have effects in the physical world?, then it seems that the physicalist can answer this by saying that mental states are identical with physical states.

But there is a complication here. For it seems that physicalists can only propose this solution to the problem of psychophysical causation if mental causes are identical with physical causes. Yet if properties or states are causes, as many reductive physicalists assume, then nonreductive physicalists are not entitled to this solution because they do not identify mental and physical properties. This is the problem of MENTAL CAUSATION for nonreductive physicalists (see Davidson 1993; Crane 1995; Jackson 1996).

On the other hand, even if the physicalist can solve this problem of mental causation, there is a deeper reason why there is more to the mind-body problem than the problem of psychophysical interaction. The reason is that, according to many philosophers, physicalism is not the "solution" to the mind-body problem, but something that gives rise to a particular version of that problem. They reason as follows: Because we know that the world is completely physical, if the mind exists, it too must be physical. However, it seems hard to understand how certain aspects of mind—notably, consciousness—could just be physical features of the brain.

How can the complex subjectivity of a conscious experience be produced by the gray matter of the brain? As McGinn (1989) puts it, neurons and synapses seem "the wrong kind" of material to produce consciousness. The problem here is one of intelligibility: Because we know that the mental is physical, consciousness must have its origins in the brain. But how can we make sense of this mysterious fact?

Thomas Nagel (1974) dramatized this in a famous paper, saying that when a creature is conscious, there is something it is *like* to be that creature: There is something it is like to be a bat, but there is nothing it is like to be a stone. The heart of the mind-body problem for Nagel was the apparent fact that we cannot understand *how* consciousness can just be a physical property of the brain, even though we know that in some sense physicalism is true (see also Chalmers 1996).

Some physicalists respond by saying that this problem is illusory: if physicalism *is* true, then consciousness is just a physical property, and it simply begs the question against physicalism to wonder whether this *can* be true (see Lewis 1983). But Nagel's criticism can be sharpened, as it has been by what Frank Jackson calls the "knowledge argument" (Jackson 1982; see also Robinson 1982). Jackson argues that even if we knew all the physical facts about, say, pain, we would not ipso facto know what it is like to be in pain. Someone omniscient about the physical facts about pain would learn something new when they learn what it is like to be in pain. Therefore there is some knowledge— knowledge of WHAT-IT'S-LIKE—that is not knowledge of any physical fact. Hence not all facts are physical facts. (For physicalist responses to Jackson's argument, see Lewis 1990; Dennett 1991; Churchland 1985.)

In late-twentieth-century philosophy of mind, discussions of the mind-body problem revolve around the twin poles of the problem of psychophysical causation and the problem of consciousness. And while it is possible to see these as independent problems, there is nonetheless a link between them, which can be expressed as a dilemma: if the mental is not physical, then how can we make sense of its causal interaction with the physical? But if it is physical, how can we make sense of the phenomena of consciousness? These two questions, in effect, define the contemporary debate on the mind-body problem.

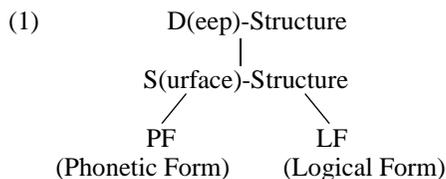
Minimalism

Minimalism is the latest (though still programmatic) development of an approach to SYNTAX—transformational GENERATIVE GRAMMAR—first developed by Noam Chomsky in the 1950s and successively modified in the four decades since. The fundamental idea was and continues to be that a sentence is the result of some sort of computation producing a derivation, beginning with an abstract structural representation, sequentially altered by structure-dependent transformations. The Minimalist Program maintains that these derivations and representations conform to an "economy" criterion demanding that they be minimal in a sense determined by the language faculty: no extra steps in derivations, no extra symbols in representations, and no representations beyond those that are conceptually necessary.

As articulated by Chomsky (1995), minimalism can best be understood in juxtaposition to its predecessor, the "Government-Binding" (GB) model of Chomsky (1981, 1982). (It should be pointed out that Chomsky prefers the name "principles and parameters" for the model, reasoning that government and binding are just two among many technical devices in the theory, and not necessarily the most important ones. For some discussion, see Chomsky and Lasnik 1993, a work that can be regarded as the culmination of the GB framework or the beginnings of minimalism.) In that model, there are four significant levels of representation, related by derivation as in following diagram:

(1)   D(eep)-Structure
                    |
         S(urface)-Structure
           /   \
        PF   LF
  (Phonetic Form)   (Logical Form)


Items are taken from the LEXICON and inserted into the D-Structure in accord with their thematic (θ) relations (roughly, *subject of . . . object of . . .* etc.). Transformations alter this D-Structure representation, the movement transformations leaving traces that mark the positions from which movement took place, eventually producing an S-Structure. Transformations of the same character (and arguably the same transformations) continue the derivation to LF, the SYNTAX-SEMANTICS INTERFACE with the conceptual-intentional system of the mind (cf. LOGICAL FORM). Rules of the phonological component continue the derivation from S-Structure to PF, the interface with the articulatory-perceptual system. The portion of the derivation between D-Structure and S-Structure is often called "overt syntax"; that between S-Structure and LF is called "covert syntax" because operations in that portion of the derivation have no phonetic effects, given the organization in (1). Under the traditional view that a human language is a way of relating sound (more generally, gesture, as in SIGN LANGUAGES) and meaning, the interface levels PF and LF are assumed to be ineliminable. Minimalism seeks to establish that these necessary levels of representation are the only levels.

