To the memory of Henry Bradford Stanton (a.k.a "Harry the hat"), 1921–1997, and to his wife Betty upon her retirement, after twenty-one years with Bradford Books. Harry and Betty were its cofounders and a major force in their own right in the flowering and cross-fertilization of the interdisciplinary cognitive sciences.

Preface

The *MIT Encyclopedia of the Cognitive Sciences* (*MITECS* to its friends) has been four years in the making from conception to publication. It consists of 471 concise articles, nearly all of which include useful lists of references and further readings, preceded by six longer introductory essays written by the volume's advisory editors. We see *MITECS* as being of use to students and scholars across the various disciplines that contribute to the cognitive sciences, including psychology, neuroscience, linguistics, philosophy, anthropology and the social sciences more generally, evolutionary biology, education, computer science, artificial intelligence, and ethology.

Although we prefer to let the volume speak largely for itself, it may help to provide some brief details about the aims and development of the project. One of the chief motivations for this undertaking was the sense that, despite a number of excellent works that overlapped with the ambit of cognitive science as it was traditionally conceived, there was no single work that adequately represented the full range of concepts, methods, and results derived and deployed in cognitive science over the last twenty-five years.

Second, each of the various cognitive sciences differs in its focus and orientation; in addition, these have changed over time and will continue to do so in the future. We see *MITECS* as aiming to represent the scope of this diversity, and as conveying a sense of both the history and future of the cognitive sciences.

Finally, we wanted, through discussions with authors and as a result of editorial review, to highlight links across the various cognitive sciences so that readers from one discipline might gain a greater insight into relevant work in other fields. *MITECS* represents far more than an alphabetic list of topics in the cognitive sciences; it captures a good deal of the structure of the whole enterprise at this point in time, the ways in which ideas are linked together across topics and disciplines, as well as the ways in which authors from very different disciplines converge and diverge in their approaches to very similar topics. As one looks through the encyclopedia as a whole, one takes a journey through a rich and multidimensional landscape of interconnected ideas. Categorization is rarely just that, especially in the sciences. Ideas and patterns are related to one another, and the grounds for categorizations are often embedded in complex theoretical and empirical patterns. *MITECS* illustrates the richness and intricacy of this process and the immense value of cognitive science approaches to many questions about the mind.

All three of the motivations for *MITECS* were instrumental in the internal organization of the project. The core of *MITECS* is the 471 articles themselves, which were assigned to one of six fields that constitute the foundation of the cognitive sciences. One or two advisory editors oversaw the articles in each of these fields and contributed the introductory essays. The fields and the corresponding advisory editors are

Philosophy (Robert A. Wilson)
Psychology (Keith J. Holyoak)
Neurosciences (Thomas D. Albright and Helen J. Neville)
Computational Intelligence (Michael I. Jordan and Stuart Russell)
Linguistics and Language (Gennaro Chierchia)
Culture, Cognition, and Evolution (Dan Sperber and Lawrence Hirschfeld)

These editors advised us regarding both the topics and authors for the articles and assisted in overseeing the review process for each. Considered collectively, the articles represent much of the diversity to be found in the corresponding fields and indicate much of what has been, is, and might be of value for those thinking about cognition from one or another interdisciplinary perspective.

Each introduction has two broad goals. The first is to provide a road map through *MITECS* to the articles in the corresponding section. Because of the arbitrariness of

assigning some articles to one section rather than another, and because of the interdisciplinary vision guiding the volume, the introductions mention not only the articles in the corresponding section but also others from overlapping fields. The second goal is to provide a perspective on the nature of the corresponding discipline or disciplines, particularly with respect to the cognitive sciences. Each introduction should stand as a useful overview of the field it represents. We also made it clear to the editors that their introductions did not have to be completely neutral and could clearly express their own unique perspectives. The result is a vibrant and engaging series of essays.

We have been fortunate in being able to enlist many of the world's leading authorities as authors of the articles. Our directions to contributors were to write articles that are both representative of their topic and accessible to advanced undergraduates and graduate students in the field. The review process involved assigning two reviewers to each article, one an expert from within the same field, the other an outsider from another field represented in *MITECS*; nearly all reviewers were themselves contributors to *MITECS*. In addition, every article was read by at least one of the general editors. Articles that did not seem quite right to either or both of us or to our reviewers were sometimes referred to the advisory editors. One might think that with such short articles (most being between 1,000 and 1,500 words in length), the multiple levels of review were unnecessary, but the selectivity that this brevity necessitated made such a review process all the more worthwhile. Relatedly, as more than one contributor noted in explaining his own tardiness: "This article would have been written sooner if it hadn't been so short!".

Of course the content of the articles will be the chief source of their value to the reader, but given the imposed conciseness, an important part of their value is the guide that their references and further readings provide to the relevant literature. In addition, each article contains cross-references, indicated in SMALL CAPITALS, to related articles and a short list of "see also" cross-references at the end of the article. Responsibility for these cross-references lies ultimately with one of us (RAW), though we are thankful to those authors who took the time to suggest cross-references for their own articles.

We envisioned that many scholars would use *MITECS* as a frequent, perhaps even daily, tool in their research and have designed the references, readings, and cross-references with that use in mind. The electronic version will allow users to download relevant references into their bibliography databases along with considerable cross-classification information to aid future searches. Both of us are surprised at the extent to which we have already come to rely on drafts of articles in *MITECS* for these purposes in our own scholarly pursuits.

Philosophy

Robert A. Wilson

The areas of philosophy that contribute to and draw on the cognitive sciences are various; they include the philosophy of mind, science, and language; formal and philosophical logic; and traditional metaphysics and epistemology. The most direct connections hold between the philosophy of mind and the cognitive sciences, and it is with classical issues in the philosophy of mind that I begin this introduction (section 1). I then briefly chart the move from the rise of materialism as the dominant response to one of these classic issues, the mind-body problem, to the idea of a science of the mind. I do so by discussing the early attempts by introspectionists and behaviorists to study the mind (section 2). Here I focus on several problems with a philosophical flavor that arise for these views, problems that continue to lurk backstage in the theater of contemporary cognitive science.

Between these early attempts at a science of the mind and today's efforts lie two general, influential philosophical traditions, ordinary language philosophy and logical positivism. In order to bring out, by contrast, what is distinctive about the contemporary naturalism integral to philosophical contributions to the cognitive sciences, I sketch the approach to the mind in these traditions (section 3). And before getting to contemporary naturalism itself I take a quick look at the philosophy of science, in light of the legacy of positivism (section 4).

In sections 5 through 7 I get, at last, to the mind in cognitive science proper. Section 5 discusses the conceptions of mind that have dominated the contemporary cognitive sciences, particularly that which forms part of what is sometimes called "classic" cognitive science and that of its connectionist rival. Sections 6 and 7 explore two specific clusters of topics that have been the focus of philosophical discussion of the mind over the last 20 years or so, folk psychology and mental content. The final sections gesture briefly at the interplay between the cognitive sciences and logic (section 8) and biology (section 9).

1 Three Classic Philosophical Issues About the Mind

i. The Mental-Physical Relation

The relation between the mental and the physical is the deepest and most recurrent classic philosophical topic in the philosophy of mind, one very much alive today. In due course, we will come to see why this topic is so persistent and pervasive in thinking about the mind. But to convey something of the topic's historical significance let us begin with a classic expression of the puzzling nature of the relation between the mental and the physical, the MIND-BODY PROBLEM.

This problem is most famously associated with RENÉ DESCARTES, the preeminent figure of philosophy and science in the first half of the seventeenth century. Descartes combined a thorough-going mechanistic theory of nature with a *dualistic* theory of the nature of human beings that is still, in general terms, the most widespread view held by ordinary people outside the hallowed halls of academia. Although nature, including that of the human body, is material and thus completely governed by basic principles of mechanics, human beings are special in that they are composed both of material and nonmaterial or mental stuff, and so are not so governed. In Descartes's own terms, people are essentially a combination of mental substances (minds) and material substances (bodies). This is Descartes's *dualism*. To put it in more common-sense terms, people have both a mind and a body.

Although dualism is often presented as a possible solution to the mind-body problem, a possible position that one might adopt in explaining how the mental and physical are related, it serves better as a way to bring out why there is a "problem" here at all. For if the mind is one type of thing, and the body is another, how do these two

types of things interact? To put it differently, if the mind really is a nonmaterial substance, lacking physical properties such as spatial location and shape, how can it be both the cause of effects in the material world—like making bodies move—and itself be causally affected by that world—as when a thumb slammed with a hammer (bodily cause) causes one to feel pain (mental effect)? This problem of causation between mind and body has been thought to pose a largely unanswered problem for Cartesian dualism.

It would be a mistake, however, to assume that the mind-body problem in its most general form is simply a consequence of dualism. For the general question as to how the mental is related to the physical arises squarely for those convinced that some version of materialism or PHYSICALISM must be true of the mind. In fact, in the next section, I will suggest that one reason for the resilience and relevance of the mind-body problem has been the *rise* of materialism over the last fifty years.

Materialists hold that all that exists is material or physical in nature. Minds, then, are somehow or other composed of arrangements of physical stuff. There have been various ways in which the "somehow or other" has been cashed out by physicalists, but even the view that has come closest to being a consensus view among contemporary materialists—that the mind *supervenes* on the body—remains problematic. Even once one adopts materialism, the task of articulating the relationship between the mental and the physical remains, because even physical minds have special properties, like intentionality and consciousness, that require further explanation. Simply proclaiming that the mind is not made out of distinctly mental substance, but is material like the rest of the world, does little to explain the features of the mind that seem to be distinctively if not uniquely features of physical minds.

ii. The Structure of the Mind and Knowledge

Another historically important cluster of topics in the philosophy of mind concerns what is in a mind. What, if anything, is distinctive of the mind, and how is the mind structured? Here I focus on two dimensions to this issue.

One dimension stems from the RATIONALISM VS. EMPIRICISM debate that reached a high point in the seventeenth and eighteenth centuries. Rationalism and empiricism are views of the nature of human knowledge. Broadly speaking, empiricists hold that all of our knowledge derives from our sensory, experiential, or empirical interaction with the world. Rationalists, by contrast, hold the negation of this, that there is some knowledge that does not derive from experience.

Since at least our paradigms of knowledge—of our immediate environments, of common physical objects, of scientific kinds—seem obviously to be based on sense experience, empiricism has significant intuitive appeal. Rationalism, by contrast, seems to require further motivation: minimally, a list of knowables that represent a prima facie challenge to the empiricist's global claim about the foundations of knowledge. Classic rationalists, such as Descartes, Leibniz, Spinoza, and perhaps more contentiously KANT, included knowledge of God, substance, and abstract ideas (such as that of a triangle, as opposed to ideas of particular triangles). Empiricists over the last three hundred years or so have either claimed that there was nothing to know in such cases, or sought to provide the corresponding empiricist account of how we could know such things from experience.

The different views of the sources of knowledge held by rationalists and empiricists have been accompanied by correspondingly different views of the mind, and it is not hard to see why. If one is an empiricist and so holds, roughly, that there is nothing in the mind that is not first in the senses, then there is a fairly literal sense in which *ideas,* found in the mind, are complexes that derive from *impressions* in the senses. This in turn suggests that the processes that constitute cognition are themselves elaborations of those that constitute perception, that is, that cognition and perception differ only in degree, not kind. The most commonly postulated mechanisms governing these processes are *association* and *similarity,* from Hume's laws of association to feature-extraction in contemporary connectionist networks. Thus, the mind tends to be viewed by empiricists as a *domain-general* device, in that the principles that govern its opera-

tion are constant across various types and levels of cognition, with the common empirical basis for all knowledge providing the basis for parsimony here.

By contrast, in denying that all knowledge derives from the senses, rationalists are faced with the question of what other sources there are for knowledge. The most natural candidate is the mind itself, and for this reason rationalism goes hand in hand with NATIVISM about both the source of human knowledge and the structure of the human mind. If some ideas are innate (and so do not need to be derived from experience), then it follows that the mind already has a relatively rich, inherent structure, one that in turn limits the malleability of the mind in light of experience. As mentioned, classic rationalists made the claim that certain ideas or CONCEPTS were innate, a claim occasionally made by contemporary nativists—most notably Jerry Fodor (1975) in his claim that *all* concepts are innate. However, contemporary nativism is more often expressed as the view that certain implicit knowledge that we have or principles that govern how the mind works—most notoriously, linguistic knowledge and principles—are innate, and so not learned. And because the types of knowledge that one can have may be endlessly heterogeneous, rationalists tend to view the mind as a *domain-specific* device, as one made up of systems whose governing principles are very different. It should thus be no surprise that the historical debate between rationalists and empiricists has been revisited in contemporary discussions of the INNATENESS OF LANGUAGE, the MODULARITY OF MIND, and CONNECTIONISM.