Introduced into syntactic theory by Chomsky (1965), D-Structure was stipulated to be the locus of all lexical insertion, the input to the transformational component, and, most importantly, the representation determining thematic relations, as indicated above. Given traces, already a central part of the GB theory, the role of D-Structure in determining thematic relations becomes insignificant. Being theory internal, the other arguments for its existence disappear under more recent developments of the theory. S-Structure, the terminus of overt syntax within the GB framework, has a number of central properties, particularly concerning abstract case (dubbed "Case" by Chomsky 1980) and binding (structural constraints on anaphoric relations; cf. BINDING THEORY and ANAPHORA).

In a partial return to the technical apparatus of pre-1965 transformational theory (as in Chomsky 1955), minimalism has lexical items inserted "on-line" in the course of the syntactic derivation, roughly in accord with the fundamental notions of X-BAR THEORY and θ-theory. The derivation proceeds bottom-up: the most deeply embedded structural unit is created first, then combined with the head of which it is the complement to create a larger unit, and so on. Consider first the following simplified example (assuming the widely accepted "VP-internal subject hypothesis," under which the subject is initially introduced into the structure inside VP, then moves to an external position):

(2) [$_{IP}$ The woman [$_{I'}$ will [$_{VP}$ *t* [$_{V'}$ see [$_{DP}$ the man]]]]]

In the derivation of (2), first the noun (N) *man* is combined with the determiner (D) *the* to form the determiner phrase (DP) *the man.* This DP then combines with the verb *see* to produce an intermediate projection V'. (Phrase labels of the X' type, while convenient for exposition, are largely holdovers from earlier models, with no particular significance within the minimalist approach.) The DP *the woman* is created in the same fashion as *the man,* and is combined with the V' to produce the VP. Next, this VP merges with the tense/inflectional element *will* producing I'. The DP *the woman* finally moves to the specifier position of I', yielding the full clausal projection IP. In a more complicated derivation, such as that yielding (3), the derivation of the embedded clause proceeds exactly as in the case of (2):

(3) I think the woman will see the man

(2) has combined with the verb *think* to produce a V', and so on. Notice that the movement of *the woman* to the embedded subject position precedes the merger of the embedded sentence into the larger V', so that there is no one representation following all lexical insertion and preceding all transformations. That is, there is no D-Structure.

On the other hand, S-Structure, persists in one trivial sense: it is the point where the derivation divides, branching toward LF on one path and toward PF on the other. The more significant question is whether it has any of the further properties it has in the GB framework. One of the primary technical goals of the minimalist research program is to establish that these further properties (involving Case and binding, for instance) are actually properties of LF, contrary to previous arguments (as suggested in Chomsky 1986, contra Chomsky 1981). The attempts to attain this goal generally involve more operations attributed to covert syntax than in previous models.

Another technical goal is to reduce all constraints on representation to *bare output conditions,* determined by the properties of the external systems that PF and LF must interface with. Internal to the computational system, the desideratum is that constraints on transformational derivations will be reduced to general principles of economy. Derivations beginning from the same lexical choices (the *numeration,* in Chomsky's term) are compared in terms of number of steps, length of movements, and so on, with the less economical ones being rejected. An example is the minimalist deduction of the Chomsky (1973) *Superiority Condition,* which demands that when multiple items are available for WH-MOVEMENT in a language, such as English, allowing only one item to move, it is the "highest" item that will be chosen:

(4)   Who *t* will read what

(5)   *What will who read *t.*

Economy, in the form of "Shortest Move," selects (4) over (5) because the sentence-initial interrogative position "needs" a *Wh*-expression, and is closer to the subject than it is to the object. Many of the movement constraints falling under the *Relativized Minimality Constraint* of Rizzi (1990) are susceptible to a parallel analysis. This constraint, which had an important impact on the developing Minimalist Program, forbids movement to a position of a certain type: head position, A(rgument type)-position, A' (non-A)-position across an intervening position of the same type. Within the minimalist approach, the effects of this constraint are taken to fall under general economy constraints on derivation.

Theoretical developments in the minimalist direction, many well before minimalism was formulated as a program, have generally led to greater breadth and depth of understanding. Thus there is reason to expect that the Minimalist Program may eventually give rise to an articulated theory of linguistic structure, one that can resolve the traditional tension in linguistic theory between *descriptive adequacy* (the need to account for the phenomena of particular languages) and *explanatory adequacy* (the goal of explaining how linguistic knowledge arises in the mind so quickly and on the basis of such limited evidence).

Minimum Description Length

Minimum message length (MML) is a criterion for comparing competing theories about, or inductive inferences from, a given body of data. A very similar criterion, also to be described, is *minimum description length* (MDL). The basic concept behind both criteria is an operational form of Occam's razor (see PARSIMONY AND SIMPLICITY). A "good" theory induced from some data should enable the data to be encoded briefly. In human terms, a good theory introduces concepts, assumptions, and inference rules or "laws" that, if taken as true, allow much of the data to be deduced.

For example, suppose the data to be measurements of the forces applied to several physical bodies, and their resulting accelerations, where each body is subjected to a number of experiments using different forces. If we propose the concept that each body has a "mass," and the law that acceleration is given by force divided by mass, then the given data may be restated more briefly. If for each body, we state an assumed value for its mass, then for each experiment on that body we need only state the applied force because its acceleration can then be deduced. In practice, matters are a little more complicated: we cannot expect the measured acceleration in each case to equal the deduced value exactly because of inaccuracies of measurement (and because our proposed "law" is not quite right). Thus, for each experiment, the restatement of the data must include a statement of the small amount by which the measured acceleration differs from the deduced value, but if these corrections are sufficiently small, writing them out will need much less space than writing out the original data values.

Note that the restated data are unintelligible to a reader who does not know the "law" we have induced and the body masses we have estimated from the original data. Thus we

insist that the restated data be preceded by a statement of whatever theory, laws, and quantities we have inferred and assumed in the restating.

This leads to the idea of a special form of message for encoding data, termed an EXPLANATION. An *explanation* is a message that first states a theory (or hypothesis) about the data, and perhaps also some values estimated for unobserved concepts in the theory (e.g., the masses of the bodies in our example), and that then states the data in a short encoding that assumes the theory and values are correct. Equivalently, the second part of the message states all those details of the data which cannot be deduced from the first part of the message.

The MML principle is to prefer that theory which leads to the shortest explanation of the data. As the explanation contains a statement of the theory as well as the data encoded by assuming the theory, overly complex theories will not give the shortest explanations. A complex theory, by implying much about the data, gives a short second part, but a long first part. An overly simple theory needs only a short first part for its assertion, but has few or imprecise implications for the data, needing a long second part.

Message length can be quantified using INFORMATION THEORY: An event of probability P can be encoded in –log P binary digits, or bits, using base 2 logs. Hence the length of the second part of an explanation is just –log (probability of data given the theory). Also, if a Bayesian "prior probability" over theories is assumed, the length of the first part is –log (prior probability of theory). The shortest explanation then yields the theory of highest posterior probability, as do some other Bayesian methods. However, MML actually achieves a shorter message by choosing a code for theories that, in general, does not provide for all possible theories. Theories so similar that the available data cannot be expected to reliably distinguish between them are amalgamated and represented in the code by a single theory, credited with the sum of their prior probabilities. In particular, when a theory includes a real-valued parameter, only a subset of the possible values for the parameter is allowed for in the code. Although the prior over the parameter must be a density, this amalgamation gives a nonzero prior probability to each of the subset of parameter values. This makes MML invariant under transformations of the parameter space, unlike Bayesian maximum A-posterior density (MAP) methods.

MDL differs from MML in replacing Bayesian coding of theories with coding deemed to be efficient and "natural." In practice, there is usually little difference in the two approaches, but in some cases MML gives better parameter estimates than MDL, which usually relies on *maximum likelihood* estimates.

General theoretical results show MML optimally separates information about general patterns in the data, which appears in the first part, from patternless "noise," which appears in the second part. The method is statistically consistent: if the "true" model of the data is in the set of theories considered, enough data will reveal it. It also is not misleading: If there is no pattern in the data, no theory-based explanation will be shorter than the original statement of the data, thus no theory will be inferred. Successful appli-

cations of MML in MACHINE LEARNING include clustering, DECISION TREES, factor analysis, ARMA processes, function estimation, and BAYESIAN NETWORKS.

Message length can also be quantified via Kolmogorov complexity: The information in a given binary string is the length of the shortest input to a TURING machine causing output of the given string. This approach is equivalent to MML, with the set of possible "theories" including all computable functions. Practical applications, while very general, are limited by the undecidability of the "halting problem," although such quantification may provide a basis for a descriptive account of scientific process, which seems to evolve and retain those theories best able to give short explanations.

Mobile Robots

Mobile robots have long held a fascination, from science fiction (*Star Wars'* R2D2 and C3PO, *Forbidden Planet*'s Robby) to science fact. For artificial intelligence researchers, the lure has been to enable a machine to emulate the behavioral, perceptual, and cognitive skills of humans, and to investigate how an artifact can successfully interact, in real time, with an uncertain, dynamic environment. While most research has focused on autonomous navigation and on software architectures for autonomous robots, mobile robots have also been used for investigating planning, MANIPULATION AND GRASPING, learning, perception, human-robot interaction (such as gesture recognition), and robot-robot (multiagent) interaction. Representative applications for mobile robots include service robots (mail delivery, hospital delivery, cleaning), security, agriculture,

mining, waste remediation and disposal, underwater exploration, and planetary exploration, such as NASA's *Sojourner* Rover on Mars.