A second dimension to the issue of the structure of the mind concerns the place of CONSCIOUSNESS among mental phenomena. From WILLIAM JAMES's influential analysis of the phenomenology of the stream of consciousness in his *The Principles of Psychology* (1890) to the renaissance that consciousness has experienced in the last ten years (if publication frenzies are anything to go by), consciousness has been thought to be the most puzzling of mental phenomena. There is now almost universal agreement that conscious mental states are a part of the mind. But how large and how important a part? Consciousness has sometimes been thought to exhaust the mental, a view often attributed to Descartes. The idea here is that everything mental is, in some sense, conscious or available to consciousness. (A version of the latter of these ideas has been recently expressed in John Searle's [1992: 156] *connection principle*: "all unconscious intentional states are in principle accessible to consciousness.")

There are two challenges to the view that everything mental is conscious or even available to consciousness. The first is posed by the *unconscious*. SIGMUND FREUD's extension of our common-sense attributions of belief and desire, our folk psychology, to the realm of the unconscious played and continues to play a central role in PSYCHO-ANALYSIS. The second arises from the conception of cognition as information processing that has been and remains focal in contemporary cognitive science, because such information processing is mostly *not* available to consciousness. If cognition so conceived is mental, then most mental processing is not available to consciousness.

iii. The First- and Third-Person Perspectives

Occupying center stage with the mind-body problem in traditional philosophy of mind is the *problem of other minds,* a problem that, unlike the mind-body problem, has all but disappeared from philosophical contributions to the cognitive sciences. The problem is often stated in terms of a contrast between the relatively secure way in which I "directly" know about the existence of *my own* mental states, and the far more epistemically risky way in which I must infer the existence of the mental states of others. Thus, although I can know about my own mental states simply by introspection and self-directed reflection, because this way of finding out about mental states is peculiarly first-person, I need some other type of evidence to draw conclusions about the mental states of others. Naturally, an agent's behavior is a guide to what mental states he or she is in, but there seems to be an epistemic gap between this sort of evidence and the attribution of the corresponding mental states that does not exist in the case of self-ascription. Thus the problem of other minds is chiefly an *epistemological* problem, sometimes expressed as a form of skepticism about the justification that we have for attributing mental states to others.

There are two reasons for the waning attention to the problem of other minds *qua problem* that derive from recent philosophical thought sensitive to empirical work in the cognitive sciences. First, research on introspection and SELF-KNOWLEDGE has raised questions about how "direct" our knowledge of our own mental states and of the SELF is, and so called into question traditional conceptions of first-person knowledge of mentality. Second, explorations of the THEORY OF MIND, ANIMAL COMMUNICATION, and SOCIAL PLAY BEHAVIOR have begun to examine and assess the sorts of attribution of mental states that are actually justified in empirical studies, suggesting that third-person knowledge of mental states is not as limited as has been thought. Considered together, this research hints that the contrast between first- and third-person knowledge of the mental is not as stark as the problem of other minds seems to intimate.

Still, there is something distinctive about the first-person perspective, and it is in part as an acknowledgment of this, to return to an earlier point, that consciousness has become a hot topic in the cognitive sciences of the 1990s. For whatever else we say about consciousness, it seems tied ineliminably to the first-person perspective. It is a state or condition that has an irreducibly *subjective* component, something with an essence to be experienced, and which presupposes the existence of a subject of that experience. Whether this implies that there are QUALIA that resist complete characterization in materialist terms, or other limitations to a science of the mind, remain questions of debate.

2   From Materialism to Mental Science

In raising issue *i.*, the mental-physical relation, in the previous section, I implied that materialism was the dominant ontological view of the mind in contemporary philosophy of mind. I also suggested that, if anything, general convergence on this issue has intensified interest in the mind-body problem. For example, consider the large and lively debate over whether contemporary forms of materialism are compatible with genuine MENTAL CAUSATION, or, alternatively, whether they commit one to EPIPHENOMENALISM about the mental (Kim 1993; Heil and Mele 1993; Yablo 1992). Likewise, consider the fact that despite the dominance of materialism, some philosophers maintain that there remains an EXPLANATORY GAP between mental phenomena such as consciousness and any physical story that we are likely to get about the workings of the brain (Levine 1983; cf. Chalmers 1996). Both of these issues, very much alive in contemporary philosophy of mind and cognitive science, concern the mind-body problem, even if they are not always identified in such old-fashioned terms.

I also noted that a healthy interest in the first-person perspective persists within this general materialist framework. By taking a quick look at the two major initial attempts to develop a systematic, scientific understanding of the mind—late nineteenth-century introspectionism and early twentieth-century behaviorism—I want to elaborate on these two points and bring them together.

Introspectionism was widely held to fall prey to a problem known as the *problem of the homunculus*. Here I argue that behaviorism, too, is subject to a variation on this very problem, and that both versions of this problem continue to nag at contemporary sciences of the mind.

Students of the history of psychology are familiar with the claim that the roots of contemporary psychology can be dated from 1879, with the founding of the first experimental laboratory devoted to psychology by WILHELM WUNDT in Leipzig, Germany. As an *experimental* laboratory, Wundt's laboratory relied on the techniques introduced and refined in physiology and psychophysics over the preceding fifty years

by HELMHOLTZ, Weber, and Fechner that paid particular attention to the report of SEN-SATIONS. What distinguished Wundt's as a laboratory of *psychology* was his focus on the data reported in consciousness via the first-person perspective; psychology was to be the science of immediate experience and its most basic constituents. Yet we should remind ourselves of how restricted this conception of psychology was, particularly relative to contemporary views of the subject.

First, Wundt distinguished between mere INTROSPECTION, first-person reports of the sort that could arise in the everyday course of events, and experimentally manipu-lable self-observation of the sort that could only be triggered in an experimental con-text. Although Wundt is often thought of as the founder of an introspectionist methodology that led to a promiscuous psychological ontology, in disallowing mere introspection as an appropriate method for a science of the mind he shared at least the sort of restrictive conception of psychology with *both* his physiological predecessors and his later behaviorist critics.

Second, Wundt thought that the vast majority of ordinary thought and cognition was *not* amenable to acceptable first-person analysis, and so lay beyond the reach of a scientific psychology. Wundt thought, for example, that belief, language, personality, and SOCIAL COGNITION could be studied systematically only by detailing the cultural mores, art, and religion of whole societies (hence his four-volume *Völkerpsychologie* of 1900–1909). These studies belonged to the humanities (*Geisteswissenshaften*) rather than the experimental sciences (*Naturwissenschaften*), and were undertaken by anthropologists inspired by Wundt, such as BRONISLAW MALINOWSKI.

Wundt himself took one of his early contributions to be a solution of the mind-body problem, for that is what the data derived from the application of the experimental method to distinctly psychological phenomena gave one: correlations between the mental and the physical that indicated how the two were systematically related. The discovery of psychophysical laws of this sort showed how the mental was related to the physical. Yet with the expansion of the domain of the mental amenable to experi-mental investigation over the last 150 years, the mind-body problem has taken on a more acute form: just how do we get all that mind-dust from merely material mechan-ics? And it is here that the problem of the homunculus arises for introspectionist psy-chology after Wundt.

The problem, put in modern guise, is this. Suppose that one introspects, say, in order to determine the location of a certain feature (a cabin, for example) on a map that one has attempted to memorize (Kosslyn 1980). Such introspection is typically reported in terms of exploring a mental image with one's *mind's eye*. Yet we hardly want our psychological story to end there, because it posits a process (introspection) and a processor (the mind's eye) that themselves cry out for further explanation. The problem of the homunculus is the problem of leaving undischarged homunculi ("little men" or their equivalents) in one's *explanantia,* and it persists as we consider an elab-oration on our initial introspective report. For example, one might well report forming a mental image of the map, and then scanning around the various features of the map, zooming in on them to discern more clearly what they are to see if any of them is the sought-after cabin. To take this introspective report seriously as a guide to the under-lying psychological mechanisms would be to posit, minimally, an *imager* (to form the initial image), a *scanner* (to guide your mind's eye around the image), and a *zoomer* (to adjust the relative sizes of the features on the map). But here again we face the problem of the homunculus, because such "mechanisms" themselves require further psychological decomposition.

To be faced with the problem of the homunculus, of course, is not the same as to succumb to it. We might distinguish two understandings of just what the "problem" is here. First, the problem of the homunculus could be viewed as a problem specifically for introspectionist views of psychology, a problem that was never successfully met and that was principally responsible for the abandonment of introspectionism. As such, the problem motivated BEHAVIORISM in psychology. Second, the problem of the homunculus might simply be thought of as a challenge that *any* view that posits inter-nal mental states must respond to: to show how to discharge all of the homunculi introduced in a way that is acceptably materialistic. So construed, the problem

remains one that has been with us more recently, in disputes over the psychological reality of various forms of GENERATIVE GRAMMAR (e.g., Stabler 1983); in the nativism that has been extremely influential in post-Piagetian accounts of COGNITIVE DEVELOPMENT (Spelke 1990; cf. Elman et al. 1996); and in debates over the significance of MENTAL ROTATION and the nature of IMAGERY (Kosslyn 1994; cf. Pylyshyn 1984: ch.8).

With Wundt's own restrictive conception of psychology and the problem of the homunculus in mind, it is with some irony that we can view the rise and fall of behaviorism as the dominant paradigm for psychology subsequent to the introspectionism that Wundt founded. For here was a view so deeply indebted to materialism and the imperative to explore psychological claims only by reference to what was acceptably experimental that, in effect, in its purest form it appeared to do away with the distinctively mental altogether! That is, because objectively observable behavioral responses to objectively measurable stimuli are all that could be rigorously explored, experimental psychological investigations would need to be significantly curtailed, relative to those of introspectionists such as Wundt and Titchener. As J. B. Watson said in his early, influential "Psychology as the Behaviorist Views It" in 1913, "Psychology as behavior will, after all, have to neglect but few of the really essential problems with which psychology as an introspective science now concerns itself. In all probability even this residue of problems may be phrased in such a way that refined methods in behavior (which certainly must come) will lead to their solution" (p. 177).

Behaviorism brought with it not simply a global conception of psychology but specific methodologies, such as CONDITIONING, and a focus on phenomena, such as that of LEARNING, that have been explored in depth since the rise of behaviorism. Rather than concentrate on these sorts of contribution to the interdisciplinary sciences of the mind that behaviorists have made, I want to focus on the central problem that faced behaviorism as a research program for reshaping psychology.

One of the common points shared by behaviorists in their philosophical and psychological guises was a commitment to an *operational* view of psychological concepts and thus a suspicion of any reliance on concepts that could not be operationally characterized. Construed as a view of scientific *definition* (as it was by philosophers), operationalism is the view that scientific terms must be defined in terms of observable and measurable operations that one can perform. Thus, an operational definition of "length," as applied to ordinary objects, might be: "the measure we obtain by laying a standard measuring rod or rods along the body of the object." Construed as a view of scientific *methodology* (as it was by psychologists), operationalism claims that the subject matter of the sciences should be objectively observable and measurable, by itself a view without much content.

The real bite of the insistence on operational definitions and methodology for psychology came via the application of operationalism to unobservables, for the various feelings, sensations, and other internal states reported by introspection, themselves unobservable, proved difficult to operationalize adequately. Notoriously, the introspective reports from various psychological laboratories produced different listings of the basic feelings and sensations that made up consciousness, and the lack of agreement here generated skepticism about the reliability of introspection as a method for revealing the structure of the mind. In psychology, this led to a focus on behavior, rather than consciousness, and to its exploration through observable stimulus and response: hence, behaviorism. But I want to suggest that this reliance on operationalism itself created a version of the problem of the homunculus for behaviorism. This point can be made in two ways, each of which offers a reinterpretation of a standard criticism of behaviorism. The first of these criticisms is usually called "philosophical behaviorism," the attempt to provide conceptual analyses of mental state terms exclusively in terms of behavior; the second is "psychological behaviorism," the research program of studying objective and observable behavior, rather than subjective and unobservable inner mental episodes.