At the most basic level, mobile robots must perceive the world, decide what to do based on their goals and perceptions, and then act. The first two issues are the most challenging: how to reliably perceive the world with uncertain, unreliable sensors, and how to make rational decisions about what to do in the face of UNCERTAINTY about the perceived world and the effects of actions (both the robot's and those of other agents). For example, a mobile robot for the home must perceive furniture, stairs, children, pets, toys, and so on, and decide how to act correctly in a myriad of different situations.

Early work in indoor mobile robots demonstrated some basic capabilities of robots to perceive their environment (e.g., Stanford's CART; Moravec 1983), plan how to accomplish relatively simple tasks (e.g., SRI's Shakey; Fikes, Hart, and Nilsson 1972), and successfully move about in (relatively) unstructured environments. Early outdoor mobile robots, such as Carnegie Mellon's Navlab (Thorpe 1990), demonstrated similar capabilities for on-road vehicles. For these robot systems, speed was not much of an issue, nor was reacting to a dynamically changing environment—it was enough just to operate successfully using a sequential perceive/decide/act cycle in a previously unknown, albeit static, world. These and similar efforts resulted in new planning and plan execution algorithms (e.g., STRIPS; Fikes, Hart, and Nilsson 1972; see also PLANNING), new techniques to perceive the environment (Moravec 1983, 1988), and new software architectures for integrating and controlling complex robot systems (Thorpe 1990).

Starting in the mid-1980s, research focused more heavily on improving capabilities for navigating in more unstructured, dynamic environments, which typically involved handling greater levels of uncertainty. Notable advances were made in perceiving obstacles, avoiding obstacles, and in *map-based navigation* (following a map to get from location to location, without getting lost).

A key component to successful navigation is reliable perception of objects (obstacles) that may impede motion. For indoor mobile robots, a ring of ultrasonic sensors is often used for obstacle detection. These sensors give reasonably good range estimates, and the data can be improved by integrating measurements over time to reduce sensor noise (e.g., the *occupancy grids* of Moravec 1988). Outdoor robots often use stereo vision (see also MACHINE VISION and STEREO AND MOTION PERCEPTION). While computationally expensive, stereo has the advantages of being able to detect objects at greater distances and with good resolution. It also gives three-dimensional data, which is important for outdoor, rough-terrain navigation. Color vision has also been successfully employed, especially to detect boundaries, such as between walls and floors. Other researchers have investigated using lasers (e.g., *Sojourner*), radar, and infrared sensors to detect objects in the environment.

Deciding how to move is often divided into local navigation (obstacle avoidance), for reacting quickly, and global, map-based navigation, for planning good routes. Many techniques have been developed for avoiding obstacles

while continuing to move toward some desired goal. The *potential field* approach (Khatib 1985; Arkin 1989) treats obstacles as repulsive forces and goals as attractors. The vector sum of all forces is used to determine the desired robot heading. This calculation can be done very quickly, enabling robots to avoid moving obstacles, as well. The *vector field histogram* approach (Borenstein 1991) essentially looks for wide openings through which to head. It overcomes some of the problems the *potential field* approach has in dealing with crowded environments. More recently, real-time obstacle avoidance algorithms have been developed that take the robot's dynamics into account, enabling much higher travel speeds (Fox, Burgard, and Thrun 1997). Also, approaches using machine learning techniques to learn how to avoid obstacles have proven effective, especially for high-speed highway travel (Thorpe 1990; see also ROBOTICS AND LEARNING and REINFORCEMENT LEARNING)

Early approaches to global, map-based navigation were based on metric maps—geometrically accurate, usually grid-based, representations. To estimate position with respect to the map, robots would typically use *dead reckoning,* (also called "internal odometry"—measuring position and orientation by counting wheel rotations). Such approaches were not very reliable: Position, and especially orientation, error would gradually increase until the robot was hopelessly lost. (On the other hand, widespread use of the Global Positioning System or GPS and inertial navigation units or INUs have made position estimation a non-issue for many outdoor robots.)

To avoid this problem of "dead reckoning error," and to avoid the need for geometrically accurate maps, researchers developed *landmark-based* navigation schemes (Kuipers and Byun 1993; Kortenkamp and Weymouth 1994). In these approaches, the map is represented as a topological graph, with nodes representing *landmarks* ("important places," such as corridor junctions or doorways) and with arcs representing methods for traveling from landmark to landmark (e.g., "Turn right and travel forward, using local obstacle avoidance"). Each landmark is associated with a set of features that can be used by the robot to determine when it has arrived at that place. Researchers have used both sonar (e.g., to detect corridor junctions) and vision as the basis for defining landmarks (Kortenkamp and Weymouth 1994). Landmark-based navigation can be fairly reliable and is readily amenable to learning a map of the environment. It has difficulties, however, in situations where landmarks can be easily confused (e.g., two junctions very near one another) or where the robot misses seeing particular landmarks.

To combine the best of the metric and landmark-based schemes, some researchers have investigated *probabilistic* approaches that explicitly represent map, actuator, and sensor uncertainty. One approach uses partially observable Markov decision process (POMDP) models to model the robot's state—its position and orientation (Nourbakhsh, Powers, and Birchfield 1995; Simmons and Koenig 1995). The robot maintains a probability distribution over what state it is in, and updates the probability distribution based on Bayes's rule as it moves and observes features (see also HIDDEN MARKOV MODELS). The robot associates actions with either states or probability distributions, and uses its

Figure 1.

belief state to decide how to best move. Such probabilistic navigation approaches tend to be very reliable: While the robot may never know exactly where it is, neither does it ever (or rarely) get lost. The approach has been used in an office delivery robot, Carnegie Mellon's Xavier (Simmons et al. 1997; see figure 1), which has traveled over 150 kilometers with a 95 percent success rate, and in a museum tour guide robot, Bonn University's Rhino, which has a greater than 98 percent success rate in achieving its intended tasks.

A sequential perceive/decide/act cycle is often inadequate to ensure real-time response. Mobile robots must be able to do all this concurrently. To this end, much research in mobile robots has focused on *execution architectures* that support concurrent perception, action, and planning (see also INTELLIGENT AGENT ARCHITECTURE). *Behavior-based* architectures consist of concurrently operating sets of behaviors that process sensor information and locally determine the best action to take (Brooks 1986; see also BEHAVIOR-BASED ROBOTICS). The decisions of all applicable behaviors are *arbitrated* using different types of voting mechanisms. Behavior-based systems tend to be very reactive to change in the environment and can be very robust, but it is often difficult to ensure that unintended interactions

among behaviors do not occur. An *executive* (or *sequencer*) is often used to manage the flow of control in robot systems. The executive is typically responsible for decomposing tasks into subtasks, sequencing tasks and dispatching them at the right times, and providing constructs for monitoring execution and handling exceptions (Firby 1987; Gat 1996; Simmons 1994). *Tiered* (or *layered*) architectures integrate planners, an executive, and behaviors in a hierarchical fashion, to enable very complex and reliable behavior (Bonasso et al. 1997). While such layered architectures are relatively new, they have proven to be quite flexible and are rapidly gaining popularity. Other architectural approaches include layers of more and more abstract feedback loops (Albus 1991) and architectures where the role of the planner is to provide schedules that can be guaranteed to run on a real-time system (Musliner, Durfee, and Shin 1993).

Modal Logic

In classical propositional LOGIC all the operators are *truth-functional.* That is to say, the truth or falsity of a complex formula depends only on the truth or falsity of its simpler propositional constituents. Modal logic is concerned to understand propositions about what *must* or *might* be the case. We might, for example, have two propositions alike in truth value, both true say, where one is true and could not possibly be false, while the other is true but might easily have been false. Thus it *must* be that $2 + 2 = 4$, but while it is true that I am writing this entry, it might easily not have been. Modal logic extends the well-formed formulas (wff) of classical logic by the addition of a one-place sentential operator L (or $\square$), interpreted as meaning "It is necessary that." Using this operator, a one-place operator M (or $\Diamond$) meaning "It is possible that" may be defined as $\sim L\sim$, where $\sim$ is a (classical) negation operator, and a two-place operator

$\dashv$ meaning "entails" may be defined as $\alpha \dashv \beta =_{df} L(\alpha \supset \beta)$, where $\supset$ is classical material implication. In fact, any one of L, M, or $\dashv$ can be taken as primitive, and the others defined in terms of it.

Although Lp is usually read as "Necessarily p," it need not be restricted to a single narrowly conceived sense of "necessarily." Very often, for example, when we say that something *must* be so, we can be taken to be claiming that it *is* so; and if we take L to express "must be" in this sense, we shall want to have it as a principle that whenever Lp is true, so is p itself. A system of logic that expresses this idea will have $Lp \supset p$ as one of its valid formulas. On the other hand, there are uses of words such as "must" and "necessary" that express not what necessarily *is so* but rather what *ought to be so,* and if we interpret L in accordance with these uses, we shall want to allow the possibility that Lp may be true but p itself false because people do not always do what they ought to do. And fruitful systems of logic have been inspired by the idea of taking the necessity operator to mean, for example, "It will always be the case that," "It is known that," or "It is provable that." In fact, one of the important features of modal logic is that out of the same basic material can be constructed a variety of systems that reflect a variety of interpretations of L, within a range that can be indicated, somewhat loosely, by calling L a "necessity operator."

In the early days of modal logic, disputes centered round the question of whether a given principle of modal logic was correct. Typically, these disputes involved formulas in which one modal operator occurs within the scope of another—formulas such as $Lp \supset LLp$. Is a necessary proposition necessarily necessary? A number of different modal systems were produced that reflected different views about which principles were correct. Until the early sixties, however, modal logics were discussed almost exclusively as axiomatic systems without access to a notion of validity of the kind used, for example, in the truth table method for determining the validity of wff of the classical propositional calculus. The semantical breakthrough came by using the idea that a necessary proposition is one true in all possible worlds. But whether another world counts as possible may be held to be relative to the world of origin. Thus an interpretation or *model* for a modal system would consist of a set W of possible worlds and a relation R of *accessibility* between them. For any wff α and world w, $L\alpha$ will be true at w iff α itself is true at every w' such that wRw'. It can then happen that whether a principle of modal logic holds can depend on properties of the accessibility relation. Suppose that R is required to be transitive, that is, suppose that, for any worlds w_1, w_2, and w_3, if w_1Rw_2 and w_2Rw_3, then w_1Rw_3. If so, then $Lp \supset LLp$ will be valid, but if nontransitive models are permitted, it need not be. If R is reflexive, that is, if wRw for every world w, then $Lp \supset p$ is valid. Thus different systems of modal logic can represent different ways of restricting necessity.