First, as Geach (1957: chap. 4) pointed out with respect to belief, behaviorist analyses of individual folk psychological states are bound to fail, because it is only in concert with many other propositional attitudes that any given such attitude has

behavioral effects. Thus, to take a simple example, we might characterize the belief that it is raining as the tendency to utter "yes" when asked, "Do you believe that it is raining?" But one reason this would be inadequate is that one will engage in this verbal behavior only if one *wants* to answer truthfully, and only if one *hears* and *understands* the question asked, where each of the italicized terms above refers to some other mental state. Because the problem recurs in *every* putative analysis, this implies that a behavioristically acceptable construal of folk psychology is not possible. This point would seem to generalize beyond folk psychology to representational psychology more generally.

So, in explicitly attempting to do without internal mental representations, behaviorists themselves are left with mental states that must simply be assumed. Here we are not far from those undischarged homunculi that were the bane of introspectionists, especially once we recognize that the metaphorical talk of "homunculi" refers precisely to internal mental states and processes that themselves are not further explained.

Second, as Chomsky (1959: esp. p. 54) emphasized in his review of Skinner's *Verbal Behavior,* systematic attempts to operationalize psychological language invariably smuggle in a reference to the very mental processes they are trying to do without. At the most general level, the behavior of interest to the linguist, Skinner's "verbal behavior," is difficult to characterize adequately without at least an implicit reference to the sorts of psychological mechanism that generate it. For example, linguists are not interested in mere noises that have the same physical properties—"harbor" may be pronounced so that its first syllable has the same acoustic properties as an exasperated grunt—but in parts of speech that are taxonomized at least partially in terms of the surrounding mental economy of the speaker or listener.

The same seems true for *all* of the processes introduced by behaviorists—for example, stimulus control, reinforcement, conditioning—insofar as they are used to characterize complex, human behavior that has a natural psychological description (making a decision, reasoning, conducting a conversation, issuing a threat). What marks off their instances as behaviors *of the same kind* is not exclusively their physical or behavioral similarity, but, in part, the common, internal psychological processes that generate them, and that they in turn generate. Hence, the irony: behaviorists, themselves motivated by the idea of reforming psychology so as to generalize about objective, observable behavior and so avoid the problem of the homunculus, are faced with undischarged homunculi, that is, irreducibly mental processes, in their very own alternative to introspectionism.

The two versions of the problem of the homunculus are still with us as a Scylla and Charybdis for contemporary cognitive scientists to steer between. On the one hand, theorists need to avoid building the very cognitive abilities that they wish to explain into the models and theories they construct. On the other, in attempting to side-step this problem they also run the risk of masking the ways in which their "objective" taxonomic categories presuppose further internal psychological description of precisely the sort that gives rise to the problem of the homunculus in the first place.

3   A Detour Before the Naturalistic Turn

Given the state of philosophy and psychology in the early 1950s, it is surprising that within twenty-five years there would be a thriving and well-focused interdisciplinary unit of study, cognitive science, to which the two are central. As we have seen, psychology was dominated by behaviorist approaches that were largely skeptical of positing internal mental states as part of a serious, scientific psychology. And Anglo-American philosophy featured two distinct trends, each of which made philosophy more insular with respect to other disciplines, and each of which served to reinforce the behaviorist orientation of psychology.

First, ordinary language philosophy, particularly in Great Britain under the influence of Ludwig Wittgenstein and J. L. Austin, demarcated distinctly philosophical problems as soluble (or dissoluble) chiefly by reference to what one would ordinarily say, and tended to see philosophical views of the past and present as the result of confusions in how philosophers and others come to use words that generally have a clear sense in their ordinary contexts. This approach to philosophical issues in the post-war period has recently been referred to by Marjorie Grene (1995: 55) as the "Bertie Wooster season in philosophy," a characterization I suspect would seem apt to many philosophers of mind interested in contemporary cognitive science (and in P. G. Wodehouse). Let me illustrate how this approach to philosophy served to isolate the philosophy of mind from the sciences of the mind with perhaps the two most influential examples pertaining to the mind in the ordinary language tradition.

In *The Concept of Mind,* Gilbert Ryle (1949: 17) attacked a view of the mind that he referred to as "Descartes' Myth" and "the dogma of the Ghost in the Machine"—basically, dualism—largely through a repeated application of the objection that dualism consisted of an extended *category mistake*: it "represents the facts of mental life as if they belonged to one logical type or category . . . when they actually belong to another." Descartes' Myth represented a category mistake because in supposing that there was a special, inner theater on which mental life is played out, it treated the "facts of mental life" as belonging to a special category of facts, when they were simply facts about how people can, do, and would behave in certain circumstances. Ryle set about showing that for the range of mental concepts that were held to refer to private, internal mental episodes or events according to Descartes' Myth—intelligence, the will, emotion, self-knowledge, sensation, and imagination—an appeal to what one would ordinarily say both shows the dogma of the Ghost in the Machine to be false, and points to a positive account of the mind that was behaviorist in orientation. To convey why Ryle's influential views here turned philosophy of mind away from science rather than towards it, consider the opening sentences of *The Concept of Mind*: "This book offers what may with reservations be described as a theory of the mind. But it does not give new information about minds. We possess already a wealth of information about minds, information which is neither derived from, nor upset by, the arguments of philosophers. The philosophical arguments which constitute this book are intended not to increase what we know about minds, but to rectify the logical geography of the knowledge which we already possess" (Ryle 1949: 9). The "we" here refers to ordinary folk, and the philosopher's task in articulating a theory of mind is to draw on what we already know about the mind, rather than on arcane, philosophical views or on specialized, scientific knowledge.

The second example is Norman Malcolm's *Dreaming,* which, like *The Concept of Mind,* framed the critique it wished to deliver as an attack on a Cartesian view of the mind. Malcolm's (1959: 4) target was the view that "dreams are the activity of the mind during sleep," and associated talk of DREAMING as involving various mental acts, such as remembering, imagining, judging, thinking, and reasoning. Malcolm argued that such dream-talk, whether it be part of commonsense reflection on dreaming (How long do dreams last?; Can you work out problems in your dreams?) or a contribution to more systematic empirical research on dreaming, was a confusion arising from the failure to attend to the proper "logic" of our ordinary talk about dreaming. Malcolm's argument proceeded by appealing to how one would *use* various expressions and sentences that contained the word "dreaming." (In looking back at Malcolm's book, it is striking that nearly every one of the eighteen short chapters begins with a paragraph about words and what one would say with or about them.)

Malcolm's central point was that there was no way to *verify* any given claim about such mental activity occurring while one was asleep, because the commonsense criteria for the application of such concepts were incompatible with saying that a person was asleep or dreaming. And because there was no way to tell whether various attributions of mental states to a sleeping person were correct, such attributions were meaningless. These claims not only could be made without an appeal to any empirical details about dreaming or SLEEP, but implied that the whole enterprise of investigating dreaming empirically itself represented some sort of *logical* muddle.

Malcolm's point became more general than one simply about dreaming (or the word "dreaming"). As he said in a preface to a later work, written after "the notion that thoughts, ideas, memories, sensations, and so on 'code into' or 'map onto' neural firing patterns in the brain" had become commonplace: "I believe that a study of our psychological concepts can show that [such] psycho-physical isomorphism is not a coherent assumption" (Malcolm 1971: x). Like Ryle's straightening of the logical geography of our knowledge of minds, Malcolm's appeal to the study of our psychological concepts could be conducted without any knowledge gleaned from psychological science (cf. Griffiths 1997: chap. 2 on the emotions).

Quite distinct from the ordinary language tradition was a second general perspective that served to make philosophical contributions to the study of the mind "distinctive" from those of science. This was logical positivism or empiricism, which developed in Europe in the 1920s and flourished in the United States through the 1930s and 1940s with the immigration to the United States of many of its leading members, including Rudolph Carnap, Hans Reichenbach, Herbert Feigl, and Carl Hempel. The logical empiricists were called "empiricists" because they held that it was via the senses and observation that we came to know about the world, deploying this empiricism with the logical techniques that had been developed by Gottlob Frege, Bertrand Russell, and Alfred Whitehead. Like empiricists in general, the logical positivists viewed the sciences as the paradigmatic repository of knowledge, and they were largely responsible for the rise of philosophy of science as a distinct subdiscipline within philosophy.

As part of their reflection on science they articulated and defended the doctrine of the UNITY OF SCIENCE, the idea that the sciences are, in some sense, essentially unified, and their empiricism led them to appeal to PARSIMONY AND SIMPLICITY as grounds for both theory choice within science and for preferring theories that were ontological Scrooges. This empiricism came with a focus on *what could be verified,* and with it scepticism about traditional metaphysical notions, such as God, CAUSATION, and essences, whose instances could not be verified by an appeal to the data of sense experience. This emphasis on verification was encapsulated in the verification theory of meaning, which held that the meaning of a sentence was its method of verification, implying that sentences without any such method were *meaningless.* In psychology, this fueled skepticism about the existence of internal mental representations and states (whose existence could not be objectively verified), and offered further philosophical backing for behaviorism.

In contrast to the ordinary language philosophers (many of whom would have been professionally embarrassed to have been caught knowing anything about science), the positivists held that philosophy was to be informed about and sensitive to the results of science. The distinctive task of the philosopher, however, was not simply to describe scientific practice, but to offer a *rational reconstruction* of it, one that made clear the logical structure of science. Although the term "*rational reconstruction*" was used first by Carnap in his 1928 book *The Logical Construction of the World,* quite a general epistemological tract, the technique to which it referred came to be applied especially to scientific concepts and theories.

This played out in the frequent appeal to the distinction between the *context of discovery* and the *context of justification,* drawn as such by Reichenbach in *Experience and Prediction* (1938) but with a longer history in the German tradition. To consider an aspect of a scientific view in the context of discovery was essentially to raise psychological, sociological, or historical questions about how that view originated, was developed, or came to be accepted or rejected. But properly philosophical explorations of science were to be conducted in the context of justification, raising questions and making claims about the logical structure of science and the concepts it used. Rational reconstruction was the chief way of divorcing the relevant scientific theory from its mere context of discovery.

A story involving Feigl and Carnap nicely illustrates the divorce between philosophy and science within positivism. In the late 1950s, Feigl visited the University of California, Los Angeles, to give a talk to the Department of Philosophy, of which Carnap was a member. Feigl's talk was aimed at showing that a form of physicalism, the

mind-brain identity theory, faced an empirical problem, since science had little, if anything, to say about the "raw feel" of consciousness, the WHAT-IT'S-LIKE of experience. During the question period, Carnap raised his hand, and was called on by Feigl. "Your claim that current neurophysiology tells us nothing about raw feels is wrong! You have overlooked the discovery of alpha-waves in the brain," exclaimed Carnap. Feigl, who was familiar with what he thought was the relevant science, looked puzzled: "Alpha-waves? What are they?" Carnap replied: "My dear Herbert. You tell me what raw feels are, and I will tell you what alpha-waves are."

Of the multiple readings that this story invites (whose common denominator is surely Carnap's savviness and wit), consider those that take Carnap's riposte to imply that he thought that one could defend materialism by, effectively, making up the science to fit whatever phenomena critics could rustle up. A rather extreme form of rational reconstruction, but it suggests one way in which the positivist approach to psychology could be just as a priori and so divorced from empirical practice as that of Ryle and Malcolm.

4   The Philosophy of Science

The philosophy of science is integral to the cognitive sciences in a number of ways. We have already seen that positivists held views about the overall structure of science and the grounds for theory choice in science that had implications for psychology. Here I focus on three functions that the philosophy of science plays vis-à-vis the cognitive sciences: it provides a perspective on the place of psychology among the sciences; it raises questions about what any science can tell us about the world; and it explores the nature of knowledge and how it is known. I take these in turn.

One classic way in which the sciences were viewed as being unified, according to the positivists, was via reduction. REDUCTIONISM, in this context, is the view that intuitively "higher-level" sciences can be reduced, in some sense, to "lower-level" sciences. Thus, to begin with the case perhaps of most interest to MITECS readers, psychology was held to be reducible in principle to biology, biology to chemistry, chemistry to physics. This sort of reduction presupposed the existence of *bridge laws,* laws that exhaustively characterized the concepts of any higher-level science, and the generalizations stated using them, in terms of those concepts and generalizations at the next level down. And because reduction was construed as relating theories of one science to those of another, the advocacy of reductionism went hand-in-hand with a view of EXPLANATION that gave lower-level sciences at least a usurpatory power over their higher-level derivatives.

This view of the structure of science was opposed to EMERGENTISM, the view that the properties studied by higher-level sciences, such as psychology, were not mere aggregates of properties studied by lower-level sciences, and thus could not be completely understood in terms of them. Both emergentism and this form of reductionism were typically cast in terms of the relationship between laws in higher- and lower-level sciences, thus presupposing that there were, in the psychological case, PSYCHOLOGICAL LAWS in the first place. One well-known position that denies this assumption is Donald Davidson's ANOMALOUS MONISM, which claims that while mental states *are* strictly identical with physical states, our descriptions of them as mental states are neither definitionally nor nomologically reducible to descriptions of them as physical states. This view is usually expressed as denying the possibility of the bridge laws required for the reduction of psychology to biology.

Corresponding to the emphasis on scientific laws in views of the relations between the sciences is the idea that these laws state relations between NATURAL KINDS. The idea of a natural kind is that of a type or kind of thing that exists in the world itself, rather than a kind or grouping that exists because of our ways of perceiving, thinking about, or interacting with the world. Paradigms of natural kinds are biological kinds—species, such as the domestic cat (*Felis domesticus*)—and

chemical kinds—such as silver (Ag) and gold (Au). Natural kinds can be contrasted with *artifactual* kinds (such as chairs), whose members are artifacts that share common functions or purposes relative to human needs or designs; with *conventional* kinds (such as marriage vows), whose members share some sort of conventionally determined property; and from purely arbitrary groupings of objects, whose members have nothing significant in common save that they belong to the category. Views of what natural kinds are, of how extensively science traffics in them, and of how we should characterize the notion of a natural kind vis-à-vis other metaphysic notions, such as essence, intrinsic property, and causal power, all remain topics of debate in contemporary philosophy of science (e.g., van Fraassen 1989; Wilson 1999).

There is an intuitive connection between the claims that there are natural kinds, and that the sciences strive to identify them, and *scientific realism,* the view that the entities in mature sciences, whether they are observable or not, exist and our theories about them are at least approximately true. For realists hold that the sciences strive to "carve nature at its joints," and natural kinds are the pre-existing joints that one's scientific carving tries to find. The REALISM AND ANTIREALISM issue is, of course, more complicated than suggested by the view that scientific realists think there are natural kinds, and antirealists deny this—not least because there are a number of ways to deny either this realist claim or to diminish its significance. But such a perspective provides one starting point for thinking about the different views one might have of the relationship between science and reality.

Apart from raising issues concerning the relationships between psychology and other sciences and their respective objects of study, and questions about the relation between science and reality, the philosophy of science is also relevant to the cognitive sciences as a branch of epistemology or the theory of knowledge, studying a particular type of knowledge, scientific knowledge. A central notion in the general theory of knowledge is JUSTIFICATION, because being justified in what we believe is at least one thing that distinguishes knowledge from mere belief or a lucky guess. Since scientific knowledge is a paradigm of knowledge, views of justification have often been developed with scientific knowledge in mind.

The question of what it is for an individual to have a justified belief, however, has remained contentious in the theory of knowledge. Justified beliefs are those that we are entitled to hold, ones for which we have reasons, but how should we understand such entitlement and such reasons? One dichotomy here is between *internalists* about justification, who hold that having justified belief exclusively concerns facts that are "internal" to the believer, facts about his or her internal cognitive economy; and *externalists* about justification, who deny this. A second dichotomy is between *naturalists,* who hold that what cognitive states are justified may depend on facts about cognizers or about the world beyond cognizers that are uncovered by empirical science; and *rationalists,* who hold that justification is determined by the relations between one's cognitive states that the agent herself is in a special position to know about. Clearly part of what is at issue between internalists and externalists, as well as between naturalists and rationalists, is the role of the first-person perspective in accounts of justification and thus knowledge (see also Goldman 1997).

These positions about justification raise some general questions about the relationship between EPISTEMOLOGY AND COGNITION, and interact with views of the importance of first- and third-person perspectives on cognition itself. They also suggest different views of RATIONAL AGENCY, of what it is to be an agent who acts on the basis of justified beliefs. Many traditional views of rationality imply that cognizers have LOGICAL OMNISCIENCE, that is, that they believe all the logical consequences of their beliefs. Since clearly we are not logically omniscient, there is a question of how to modify one's account of rationality to avoid this result.

5   The Mind in Cognitive Science

At the outset, I said that the relation between the mental and physical remains the central, general issue in contemporary, materialist philosophy of mind. In section 2, we saw that the behaviorist critiques of Cartesian views of the mind and behaviorism themselves introduced a dilemma that derived from the problem of the homunculus that any mental science would seem to face. And in section 3 I suggested how a vibrant skepticism about the scientific status of a distinctively psychological science and philosophy's contribution to it was sustained by two dominant philosophical perspectives. It is time to bring these three points together as we move to explore the view of the mind that constituted the core of the developing field of cognitive science in the 1970s, what is sometimes called *classic* cognitive science, as well as its successors.

If we were to pose questions central to each of these three issues—the mental-physical relation, the problem of the homunculus, and the possibility of a genuinely cognitive science, they might be:

a. What is the relation between the mental and the physical?
b. How can psychology avoid the problem of the homunculus?
c. What makes a genuinely *mental* science possible?

Strikingly, these questions received standard answers, in the form of three "isms," from the nascent naturalistic perspective in the philosophy of mind that accompanied the rise of classic cognitive science. (The answers, so you don't have to peek ahead, are, respectively, functionalism, computationalism, and representationalism.)

The answer to (a) is FUNCTIONALISM, the view, baldly put, that mental states are functional states. Functionalists hold that what really matters to the identity of types of mental states is not what their instances are made of, but how those instances are causally arranged: what causes them, and what they, in turn, cause. Functionalism represents a view of the mental-physical relation that is compatible with materialism or physicalism because even if it is the functional or causal *role* that makes a mental state the state it is, every *occupant* of any particular role could be physical. The role-occupant distinction, introduced explicitly by Armstrong (1968) and implicitly in Lewis (1966), has been central to most formulations of functionalism.

A classic example of something that is functionally identified or individuated is *money:* it's not what it's made of (paper, gold, plastic) that makes something money but, rather, the causal role that it plays in some broader economic system. Recognizing this fact about money is not to give up on the idea that money is material or physical. Even though material composition is not what determines whether something is money, every instance of money is material or physical: dollar bills and checks are made of paper and ink, coins are made of metal, even money that is stored solely as a string of digits in your bank account has *some* physical composition. There are at least two related reasons why functionalism *about the mind* has been an attractive view to philosophers working in the cognitive sciences.

The first is that functionalism at least appears to support the AUTONOMY OF PSYCHOLOGY, for it claims that even if, as a matter of fact, our psychological states are realized in states of our brains, their status as *psychological* states lies in their functional organization, which can be abstracted from this particular material stuff. This is a *nonreductive* view of psychology. If functionalism is true, then there will be distinctively psychological natural kinds that cross-cut the kinds that are determined by a creature's material composition. In the context of materialism, functionalism suggests that creatures with very different material organizations could not only have mental states, but have *the same kinds* of mental states. Thus functionalism makes sense of comparative psychological or neurological investigations across species.

The second is that functionalism allows for *nonbiological* forms of intelligence and mentality. That is, because it is the "form" not the "matter" that determines psychological kinds, there could be entirely artifactual creatures, such as robots or computers, with mental states, provided that they have the right functional organization. This idea has been central to traditional artificial intelligence (AI), where one ideal has

been to create programs with a functional organization that not only allows them to behave in some crude way like intelligent agents but to do so in a way that instantiates at least some aspects of intelligence itself.

Both of these ideas have been criticized as part of attacks on functionalism. For example, Paul and Patricia Churchland (1981) have argued that the "autonomy" of psychology that one gains from functionalism can be a cover for the emptiness of the science itself, and Jaegwon Kim (1993) has argued against the coherence of the nonreductive forms of materialism usually taken to be implied by functionalism. Additionally, functionalism and AI are the targets of John Searle's much-discussed CHINESE ROOM ARGUMENT.

Consider (c), the question of what makes a distinctively mental science possible. Although functionalism gives one sort of answer to this in its basis for a defense of the autonomy (and so distinctness) of psychology, because there are more functional kinds than those in psychology (assuming functionalism), this answer does not explain what is distinctively *psychological* about psychology. A better answer to this question is *representationalism,* also known as the representational theory of mind. This is the view that mental states are relations between the bearers of those states and internal mental representations. Representationalism answers (c) by viewing psychology as the science concerned with the forms these mental representations can take, the ways in which they can be manipulated, and how they interact with one another in mediating between perceptual input and behavioral output.

A traditional version of representationalism, one cast in terms of Ideas, themselves often conceptualized as images, was held by the British empiricists John Locke, George Berkeley, and DAVID HUME. A form of representationalism, the LANGUAGE OF THOUGHT (LOT) hypothesis, has more recently been articulated and defended by Jerry Fodor (1975, 1981, 1987, 1994). The LOT hypothesis is the claim that we are able to cognize in virtue of having a mental language, *mentalese*, whose symbols are combined systematically by syntactic rules to form more complex units, such as thoughts. Because these mental symbols are intentional or representational (they are about things), the states that they compose are representational; mental states inherit their intentionality from their constituent mental representations.

Fodor himself has been particularly exercised to use the language of thought hypothesis to chalk out a place for the PROPOSITIONAL ATTITUDES and our folk psychology within the developing sciences of the mind. Not all proponents of the representational theory of mind, however, agree with Fodor's view that the system of representation underlying thought is a *language,* nor with his defense of folk psychology. But even forms of representationalism that are less committal than Fodor's own provide an answer to the question of what is distinctive about psychology: psychology is not mere neuroscience because it traffics in a range of mental representations and posits internal processes that operate on these representations.

Representationalism, particularly in Fodoresque versions that see the language of thought hypothesis as forming the foundations for a defense of both cognitive psychology and our commonsense folk psychology, has been challenged within cognitive science by the rise of connectionism in psychology and NEURAL NETWORKS within computer science. Connectionist models of psychological processing might be taken as an existence proof that one does not need to assume what is sometimes called the RULES AND REPRESENTATIONS approach to understand cognitive functions: the language of thought hypothesis is no longer "the only game in town."

Connectionist COGNITIVE MODELING of psychological processing, such as that of the formation of past tense (Rumelhart and McClelland 1986), face recognition (Cottrell and Metcalfe 1991), and VISUAL WORD RECOGNITION (Seidenberg and McClelland 1989), typically does not posit discrete, decomposable representations that are concatenated through the rules of some language of thought. Rather, connectionists posit a COGNITIVE ARCHITECTURE made up of simple neuron-like nodes, with activity being propagated across the units proportional to the weights of the connection strength between them. Knowledge lies not in the nodes themselves but in the values of the weights connecting nodes. There seems to be nothing of a propositional form within such connectionist networks, no place for the internal sentences that are the

objects of folk psychological states and other subpersonal psychological states posited in accounts of (for example) memory and reasoning.

The tempting idea that "classicists" accept, and connectionists reject, representationalism is too simple, one whose implausibility is revealed once one shifts one's focus from folk psychology and the propositional attitudes to cognition more generally. Even when research in classical cognitive science—for example, that on KNOWLEDGE-BASED SYSTEMS and on BAYESIAN NETWORKS—is cast in terms of "beliefs" that a system has, the connection between "beliefs" and the beliefs of folk psychology has been underexplored. More importantly, the notion of representation itself has not been abandoned across-the-board by connectionists, some of whom have sought to salvage and adapt the notion of mental representation, as suggested by the continuing debate over DISTRIBUTED VS. LOCAL REPRESENTATION and the exploration of sub-symbolic forms of representation within connectionism (see Boden 1990; Haugeland 1997; Smolensky 1994).

What perhaps better distinguishes classic and connectionist cognitive science here is not the issue of whether some form of representationalism is true, but whether the question to which it is an answer needs answering at all. In classical cognitive science, what makes the idea of a genuinely *mental* science possible is the idea that psychology describes representation crunching. But in starting with the idea that neural representation occurs from single neurons up through circuits to modules and more nebulous, distributed neural systems, connectionists are less likely to think that psychology offers a distinctive level of explanation that deserves some identifying characterization. This rejection of question (c) is clearest, I think, in related DYNAMIC APPROACHES TO COGNITION, since such approaches investigate psychological states as dynamic systems that need not posit distinctly *mental* representations. (As with connectionist theorizing about cognition, dynamic approaches encompass a variety of views of mental representation and its place in the study of the mind that make representationalism itself a live issue within such approaches; see Haugeland 1991; van Gelder 1998.)