It is possible to extend modal logic by having logics that involve more than one modal operator. One particularly important class of multimodal systems is the class of *tense logics.* A tense logic has two operators, L_1 and L_2, where L_1 means "it always will be the case that" and L_2 means "it always has been the case that". (In a tense logic L_1 and L_2

are often written G and H, with their possibility versions as P for $\sim H\sim$, and F for $\sim G\sim$.) More elaborate families of modal operators are suggested by possible interpretations of modal logic in computer science. In these interpretations the "worlds" are states in the running of a program. If π is a computer program, then $[\pi]\alpha$ means that after program π has been run, α will be true. If w is any "world," then $w\mathrm{R}_\pi w'$ means that state w' results from the running of program π. This extension of modal logic is called "dynamic logic."

First-order predicate logic can also be extended by the addition of modal operators. The most interesting consequences of such extensions are those which affect "mixed" principles, principles that relate quantifiers and modal operators and that cannot be stated at the level of modal propositional logic or nonmodal predicate logic. Thus where α is any wff, $\exists x L\alpha \supset L\exists x\alpha$ is valid, but for some wff $L\exists x\alpha \supset \exists x L\alpha$ need not be. (Even if a game must have a winner, there need be no one who must win.) In some cases the principles of the extended system will depend on the propositional logic on which it is based. An example is the schema $\forall x L\alpha \supset L\forall x\alpha$ (often known as the "Barcan formula"), which is provable in some modal systems but not in others. If both directions are assumed, so that we have $\forall x L\alpha \equiv L\forall x\alpha$, then this formula expresses the principle that the domain of individuals is held constant as we move from one world to another accessible world.

When identity is added, even more questions arise. The usual axioms for identity easily allow the derivation of $(x = y) \supset L(x = y)$, but should we really say that all identities are necessary? Questions like this bring us to the boundary between modal logic and metaphysics and remind us of the rich potential that the theory of possible worlds has for illuminating such issues. POSSIBLE WORLDS SEMANTICS can be generalized to deal with any operators whose meanings are operations on propositions as sets of possible worlds, and form a congenial tool for those who think that the meaning of a sentence is its truth conditions, and that these should be taken literally as a set of possible worlds—the worlds in which the sentence is true. Such generalizations give rise to fruitful tools in providing a framework for semantical theories for natural languages.

Modeling Neuropsychological Deficits

Patterns of cognitive breakdown after brain damage in humans can often be interpreted in terms of damage to particular components of theories of normal cognition developed within cognitive science. Along with the new methods of functional neuroimaging, neurological impairments of cognition provide us with prime evidence about the organization of cognitive systems in the human brain. Yet neuropsychologists have long been aware that the relation between a behaviorally manifest cognitive deficit and an underlying cognitive lesion may be complex. As early as the nineteenth century, authors such as John Hughlings-Jackson (1873) cautioned that the brain is a distributed and highly interactive system, such that local damage to one part can unleash new modes of functioning in the remaining parts of the system. As a result, one cannot assume that a patient's behavior following brain damage is the direct result of a simple subtraction of one or more components of the mind, with those that remain functioning normally. More likely, it results from a combination of the subtraction of some components, and changes in the functioning of other components that had previously been influenced by the missing components. At stake in deciding between these two types of account is not only our understanding of cognition in neurological patients but also the inferences we draw from such patients about the organization of the normal cognitive system.

Computational modeling provides a conceptual framework, and concrete tools, for reasoning about the effects of local lesions in distributed, interactive systems such as the brain (Farah 1994). It has proved helpful in understanding a number of different neuropsychological disorders. In the second part of this article, three examples will be presented of computational models that provide alternative interpretations of a neuropsychological disorder, with correspondingly different implications for theories of normal cognition.

Many of the computational models used in neuropsychology are parallel distributed processing (PDP) models (see COGNITIVE MODELING, CONNECTIONIST and NEURAL NETWORKS), which share certain features with what is known of brain function. These brain-like features include the use of distributed representations, the large number of inputs to and outputs from each unit, the modifiable connections between units, the existence of both inhibitory and excitatory connections, summation rules, bounded activations, and thresholds. Of course, there are many important differences between the computation of PDP models and real brains; for example, even the biggest PDP networks are tiny compared to the brain, PDP models have just one kind of "unit," compared to a variety of types of neurons, and just one kind of activation (which can act excitatorily or inhibitorily) rather than a multitude of different neurotransmitters, and so on. Computational architectures other than PDP, which have fewer patent correspondences to real neural computation, have also been used to mediate inferences between the behavioral impairments of brain-damaged patients and theories of normal cognition. The final example to be summarized here is a production system model (see also PRODUCTION SYSTEMS), which sacrifices some explicit resemblances to brain function in the service of making explicit other key aspects of the theory used to explain patient behavior.