Finally, consider (b), the question of how to avoid the problem of the homunculus in the sciences of the mind. In classic cognitive science, the answer to (b) is *computationalism,* the view that mental states are computational, an answer which integrates and strengthens functionalist materialism and representationalism as answers to our previous two questions. It does so in the *way* in which it provides a more precise characterization of the nature of the functional or causal relations that exist between mental states: these are *computational relations between mental representations*. The traditional way to spell this out is the COMPUTATIONAL THEORY OF MIND, according to which the mind is a digital computer, a device that stores symbolic representations and performs operations on them in accord with *syntactic* rules, rules that attend only to the "form" of these symbols. This view of computationalism has been challenged not only by relatively technical objections (such as that based on the FRAME PROBLEM), but also by the development of neural networks and models of SITUATED COGNITION AND LEARNING, where (at least some) informational load is shifted from internal codes to organism-environment interactions (cf. Ballard et al. 1997).

The computational theory of mind avoids the problem of the homunculus because digital computers that exhibit some intelligence exist, and they do not contain undischarged homunculi. Thus, if *we* are fancy versions of such computers, then we can understand our intelligent capacities without positing undischarged homunculi. The way this works in computers is by having a series of programs and languages, each compiled by the one beneath it, with the most basic language directly implemented in the hardware of the machine. We avoid an endless series of homunculi because the capacities that are posited at any given level are typically simpler and more numerous than those posited at any higher level, with the lowest levels specifying instructions to perform actions that require no intelligence at all. This strategy of FUNCTIONAL DECOMPOSITION solves the problem of the homunculus if we are digital computers, assuming that it solves it for digital computers.

Like representationalism, computationalism has sometimes been thought to have been superseded by either (or both) the connectionist revolution of the 1980s, or the

Decade of the Brain (the 1990s). But as with proclamations of the death of representationalism, this notice of the death of computationalism is premature. In part this is because the object of criticism is a specific version of computationalism, not computationalism per se (cf. representationalism), and in part it is because neural networks and the neural systems in the head they model are both themselves typically claimed to be computational in some sense. It is surprisingly difficult to find an answer within the cognitive science community to the question of whether there is a univocal notion of COMPUTATION that underlies the various different computational approaches to cognition on offer. The various types of AUTOMATA postulated in the 1930s and 1940s—particularly TURING machines and the "neurons" of MCCULLOCH and PITTS, which form the intellectual foundations, respectively, for the computational theory of mind and contemporary neural network theory—have an interwoven history, and many of the initial putative differences between classical and connectionist cognitive science have faded into the background as research in artificial intelligence and cognitive modeling has increasingly melded the insights of each approach into more sophisticated hybrid models of cognition (cf. Ballard 1997).

While dynamicists (e.g., Port and van Gelder 1995) have sometimes been touted as providing a noncomputational alternative to both classic and connectionist cognitive science (e.g., Thelen 1995: 70), as with claims about the nonrepresentational stance of such approaches, such a characterization is not well founded (see Clark 1997, 1998). More generally, the relationship between dynamical approaches to both classical and connectionist views remains a topic for further discussion (cf. van Gelder and Port 1995; Horgan and Tienson 1996; and Giunti 1997).

6   *A Focus on Folk Psychology*

Much recent philosophical thinking about the mind and cognitive science remains preoccupied with the three traditional philosophical issues I identified in the first section: the mental-physical relation, the structure of the mind, and the first-person perspective. All three issues arise in one of the most absorbing discussions over the last twenty years, that over the nature, status, and future of what has been variously called commonsense psychology, the propositional attitudes, or FOLK PSYCHOLOGY.

The term *folk psychology* was coined by Daniel Dennett (1981) to refer to the systematic knowledge that we "folk" employ in explaining one another's thoughts, feelings, and behavior; the idea goes back to Sellars's Myth of Jones in "Empiricism and the Philosophy of Mind" (1956). We all naturally and without explicit instruction engage in psychological explanation by attributing beliefs, desires, hopes, thoughts, memories, and emotions to one another. These patterns of folk psychological explanation are "folk" as opposed to "scientific" since they require no special training and are manifest in everyday predictive and explanatory practice; and genuinely "psychological" because they posit the existence of various states or properties that seem to be paradigmatically mental in nature. To engage in folk psychological explanation is, in Dennett's (1987) terms, to adopt the INTENTIONAL STANCE.

Perhaps the central issue about folk psychology concerns its relationship to the developing cognitive sciences. ELIMINATIVE MATERIALISM, or eliminativism, is the view that folk psychology will find no place in any of the sciences that could be called "cognitive" in orientation; rather, the fortune of folk psychology will be like that of many other folk views of the world that have found themselves permanently out of

step with scientific approaches to the phenomena they purport to explain, such as folk views of medicine, disease, and witchcraft.

Eliminativism is sometimes motivated by adherence to reductionism (including the thesis of EXTENSIONALITY) and the ideal of the unity of science, together with the recognition that the propositional attitudes have features that set them off in kind from the types of entity that exist in other sciences. For example, they are intentional or representational, and attributing them to individuals seems to depend on factors beyond the boundary of those individuals, as the TWIN EARTH arguments suggest. These arguments and others point to a prima facie conflict between folk psychology and INDIVIDUALISM (or *internalism*) in psychology (see Wilson 1995). The apparent conflict between folk psychology and individualism has provided one of the motivations for developing accounts of NARROW CONTENT, content that depends solely on an individual's intrinsic, physical properties. (The dependence here has usually been understood in terms of the technical notion of SUPERVENIENCE; see Horgan 1993.)

There is a spin on this general motivation for eliminative materialism that appeals more directly to the issue of the how the mind is structured. The claim here is that whether folk psychology is defensible will turn in large part on how compatible its ontology—its list of what we find in a folk psychological mind—is with the developing ontology of the cognitive sciences. With respect to classical cognitive science, with its endorsement of both the representational and computational theories of mind, folk psychology is on relatively solid ground here. It posits representational states, such as belief and desire, and it is relatively easy to see how the causal relations between such states could be modeled computationally. But connectionist models of the mind, with what representation there is lying in patterns of activity rather than in explicit representations like propositions, seem to leave less room in the structure of the mind for folk psychology.

Finally, the issue of the place of the first-person perspective arises with respect to folk psychology when we ask how people deploy folk psychology. That is, what sort of psychological machinery do we folk employ in engaging in folk psychological explanation? This issue has been the topic of the SIMULATION VS. THEORY-THEORY debate, with proponents of the simulation view holding, roughly, a "first-person first" account of how folk psychology works, and theory-theory proponents viewing folk psychology as essentially a third-person predictive and explanatory tool. Two recent volumes by Davies and Stone (1995a, 1995b) have added to the literature on this debate, which has developmental and moral aspects, including implications for MORAL PSYCHOLOGY.

7   Exploring Mental Content

Although BRENTANO's claim that INTENTIONALITY is the "mark of the mental" is problematic and has few adherents today, intentionality has been one of the flagship topics in philosophical discussion of the mental, and so at least a sort of mark of that discussion. Just what the puzzle about intentionality is and what one might say about it are topics I want to explore in more detail here.

To say that something is intentional is just to say that it is *about something,* or that it *refers to something*. In this sense, statements of fact are paradigmatically intentional, since they are about how things are in the world. Similarly, a highway sign with a picture of a gas pump on it is intentional because it conveys the information that there is gas station ahead at an exit: it is, in some sense, about that state of affairs.

The beginning of chapter 4 of Jerry Fodor's *Psychosemantics* provides one lively expression of the problem with intentionality:

I suppose that sooner or later the physicists will complete the catalogue they've been compiling of the ultimate and irreducible properties of things. When they do, the likes of *spin, charm,* and *charge* will perhaps appear upon their list. But *aboutness* surely won't; intentionality simply doesn't go that deep. It's hard to see, in face of this consideration, how one can be a Realist about intentionality without

also being, to some extent or other, a Reductionist. If the semantic and the intentional are real properties of things, it must be in virtue of their identity with (or maybe of their supervenience on?) properties that are themselves *neither* intentional *nor* semantic. If aboutness is real, it must be really something else. (p. 97, emphases in original)

Although there is much that one could take issue with in this passage, my reason for introducing it here is not to critique it but to try to capture some of the worries about intentionality that bubble up from it.

The most general of these concerns the *basis* of intentionality in the natural order: given that only special parts of the world (like our minds) have intentional properties, what is it about those things that gives them (and not other things) intentionality? Since not only mental phenomena are intentional (for example, spoken and written natural language and systems of signs and codes are as well), one might think that a natural way to approach this question would be as follows. Consider all of the various sorts of "merely material" things that at least seem to have intentional properties. Then proceed to articulate why each of them is intentional, either taking the high road of specifying something like the "essence of intentionality"—something that all and only things with intentional properties have—or taking the low road of doing so for each phenomenon, allowing these accounts to vary across disparate intentional phenomena.

Very few philosophers have explored the problem of intentionality in this way. I think this is chiefly because they do not view all things with intentional properties as having been created equally. A common assumption is that even if lots of the nonmental world is intentional, its intentionality is *derived,* in some sense, from the intentionality of the mental. So, to take a classic example, the sentences we utter and write are intentional all right (they are about things). But their intentionality derives from that of the corresponding thoughts that are their causal antecedents. To take another often-touted example, computers often produce intentional output (even photocopiers can do this), but whatever intentionality lies in such output is not inherent to the machines that produce it but is derivative, ultimately, from the mental states of those who design, program, and use them and their products. Thus, there has been a focus on mental states as a sort of paradigm of intentional state, and a subsequent narrowing of the sorts of intentional phenomena discussed. Two points are perhaps worth making briefly in this regard.

First, the assumption that not all things with intentional properties are created equally is typically shared even by those who have not focused almost exclusively on mental states as paradigms of intentional states, but on languages and other public and conventional forms of representation (e.g., Horst 1996). It is just that their paradigm is different.

Second, even when mental states *have* been taken as a paradigm here, those interested in developing a "psychosemantics"—an account of the basis for the semantics of psychological states—have often turned to decidedly nonmental systems of representation in order to theorize about the intentionality of the mental. This focus on what we might think of as *proto-intentionality* has been prominent within both Fred Dretske's (1981) informational semantics and the biosemantic approach pioneered by Ruth Millikan (1984, 1993).

The idea common to such views is to get clear about the grounds of simple forms of intentionality before scaling up to the case of the intentionality of human minds, an instance of a research strategy that has driven work in the cognitive sciences from early work in artificial intelligence on KNOWLEDGE REPRESENTATION and cognitive modeling through to contemporary work in COMPUTATIONAL NEUROSCIENCE. Exploring simplified or more basic intentional systems in the hope of gaining some insight into the more full-blown case of the intentionality of human minds runs the risk, of course, of focusing on cases that leave out precisely that which is crucial to full-blown intentionality. Some (for example, Searle 1992) would claim that consciousness and phenomenology are such features.

As I hinted at in my discussion of the mind in cognitive science in section 5, construed one way the puzzle about the grounds of intentionality has a general answer in the hypothesis of computationalism. But there is a deeper problem about the grounds

of intentionality concerning *just how* at least some mental stuff could be about other stuff in the world, and computationalism is of little help here. Computationalism does not even pretend to answer the question of what it is about specific mental states (say, my belief that trees often have leaves) that gives them the content that they have—for example, that makes them *about trees*. Even if we *were* complicated Turing machines, what would it be about *my* Turing machine table that implies that I have the belief that trees often have leaves? Talking about the correspondence between the semantic and syntactic properties that symbol structures in computational systems have, and of how the former are "inherited" from the latter is well and good. But it leaves open the "just how" question, and so fails to address what I am here calling the deeper problem about the grounds of intentionality. This problem is explored in the article on MENTAL REPRESENTATION, and particular proposals for a psychosemantics can be found in those on INFORMATIONAL SEMANTICS and FUNCTIONAL ROLE SEMANTICS.

It would be remiss in exploring mental content to fail to mention that much thought about intentionality has been propelled by work in the philosophy of language: on INDEXICALS AND DEMONSTRATIVES, on theories of REFERENCE and the propositional attitudes, and on the idea of RADICAL INTERPRETATION. Here I will restrict myself to some brief comments on theories of reference, which have occupied center stage in the philosophy of language for much of the last thirty years.

One of the central goals of theories of reference has been to explain in virtue of what parts of sentences of natural languages refer to the things they refer to. What makes the name "Miranda" refer to my daughter? In virtue of what does the plural noun "dogs" refer to dogs? Such questions have a striking similarity to my above expression of the central puzzle concerning intentionality. In fact, the application of causal theories of reference (Putnam 1975, Kripke 1980) developed principally for natural languages has played a central role in disputes in the philosophy of mind that concern intentionality, including those over individualism, narrow content, and the role of Twin Earth arguments in thinking about intentionality. In particular, applying them not to the meaning of natural language terms but to the content of thought is one way to reach the conclusion that *mental* content does not supervene on an individual's physical properties, that is, that mental content is not individualistic.

GOTTLOB FREGE is a classic source for contrasting descriptivist theories of reference, according to which natural language reference is, in some sense, mediated by a speaker's descriptions of the object or property to which she refers. Moreover, Frege's notion of sense and the distinction between SENSE AND REFERENCE are often invoked in support of the claim that there is much to MEANING—linguistic or mental—that goes beyond the merely referential. Frege is also one of the founders of modern logic, and it is to the role of logic in the cognitive sciences that I now turn.

8   *Logic and the Sciences of the Mind*

Although INDUCTION, like deduction, involves drawing inferences on the basis of one or more premises, it is *deductive* inference that has been the focus in LOGIC, what is often simply referred to as "formal logic" in departments of philosophy and linguistics. The idea that it is possible to abstract away from deductive arguments given in natural language that differ in the content of their premises and conclusions goes back at least to Aristotle in the fourth century B.C. Hence the term "Aristotelian syllogisms" to refer to a range of argument forms containing premises and conclusions that begin with the words "every" or "all," "some," and "no." This abstraction makes it possible to talk about argument *forms* that are valid and invalid, and allows one to describe two arguments as being of the same *logical* form. To take a simple example, we know that any argument of the form:

> All A are B.
> No B are C.
> ———————
> No A are C.

is *formally* valid, where the emphasis here serves to highlight reference to the preservation of truth from premises to conclusion, that is, the validity, solely in virtue of the forms of the individual sentences, together with the form their arrangement constitutes. Whatever plural noun phrases we substitute for "A," "B," and "C," the resulting natural language argument will be valid: if the two premises are true, the conclusion must also be true. The same general point applies to arguments that are formally *invalid,* which makes it possible to talk about formal *fallacies,* that is, inferences that are invalid because of the forms they instantiate.

Given the age of the general idea of LOGICAL FORM, what is perhaps surprising is that it is only in the late nineteenth century that the notion was developed so as to apply to a wide range of natural language constructions through the development of the *propositional* and *predicate* logics. And it is only in the late twentieth century that the notion of logical form comes to be appropriated within linguistics in the study of SYNTAX. I focus here on the developments in logic.

Central to propositional logic (sometimes called "sentential logic") is the idea of a propositional or sentential *operator,* a symbol that acts as a function on propositions or sentences. The paradigmatic propositional operators are symbols for negation ("~"), conjunction ("&"), disjunction ("v"), and conditional ("→"). And with the development of formal languages containing these symbols comes an ability to represent a richer range of formally valid arguments, such as that manifest in the following thought:

> If Sally invites Tom, then either he will say "no," or cancel his game with Bill. But there's no way he'd turn Sally down. So I guess if she invites him, he'll cancel with Bill.

In predicate or quantificational logic, we are able to represent not simply the relations between propositions, as we can in propositional logic, but also the structure within propositions themselves through the introduction of QUANTIFIERS and the terms and predicates that they bind. One of the historically more important applications of predicate logic has been its widespread use in linguistics, philosophical logic, and the philosophy of language to formally represent increasingly larger parts of natural languages, including not just simple subjects and predicates, but adverbial constructions, tense, indexicals, and attributive adjectives (for example, see Sainsbury 1991).

These fundamental developments in logical theory have had perhaps the most widespread and pervasive effect on the foundations of the cognitive sciences of *any* contributions from philosophy or mathematics. They also form the basis for much contemporary work across the cognitive sciences: in linguistic semantics (e.g., through MODAL LOGIC, in the use of POSSIBLE WORLDS SEMANTICS to model fragments of natural language, and in work on BINDING); in metalogic (e.g., on FORMAL SYSTEMS and results such as the CHURCH-TURING THESIS and GÖDEL'S THEOREMS); and in artificial intelligence (e.g., on LOGICAL REASONING SYSTEMS, TEMPORAL REASONING, and METAREASONING).

Despite their technical payoff, the relevance of these developments in logical theory for thinking more directly about DEDUCTIVE REASONING in human beings is, ironically, less clear. Psychological work on human reasoning, including that on JUDGMENT HEURISTICS, CAUSAL REASONING, and MENTAL MODELS, points to ways in which human reasoning may be governed by structures very different from those developed in formal logic, though this remains an area of continuing debate and discussion.

9   Two Ways to Get Biological

By the late nineteenth century, both evolutionary theory and the physiological study of mental capacities were firmly entrenched. Despite this, these two paths to a biological view of cognition have only recently been re-explored in sufficient depth to warrant the claim that contemporary cognitive science incorporates a truly biological perspective on the mind. The neurobiological path, laid down by the tradition of physiological psychology that developed from the mid-nineteenth century, is certainly the better traveled of the two. The recent widening of this path by those dissatisfied with the distinctly nonbiological approaches adopted within traditional artificial intelligence has, as we saw in our discussion of computationalism, raised new questions about COMPUTATION AND THE BRAIN, the traditional computational theory of the mind, and the rules and representations approach to understanding the mind. The evolutionary path, by contrast, has been taken only occasionally and half-heartedly over the last 140 years. I want to concentrate not only on why but on the ways in which evolutionary theory is relevant to contemporary interdisciplinary work on the mind.

The theory of EVOLUTION makes a claim about the *patterns* that we find in the biological world—they are patterns of *descent*—and a claim about the predominant cause of those patterns—they are caused by the mechanism of natural selection. None of the recent debates concerning evolutionary theory—from challenges to the focus on ADAPTATION AND ADAPTATIONISM in Gould and Lewontin (1979) to more recent work on SELF-ORGANIZING SYSTEMS and ARTIFICIAL LIFE—challenges the substantial core of the theory of evolution (cf. Kauffman 1993, 1995; Depew and Weber 1995). The vast majority of those working in the cognitive sciences both accept the theory of evolution and so think that a large number of traits that organisms possess are adaptations to evolutionary forces, such as natural selection. Yet until the last ten years, the scattered pleas to apply evolutionary theory to the mind (such as those of Ghiselin 1969 and Richards 1987) have come largely from those outside of the psychological and behavioral sciences.

Within the last ten years, however, a distinctive EVOLUTIONARY PSYCHOLOGY has developed as a research program, beginning in Leda Cosmides's (1989) work on human reasoning and the Wason selection task, and represented in the collection of papers *The Adapted Mind* (Barkow, Cosmides, and Tooby 1992) and, more recently and at a more popular level, by Steven Pinker's *How the Mind Works* (1997). Evolutionary psychologists view the mind as a set of "Darwinian algorithms" designed by natural selection to solve adaptive problems faced by our hunter-gatherer ancestors. The claim is that this basic Darwinian insight can and should guide research into the cognitive architecture of the mind, since the task is one of discovering and understanding the *design* of the human mind, in all its complexity. Yet there has been more than an inertial resistance to viewing evolution as central to the scientific study of human cognition.

One reason is that evolutionary theory in general is seen as answering different questions than those at the core of the cognitive sciences. In terms of the well-known distinction between *proximal* and *ultimate* causes, appeals to evolutionary theory primarily allow one to specify the latter, and cognitive scientists are chiefly interested in the former: they are interested in the *how* rather than the *why* of the mind. Or to put it more precisely, central to cognitive science is an understanding of the *mechanisms* that govern cognition, not the various histories—evolutionary or not—that produced these mechanisms. This general perception of the concerns of evolutionary theory and the contrasting conception of cognitive science, have both been challenged by evolutionary psychologists. The same general challenges have been issued by those who think that the relations between ETHICS AND EVOLUTION and those between cognition and CULTURAL EVOLUTION have not received their due in contemporary cognitive science.

Yet despite the skepticism about this direct application of evolutionary theory to human cognition, its implicit application is inherent in the traditional interest in the

minds of *other* animals, from *aplysia* to (nonhuman) apes. ANIMAL NAVIGATION, PRIMATE LANGUAGE, and CONDITIONING AND THE BRAIN, while certainly topics of interest in their own right, gain some added value from what their investigation can tell us about *human* minds and brains. This presupposes something like the following: that there are natural kinds in psychology that transcend species boundaries, such that there is a general way of exploring how a cognitive capacity is structured, independent of the particular species of organism in which it is instantiated (cf. functionalism). Largely on the basis of research with non-human animals, we know enough now to say, with a high degree of certainty, things like this: that the CEREBELLUM is the central brain structure involved in MOTOR LEARNING, and that the LIMBIC SYSTEM plays the same role with respect to at least some EMOTIONS.

This is by way of returning to (and concluding with) the neuroscientific path to biologizing the mind, and the three classic philosophical issues about the mind with which we began. As I hope this introduction has suggested, despite the distinctively philosophical edge to all three issues—the mental-physical relation, the structure of the mind, and the first-person perspective—discussion of each of them is elucidated and enriched by the interdisciplinary perspectives provided by empirical work in the cognitive sciences. It is not only a priori arguments but complexities revealed by empirical work (e.g., on the neurobiology of consciousness, or ATTENTION and animal and human brains) that show the paucity of the traditional philosophical "isms" (dualism, behaviorism, type-type physicalism) with respect to the mental-physical relation. It is not simply general, philosophical arguments against nativism or against empiricism about the structure of the mind that reveal limitations to the global versions of these views, but ongoing work on MODULARITY AND LANGUAGE, on cognitive architecture, and on the innateness of language. And thought about introspection and self-knowledge, to take two topics that arise when one reflects on the first-person perspective on the mind, is both enriched by and contributes to empirical work on BLINDSIGHT, the theory of mind, and METAREPRESENTATION. With some luck, philosophers increasingly sensitive to empirical data about the mind will have paved a two-way street that encourages psychologists, linguists, neuroscientists, computer scientists, social scientists and evolutionary theorists to venture more frequently and more surely into philosophy.

Psychology

Keith J. Holyoak

Psychology is the science that investigates the representation and processing of information by complex organisms. Many animal species are capable of taking in information about their environment, forming internal representations of it, and manipulating these representations to select and execute actions. In addition, many animals are able to adapt to their environments by means of learning that can take place within the lifespan of an individual organism. Intelligent information processing implies the ability to acquire and process information about the environment in order to select actions that are likely to achieve the fundamental goals of survival and propagation. Animals have evolved a system of capabilities that collectively provide them with the ability to process information. They have sensory systems such as TASTE and HAPTIC PERCEPTION (touch), which provide information about the immediate environment with which the individual is in direct contact; proprioception, which provides information about an animal's own bodily states; and SMELL, AUDITION, and VISION, which provide information about more distant aspects of the environment. Animals are capable of directed, self-generated motion, including EYE MOVEMENTS and other motoric behaviors such as MANIPULATION AND GRASPING, which radically increase their ability to pick up sensory information and also to act upon their environments.

The central focus of psychology concerns the information processing that intervenes between sensory inputs and motoric outputs. The most complex forms of intelligence, observed in birds and mammals, and particularly primates (especially great apes and humans) require theories that deal with the machinery of thought and inner experience. These animals have minds and EMOTIONS; their sensory inputs are interpreted to create perceptions of the external world, guided in part by selective ATTENTION; some of the products of perception are stored in MEMORY, and may in turn influence subsequent perception. Intellectually sophisticated animals perform DECISION MAKING and PROBLEM SOLVING, and in the case of humans engage in LANGUAGE AND COMMUNICATION. Experience coupled with innate constraints results in a process of COGNITIVE DEVELOPMENT as the infant becomes an adult, and also leads to LEARNING over the lifespan, so that the individual is able to adapt to its environment within a vastly shorter time scale than that required for evolutionary change. Humans are capable of the most complex and most domain-general forms of information processing of all species; for this reason (and because those who study psychology are humans), most of psychology aims directly or indirectly to understand the nature of human information processing and INTELLIGENCE. The most general characteristics of the human system for information processing are described as the COGNITIVE ARCHITECTURE.