Computational models in neuropsychology, like all models in science, are simplifications of reality, with some theory-relevant features and some theory-irrelevant ones.

Our models allow us to find out what aspects of behavior, normal and pathological, can be explained by the theory-relevant attributes, that is, those that are shared with real brain function. Of course, some behavior may be explainable only with the incorporation of other features of neuroanatomy and neurophysiology not used in current computational models. But this is not a problem for models that already account well for patient data. In such cases, the only worry is that the model's success might depend on some theory-irrelevant simplification. We must be on the lookout for such cases, but also recognize that it is unlikely that the success of most models will happen to depend critically on their unrealistic features.

In closing, I provide pointers to three concrete examples of computational modeling in neuropsychology. Only the barest outlines can be given here of the questions to which the models are addressed, and the mechanisms by which the models provide answers.

Deep Dyslexia: Interpreting Error Types

Patients with a READING disorder known as "deep DYS-LEXIA" make two very different types of reading errors, which have been interpreted as indicating that two functionally distinct lesions are needed to account for the reading errors of these patients. Deep dyslexic patients make semantic errors, that is, errors that bear a semantic similarity to the correct word, such as reading *cat* as "dog." They also make visual errors, that is, errors that bear a visual (graphemic) similarity to the correct word, such as reading *cat* as "cot." The fact that both semantic and visual errors are common in deep dyslexia has been taken to imply that deep dyslexic patients have multiple lesions, with one affecting the visual system and another affecting semantic knowledge. However, Hinton and Shallice (1991) showed that a single lesion (removal of units) in an attractor network that has been trained to associate visual patterns with semantic patterns is sufficient to account for these patients' errors. Indeed, they showed that mixtures of error types will be the rule, rather than the exception, when a system normally functions to transform the stimulus representation from one form that has one set of similarity relations (e.g., visual, in which *cot* and *cat* are similar) to another form with different similarity relations (e.g., semantic, in which *cot* and *bed* are similar).

Covert Face Recognition: Dissociation Without Separate Systems

Prosopagnosia is an impairment of FACE RECOGNITION that can occur relatively independently of impairments in object recognition (Farah, Klein, and Levinson 1995; see OBJECT RECOGNITION, HUMAN NEUROPSYCHOLOGY). Recently it has been observed that some prosopagnosic patients retain a high degree of face recognition ability when tested in certain ways ("covert recognition"), while performing poorly on more conventional tasks ("overt recognition") and professing no conscious awareness of face recognition. This has been taken to imply that recognition and awareness depend on dissociable and distinct brain systems (De Haan, Bauer, and Greve 1992). My colleagues and I were able to account for covert recognition with a network consisting of units representing facial appearance, general information

about people, and names, but without any part of the network dedicated to awareness (Farah, O'Reilly, and Vecera 1993). The dissociations between overt and covert recognition observed in three different tasks were simulated by lesioning the visual face representations of the network. Our conclusion was that it is unnecessary to hypothesize separate cognitive components for recognition and awareness of recognition; covert recognition tasks are simply those that can tap the residual knowledge of a damaged visual system.

Frontal Lobe Impairments: Loss of an Executive System, or Working Memory?

Studies of frontal lobe function in nonhuman primates have overwhelmingly focused on WORKING MEMORY, the capacity to hold information "on-line" for an interval of seconds or minutes. By contrast, studies of frontal lobe function in humans have documented a broad array of abilities, including PLANNING, PROBLEM SOLVING, sequencing, and inhibiting impulsive responses (Kimberg, D'Esposito, and Farah 1997). The diversity of abilities affected, and their "high-level" nature, has led many to infer that the cognitive system contains a supervisory "executive," residing in the frontal lobes.

With the animal literature in mind, Dan Kimberg and I wondered whether damage to working memory might produce the varied and apparently high-level behavioral impairments associated with frontal lobe damage (Kimberg and Farah 1993). We used a production system architecture because it makes very explicit the process of weighing different sources of information to select an action. We found that damaging working memory resulted in the system failing a variety of frontal-sensitive tasks, and indeed committing the same types of errors as frontal-damaged patients. This could be understood in terms of the decreased influence of working memory on action selection, and the consequently greater contribution of other influences, including priming of recently executed actions and habit. We concluded that the behavior of frontal-damaged patients does not imply the existence of an executive.

Modularity and Language

Is language a separate mental faculty? Or is it just part of a monolithic general-purpose cognitive system? The idea that the human mind is composed of distinct faculties was hotly debated in the nineteenth century, and the debate continues today. Genetic disorders such as Williams syndrome show that individuals who cannot count to three or solve simple spatial tasks nevertheless develop remarkable language skills that resemble those of a fully fluent and proficient second-language learner (Bellugi et al. 1993; Karmiloff-Smith et al. 1997). The striking disparity in the levels of attainment of Williams syndrome individuals in different cognitive domains clearly argues for differentiated mental capacities.