See also ATTENTION; AUDITION; COGNITIVE ARCHITECTURE; COGNITIVE DEVELOPMENT; DECISION MAKING; EMOTIONS; EYE MOVEMENTS AND VISUAL ATTENTION; HAPTIC PERCEPTION; INTELLIGENCE; LANGUAGE AND COMMUNICATION; LEARNING; MANIPULATION AND GRASPING; MEMORY; PROBLEM SOLVING; SMELL; TASTE; VISION

1 The Place of Psychology within Cognitive Science

As the science of the representation and processing of information by organisms, psychology (particularly cognitive psychology) forms part of the core of cognitive science. Cognitive science research conducted in other disciplines generally has actual or potential implications for psychology. Not all research on intelligent information processing is relevant to psychology. Some work in artificial intelligence, for example, is based on representations and algorithms with no apparent connection to biological intelligence. Even though such work may be highly successful at achieving high levels of competence on cognitive tasks, it does not fall within the scope of cognitive science. For example, the Deep Blue II program that defeated the

human CHESS champion Gary Kasparov is an example of an outstanding artificial-intelligence program that has little or no apparent psychological relevance, and hence would not be considered to be part of cognitive science. In contrast, work on adaptive PRODUCTION SYSTEMS and NEURAL NETWORKS, much of which is conducted by computer scientists, often has implications for psychology. Similarly, a great deal of work in such allied disciplines as neuroscience, linguistics, anthropology, and philosophy has psychological implications. At the same time, work in psychology often has important implications for research in other disciplines. For example, research in PSYCHOLINGUISTICS has influenced developments in linguistics, and research in PSYCHOPHYSICS has guided neurophysiological research on the substrates of sensation and perception.

In terms of MARR's tripartite division of levels of analysis (computational theory, representation and algorithm, and hardware implementation), work in psychology tends to concentrate on the middle level, emphasizing how information is represented and processed by humans and other animals. Although there are many important exceptions, psychologists generally aim to develop process models that specify more than the input-output functions that govern cognition (for example, also specifying timing relations among intervening mental processes), while abstracting away from the detailed neural underpinnings of behavior. Nonetheless, most psychologists do not insist in any strict sense on the AUTONOMY OF PSYCHOLOGY, but rather focus on important interconnections with allied disciplines that comprise cognitive science. Contemporary psychology at the information-processing level is influenced by research in neuroscience that investigates the neural basis for cognition and emotion, by work on representations and algorithms in the fields of artificial intelligence and neural networks, and by work in social sciences such as anthropology that places the psychology of individuals within its cultural context. Research on the psychology of language (e.g., COMPUTATIONAL PSYCHOLINGUISTICS and LANGUAGE AND THOUGHT) is influenced by the formal analyses of language developed in linguistics. Many areas of psychology make close contact with classical issues in philosophy, especially in EPISTEMOLOGY (e.g., CAUSAL REASONING; INDUCTION; CONCEPTS).

The field of psychology has several major subdivisions, which have varying degrees of connection to cognitive science. Cognitive psychology deals directly with the representation and processing of information, with greatest emphasis on cognition in adult humans; the majority of the psychology entries that appear in this volume reflect work in this area. Developmental psychology deals with the changes in cognitive, social, and emotional functioning that occur over the lifespan of humans and other animals (see in particular COGNITIVE DEVELOPMENT, PERCEPTUAL DEVELOPMENT, and INFANT COGNITION). Social psychology investigates the cognitive and emotional factors involved in interactions between people, especially in small groups. One subarea of social psychology, SOCIAL COGNITION, is directly concerned with the manner in which people understand the minds, emotions, and behavior of themselves and others (see also THEORY OF MIND; INTERSUBJECTIVITY). Personality psychology deals primarily with motivational and emotional aspects of human experience (see FREUD for discussion of the ideas of the famous progenitor of this area of psychology), and clinical psychology deals with applied issues related to mental health. COMPARATIVE PSYCHOLOGY investigates the commonalities and differences in cognition and behavior between different animal species (see PRIMATE COGNITION; ANIMAL NAVIGATION; CONDITIONING; and MOTIVATION), and behavioral neuroscience provides the interface between research on molar cognition and behavior and their underlying neural substrate.

2   *Capsule History of Psychology*

Until the middle of the nineteenth century the nature of the mind was solely the concern of philosophers. Indeed, there are a number of reasons why some have argued that the scientific investigation of the mind may prove to be an impossible undertaking. One objection is that thoughts cannot be measured; and without measurement, science cannot even begin. A second objection is to question how humans could objectively study their own thought processes, given the fact that science itself depends on human thinking. A final objection is that our mental life is incredibly complex and bound up with the further complexities of human social interactions; perhaps cognition is simply too complex to permit successful scientific investigation.

Despite these reasons for skepticism, scientific psychology emerged as a discipline separate from philosophy in the second half of the nineteenth century. A science depends on systematic empirical methods for collecting observations and on theories that interpret these observations. Beginning around 1850, a number of individuals, often trained in philosophy, physics, physiology, or neurology, began to provide these crucial elements.

The anatomist Ernst Heinrich Weber and the physicist and philosopher Gustav Fechner measured the relations between objective changes in physical stimuli, such as brightness or weight, and subjective changes in the internal sensations the stimuli generate. The crucial finding of Weber and Fechner was that subjective differences were not simply equivalent to objective differences. Rather, it turned out that for many dimensions, the magnitude of change required to make a subjective difference ("just noticeable difference," or "jnd") increased as overall intensity increased, often following an approximately logarithmic function, known as the Weber-Fechner Law. Weber and Fechner's contribution to cognitive psychology was much more general than identifying the law that links their names. They convincingly demonstrated that, contrary to the claim that thought is inherently impossible to measure, it is in fact possible to measure mental concepts, such as the degree of sensation produced by a stimulus. Fechner called this new field of psychological measurement PSYCHOPHYSICS: the interface of psychology and physics, of the mental and the physical.

A further foundational issue concerns the speed of human thought. In the nineteenth century, many believed that thought was either instantaneous or else so fast that it could never be measured. But HERMANN VON HELMHOLTZ, a physicist and physiologist, succeeded in measuring the speed at which signals are conducted through the nervous system. He first experimented on frogs by applying an electric current to the top of a frog's leg and measuring the time it took the muscle at the end to twitch in response. Later he used a similar technique with humans, touching various parts of a person's body and measuring the time taken to press a button in response. The response time increased with the distance of the stimulus (i.e., the point of the touch) from the finger that pressed the button, in proportion to the length of the neural path over which the signal had to travel. Helmholtz's estimate of the speed of nerve signals was close to modern estimates—roughly 100 meters per second for large nerve fibers. This transmission rate is surprisingly slow—vastly slower than the speed of electricity through a wire. Because our brains are composed of neurons, our thoughts cannot be generated any faster than the speed at which neurons communicate with each other. It follows that the speed of thought is neither instantaneous nor immeasurable.

Helmholtz also pioneered the experimental study of vision, formulating a theory of color vision that remains highly influential today. He argued forcefully against the commonsensical idea that perception is simply a matter of somehow "copying" sensory input into the brain. Rather, he pointed out that even the most basic aspects of perception require major acts of construction by the nervous system. For example, it is possible for two different objects—a large object far away, and a small object nearby—to create precisely the same image on the retinas of a viewer's eyes. Yet normally the viewer will correctly perceive the one object as being larger, but further away, than the other. The brain somehow manages to unconsciously perform some basic geometrical calculations. The brain, Helmholtz argued, must construct this unified view by a process of "unconscious inference"—a process akin to reasoning without awareness.

Helmholtz's insight was that the "reality" we perceive is not simply a copy of the external world, but rather the product of the constructive activities of the brain.

Another philosopher, HERMANN EBBINGHAUS, who was influenced by Fechner's ideas about psychophysical measurements, developed experimental methods tailored to the study of human memory. Using himself as a subject, Ebbinghaus studied memory for nonsense syllables—consonant-vowel-consonant combinations, such as "zad," "bim," and "sif." He measured how long it took to commit lists of nonsense syllables to memory, the effects of repetition on how well he could remember the syllables later, and the rate of forgetting as a function of the passage of time. Ebbinghaus made several fundamental discoveries about memory, including the typical form of the "forgetting curve"—the gradual, negatively accelerated decline in the proportion of items that can be recalled as a function of time. Like Weber, Fechner, and Helmholtz, Ebbinghaus provided evidence that it is indeed possible to measure mental phenomena by objective experimental procedures.

Many key ideas about possible components of cognition were systematically presented by the American philosopher WILLIAM JAMES in the first great psychology textbook, *Principles of Psychology,* published in 1890. His monumental work included topics that remain central in psychology, including brain function, perception, attention, voluntary movement, habit, memory, reasoning, the SELF, and hypnosis. James discussed the nature of "will," or mental effort, which remains one of the basic aspects of attention. He also drew a distinction between different memory systems: *primary* memory, which roughly corresponds to the current contents of consciousness, and *secondary* memory, which comprises the vast store of knowledge of which we are not conscious at any single time, yet continually draw upon. Primary memory is closely related to what we now term *active*, *short-term*, or WORKING MEMORY, while secondary memory corresponds to what is usually called *long-term* memory.

James emphasized the *adaptive* nature of cognition: the fact that perception, memory, and reasoning operate not simply for their own sake, but to allow us to survive and prosper in our physical and social world. Humans evolved as organisms skilled in tool use and in social organization, and it is possible (albeit a matter of controversy) that much of our cognitive apparatus evolved to serve these basic functions (see EVOLUTIONARY PSYCHOLOGY). Thus, human cognition involves intricate systems for MOTOR CONTROL and MOTOR LEARNING; the capacity to understand that other people have minds, with intentions and goals that may lead them to help or hinder us; and the ability to recognize and remember individual persons and their characteristics. Furthermore, James (1890:8) recognized that the hallmark of an intelligent being is its ability to link ends with means—to select actions that will achieve goals: "The pursuance of future ends and the choice of means for their attainment are thus the mark and criterion of the presence of mentality in a phenomenon." This view of goal-directed thinking continues to serve as the foundation of modern work on PROBLEM SOLVING, as reflected in the views of theorists such as ALAN NEWELL and Herbert Simon.

Another pioneer of psychology was Sigmund Freud, the founder of psychoanalysis, whose theoretical ideas about cognition and consciousness anticipated many key aspects of the modern conception of cognition. Freud attacked the idea that the "self" has some special status as a unitary entity that somehow governs our thought and action. Modern cognitive psychologists also reject (though for different reasons) explanations of intelligent behavior that depend upon postulating a "homunculus"— that is, an internal mental entity endowed with all the intelligence we are trying to explain. Behavior is viewed not as the product of a unitary self or homunculus, but as the joint product of multiple interacting subsystems. Freud argued that the "ego"—the information-processing system that modulates various motivational forces—is not a unitary entity, but rather a complex system that includes attentional bottlenecks, multiple memory stores, and different ways of representing information (e.g., language, imagery, and physiognomic codes, or "body language"). Furthermore, as Freud also emphasized, much of information processing takes place at an unconscious level. We are aware of only a small portion of our overall mental life, a tip of the cognitive iceberg. For example, operating beneath the level of awareness are attentional "gates" that open or close to selectively attend to portions of the information that reaches our

senses, memory stores that hold information for very brief periods of time, and inaccessible memories that we carry with us always but might never retrieve for years at a time.

Given the breadth and depth of the contributions of the nineteenth-century pioneers to what would eventually become cognitive science, it is ironic that early in the twentieth century the study of cognition went into a steep decline. Particularly in the United States, psychology in the first half of the century came to be dominated by BEHAVIORISM, an approach characterized by the rejection of theories that depended on "mentalistic" concepts such as goals, intentions, or plans. The decline of cognitive psychology was in part due to the fact that a great deal of psychological research had moved away from the objective measurement techniques developed by Fechner, Helmholtz, Ebbinghaus, and others, and instead gave primacy to the method of INTROSPECTION, promoted by WILHELM WUNDT, in which trained observers analyzed their own thought processes as they performed various cognitive tasks. Not surprisingly, given what is now known about how expectancies influence the way we think, introspectionists tended to find themselves thinking in more or less the manner to which they were theoretically predisposed. For example, researchers who believed thinking always depended on IMAGERY usually found themselves imaging, whereas those who did not subscribe to such a theory were far more likely to report "imageless thought."