Studies of the brain lead to the same conclusion. The left hemisphere of the brain is the language-dominant hemisphere for right-handed individuals. In 1861, Paul BROCA identified the third frontal gyrus of the language-dominant hemisphere as an important language area. Performing autopsies on brain-damaged individuals with expressive difficulties characterized by slow, effortful "telegraphic" speech, he found that their lesions involved the third frontal gyrus, now known as "Broca's area." Using modern neuroimaging techniques, Smith and Jonides (1997) have implicated Broca's area specifically in the rehearsal of material in verbal WORKING MEMORY in normal adults, showing an increase in activation with increasing memory load. Spatial tasks requiring active maintenance of spatial information in working memory do not activate Broca's area in the left hemisphere but rather the premotor cortex of the right hemisphere. Though the overall picture of language representation in the brain is far from clear, the debates today mostly concern, not whether areas specialized for language (or object recognition or spatial relations) exist, but how these areas are distributed in the brain and organized.

In studies of normal adult language processing, modularity is discussed in broad terms where the questions concern the separability of grammatical processing from general cognitive processing and in narrow terms where the questions concern the isolability of distinct components of the grammar. One central question is whether a syntactic parser exists that is concerned only with the construction of syntactic structure in production or the identification of syntactic structure in comprehension. In studies of sentence production, Bock (1989) presents evidence for purely syntactic priming not dependent on semantic content or the particular words in a sentence. In other words, having just produced a sentence with a particular syntactic structure, speakers tend to use that same structure again even under circumstances where there is no semantic relation between the two sentences. This result is expected if syntax is a specialized component of a modular language processor in the narrow sense. Similarly in comprehension, Clifton (1993) has shown that a phrase following an optionally transitive verb is first analyzed as an object of that verb even if semantic properties of the clause dictate that ultimately it must be the subject of a following clause. Both studies provide evidence for the existence of autonomous syntactic structures that participate in language processing.

Laying out a very specific modularity thesis, Fodor (1983) hypothesizes that perceptual, or "input," systems share several important characteristics. They apply only to a limited domain, visual inputs, for example. Only domain-specific information (e.g., visual information) is applied in the input system. The operation of the input system is fast and reflexive (automatic and mandatory). There is limited access to the intermediate representations computed—essentially only the final output of the system is available to other systems. Each input system is biologically determined in the sense that its development exhibits a characteristic pace and sequence, it has an associated neural basis, and when that neural basis is damaged, characteristic deficits result. Fodor claims that language is an input system—it exhibits all of the properties of a perceptual system.

To argue that the language system, or more accurately the grammatical system, is domain-specific, Fodor notes that perceivers integrate auditory and visual information about a speech input, perceiving an "average" when the two conflict. Presented with a videotaped speaker forming a consonant in the back of the mouth ("ga") and a synchronized auditory input "ba," perceivers will integrate the forward (labial) articulation of the "ba" with the evidence about the place of articulation of "ga" from the video and perceive "da"—a sound produced farther back in the mouth than labials such as "ba" but farther forward than sounds such as "ga." This is known as the "McGurk effect" (McGurk and MacDonald 1976). The point about the McGurk effect is that it is not simply a guess on the part of confused perceivers about how they can resolve conflicting perceptual inputs. It is an actual perceptual illusion, as expected if SPEECH PERCEPTION is part of an input system specialized for speech inputs.

The most controversial aspect of Fodor's thesis is the claim that language processing is "informationally encapsulated," that only domain-specific information is consulted within a module. The question is whether the massive effects of nonlinguistic world knowledge actually occur after an initial hypothesis has already been identified within the language module on the basis of purely linguistic knowledge or whether world knowledge can direct the grammatical processing of the input. Word recognition is one area where this debate has been played out.

Word recognition studies demonstrate that both meanings of an ambiguous word are activated (Swinney 1979), at least when the word occurs in a semantically neutral sentence. In a semantically biased sentence favoring the more frequent meaning of the ambiguous word, only the dominant (frequent) meaning of the word is activated, suggesting

that perhaps word recognition is not informationally encapsulated. On the other hand, in a sentence biased toward the less frequent meaning of the ambiguous word, *both* the contextually appropriate and the contextually inappropriate meaning of the ambiguous words are activated, as we would expect if word recognition were informationally encapsulated. Proponents of modularity take heart in this latter finding and explain the former finding in terms of the frequent meaning being activated and accepted so quickly that it can inhibit the activation of the less frequent meaning (Rayner and Frazier 1989). Opponents of modularity focus on the former finding and note that it indicates that context can influence word recognition under at least some circumstances (Duffy, Morris, and Rayner 1988, for example).

Ultimately, the survival of Fodor's modularity thesis may depend on its explanatory value. Precisely because a module operates mandatorily and consults only restricted information (identifiable in advance of any particular input), the identification, access, or computation of information can be fast. The grammatical processor's job is a structured and limited one.

If the grammar or grammatical subsystems act as modules, it also becomes less surprising that grammars have the eccentric properties that they do, relying on strict module-internal notions of prominence such as "c-command" (Reinhart 1983), rather than on generally available notions based on, say, precedence, loudness, or the importance of the information conveyed. For many linguists, it is the reappearance within and across languages of the same peculiar notion of prominence or locality that most convincingly argues that grammars form, not loose associations of "biases" or co-occurrence probabilities, but specialized systems or modules.