The apparent subjectivity and inconstancy of the introspective method encouraged charges that all cognitive theories (rather than simply the method itself, as might seem more reasonable) were "unscientific." Cognitive theories were overshadowed by the behaviorist theories of such leading figures as John Watson, Edward Thorndike, Clark Hull, and B. F. Skinner. Although there were major differences among the behaviorists in the degree to which they actually avoided explanations based on assumptions about unobservable mental states (e.g., Hull postulated such states rather freely, whereas Watson was adamant that they were scientifically illicit), none supported the range of cognitive ideas advanced in the nineteenth century.

Cognitive psychology did not simply die out during the era of behaviorism. Working within the behaviorist tradition, Edward Tolman pursued such cognitive issues as how animals represented spatial information internally as COGNITIVE MAPS of their environment. European psychologists were far less captivated with behaviorism than were Americans. In England, Sir FREDERICK BARTLETT analyzed the systematic distortions that people exhibit when trying to remember stories about unfamiliar events, and introduced the concept of "schema" (see SCHEMATA) as a mental representation that captures the systematic structural relations in categories of experience. In Soviet Russia, the neuropsychologist Aleksandr LURIA provided a detailed portrait of links between cognitive functions and the operation of specific regions of the brain. Another Russian, LEV VYGOTSKY, developed a sociohistorical approach to cognitive development that emphasized the way in which development is constructed through social interaction, cultural practices, and the internalization of cognitive tools. Vygotsky emphasized social interaction through language in the development of children's concepts. The Swiss psychologist JEAN PIAGET spent decades refining a theory of cognitive development. Piaget's theory emphasizes milestones in the child's development including decentration, the ability to perform operations on concrete objects, and finally the ability to perform operations on thoughts and beliefs. Given its emphasis on logical thought, Piaget's theory is closely related to SCIENTIFIC THINKING AND ITS DEVELOPMENT.

In addition, the great German tradition in psychology, which had produced so many of the nineteenth-century pioneers, gave rise to a new cognitive movement in the early twentieth century: GESTALT PSYCHOLOGY. The German word *Gestalt* translates roughly as "form," and the Gestalt psychologists emphasized that the whole form is something different from the mere sum of its parts, due to emergent properties that arise as new relations are created. Gestalt psychology was in some ways an extension of Helmholtz's constructivist ideas, and the greatest contributions of this intellectual movement were in the area of GESTALT PERCEPTION. Where the behaviorists insisted that psychology was simply the study of how objective stimuli come to elicit objective responses, the Gestaltists pointed to simple demonstrations casting doubt on

the idea that "objective" stimuli—that is, stimuli perceived in a way that can be described strictly in terms of the sensory input—even exist. Figure 1 illustrates a famous Gestalt example of the constructive nature of perception, the ambiguous Necker cube. Although this figure is simply a flat line drawing, we immediately perceive it as a three-dimensional cube. Moreover, if you look carefully, you will see that the figure can actually be seen as either of two different three-dimensional cubes. The same objective stimulus—the two-dimensional line drawing—gives rise to two distinct three-dimensional perceptions.

Although many of the major contributions by key Gestalt figures such as Max Wertheimer were in the area of perception, their central ideas were extended to memory and problem solving as well, through the work of people such as Wolfgang Köhler and Karl Duncker. Indeed, one of the central tenets of Gestalt psychology was that high-level thinking is based on principles similar to those that govern basic perception. As we do in everyday language, Gestalt psychologists spoke of suddenly "seeing" the solution to a problem, often after "looking at it" in a different way and achieving a new "insight." In all the areas in which they worked, the Gestalt idea of "a whole different from the sum of parts" was based on the fundamental fact that organized configurations are based not simply on individual elements, but also on the relations between those elements. Just as H_2O is not simply two hydrogen atoms and one oxygen atom, but also a particular spatial organization of these elements into a configuration that makes a molecule of water, so too "squareness" is more than four lines: it crucially depends on the way the lines are related to one another to make four right angles. Furthermore, relations can take on a "life of their own," separable from any particular set of elements. For example, we can take a tune, move it to a different key so that all the notes are changed, and still immediately recognize it as the "same" tune as long as the relations among the notes are preserved. A focus on relations calls attention to the centrality of the BINDING PROBLEM, which involves the issue of how elements are systematically organized to fill relational roles. Modern work on such topics as ANALOGY and SIMILARITY emphasizes the crucial role of relations in cognition.

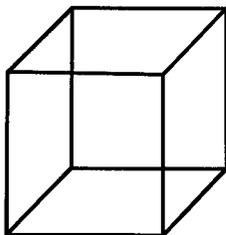
Modern cognitive psychology emerged in the second half of this century. The "cognitive revolution" of the 1950s and 1960s involved not only psychology but also the allied disciplines that now contribute to cognitive science. In the 1940s the Canadian psychologist DONALD HEBB began to draw connections between cognitive processes and neural mechanisms, anticipating modern cognitive neuroscience. During World War II, many experimental psychologists (including JAMES GIBSON) were confronted with such pressing military problems as finding ways to select good pilots and train radar operators, and it turned out that the then-dominant stimulus-response theories simply had little to offer in the way of solutions. More detailed process models of human information processing were needed. After the war, DONALD BROADBENT in England developed the first such detailed model of attention. Even more importantly, Broadbent helped develop and popularize a wide range of experimental tasks in which an observer's attention is carefully controlled by having him or her perform some task, such as listening to a taped message for a particular word, and then precisely measuring how quickly responses can be made and what can be remembered. In the United States, William K. Estes added to the mathematical tools available for theory building and data analysis, and Saul Sternberg developed a method for decomposing reaction times into component processes using a simple recognition task.


Figure 1.

Meanwhile, the birth of computer science provided further conceptual tools. Strict behaviorists had denounced models of internal mental processes as unscientific. However, the modern digital computer provided a clear example of a device that took inputs, fed them through a complex series of internal procedures, and then produced outputs. As well as providing concrete examples of what an information-processing device could be, computers made possible the beginnings of artificial intelligence—the construction of computer programs designed to perform tasks that require intelligence, such as playing chess, understanding stories, or diagnosing diseases. Herbert Simon (1978 Nobel Laureate in Economics) and Allan Newell were leaders in building close ties between artificial intelligence and the new cognitive psychology. It was also recognized that actual computers represent only a small class of a much larger set of theoretically possible computing devices, which had been described back in the 1940s by the brilliant mathematician ALAN TURING. Indeed, it was now possible to view the brain itself as a biological computer, and to use various real and possible computing devices as models of human cognition. Another key influence on modern cognitive psychology came from the field of linguistics. In the late 1950s work by the young linguist Noam Chomsky radically changed conceptions of the nature of human language by demonstrating that language could not be learned or understood by merely associating adjacent words, but rather required computations on abstract structures that existed in the minds of the speaker and listener.

The collective impact of this work in the mid-twentieth century was to provide a seminal idea that became the foundation of cognitive psychology and also cognitive science in general: the COMPUTATIONAL THEORY OF MIND, according to which human cognition is based on mental procedures that operate on abstract mental representations. The nature of the COGNITIVE ARCHITECTURE has been controversial, including proposals such as PRODUCTION SYSTEMS and NEURAL NETWORKS. In particular, there has been disagreement as to whether procedures and representations are inherently separable or whether procedures actually embody representations, and whether some mental representations are abstract and amodal, rather than tied to specific perceptual systems. Nonetheless, the basic conception of biological information processing as some form of computation continues to guide psychological theories of the representation and processing of information.

3   The Science of Information Processing

In broad strokes, an intelligent organism operates in a perception-action cycle (Neisser 1967), taking in sensory information from the environment, performing internal computations on it, and using the results of the computation to guide the selection and execution of goal-directed actions. The initial sensory input is provided by separate sensory systems, including smell, taste, haptic perception, and audition. The most sophisticated sensory system in primates is vision (see MID-LEVEL VISION; HIGH-LEVEL VISION), which includes complex specialized subsystems for DEPTH PERCEPTION, SHAPE PERCEPTION, LIGHTNESS PERCEPTION, and COLOR VISION.

The interpretation of sensory inputs begins with FEATURE DETECTORS that respond selectively to relatively elementary aspects of the stimulus (e.g., lines at specific orientations in the visual field, or phonetic cues in an acoustic speech signal). Some basic properties of the visual system result in systematic misperceptions, or ILLUSIONS. TOP-DOWN PROCESSING IN VISION serves to integrate the local visual input with the broader context in which it occurs, including prior knowledge stored in memory. Theorists working in

the tradition of Gibson emphasize that a great deal of visual information may be provided by higher-order features that become available to a perceiver moving freely in a natural environment, rather than passively viewing a static image (see ECOLOGICAL PSYCHOLOGY). In their natural context, both perception and action are guided by the AFFORDANCES of the environment: properties of objects that enable certain uses (e.g., the elongated shape of a stick may afford striking an object otherwise out of reach).

Across all the sensory systems, psychophysics methods are used to investigate the quantitative functions relating physical inputs received by sensory systems to subjective experience (e.g., the relation between luminance and perceived brightness, or between physical and subjective weight). SIGNAL DETECTION THEORY provides a statistical method for measuring how accurately observers can distinguish a signal from noise under conditions of uncertainty (i.e., with limited viewing time or highly similar alternatives) in a way that separates the signal strength received from possible response bias. In addition to perceiving sensory information about objects at locations in space, animals perceive and record information about time (see TIME IN THE MIND).

Knowledge about both space and time must be integrated to provide the capability for animal and HUMAN NAVIGATION in the environment. Humans and other animals are capable of forming sophisticated representations of spatial relations integrated as COGNITIVE MAPS. Some more central mental representations appear to be closely tied to perceptual systems. Humans use various forms of imagery based on visual, auditory and other perceptual systems to perform internal mental processes such as MENTAL ROTATION. The close connection between PICTORIAL ART AND VISION also reflects the links between perceptual systems and more abstract cognition.

A fundamental property of biological information processing is that it is capacity-limited and therefore necessarily selective. Beginning with the seminal work of Broadbent, a great deal of work in cognitive psychology has focused on the role of attention in guiding information processing. Attention operates selectively to determine what information is received by the senses, as in the case of EYE MOVEMENTS AND VISUAL ATTENTION, and also operates to direct more central information processing, including the operation of memory. The degree to which information requires active attention or memory resources varies, decreasing with the AUTOMATICITY of the required processing.

Modern conceptions of memory maintain some version of William James's basic distinction between primary and secondary memory. Primary memory is now usually called WORKING MEMORY, which is itself subdivided into multiple stores involving specific forms of representation, especially phonological and visuospatial codes. Working memory also includes a central executive, which provides attentional resources for strategic management of the cognitive processes involved in problem solving and other varieties of deliberative thought. Secondary or long-term memory is also viewed as involving distinct subsystems, particularly EPISODIC VS. SEMANTIC MEMORY. Each of these subsystems appears to be specialized to perform one of the two basic functions of long-term memory. One function is to store individuated representations of "what happened when" in specific contexts (episodic memory); a second function is to extract and store generalized representations of "the usual kind of thing" (semantic memory). Another key distinction, related to different types of memory measures, is between IMPLICIT VS. EXPLICIT MEMORY. In explicit tests (typically recall or recognition tests), the person is aware of the requirement to access memory. In contrast, implicit tests (such as completing a word stem, or generating instances of a category) make no reference to any particular memory episode. Nonetheless, the influence of prior experiences may be revealed by the priming of particular responses (e.g., if the word "crocus" has recently been studied, the person is more likely to generate "crocus" when asked to list flowers, even if they do not explicitly remember having studied the word). There is evidence that implicit and explicit knowledge are based on separable neural systems. In particular, forms of amnesia caused by damage to the hippocampus and related structures typically impair explicit memory for episodes, but not implicit memory as revealed by priming measures.

A striking part of human cognition is the ability to speak and comprehend language. The psychological study of language, or psycholinguistics, has a close rela-

tionship to work in linguistics and on LANGUAGE ACQUISITION. The complex formal properties of language, together with its apparent ease of acquisition by very young children, have made it the focus of debates about the extent and nature of NATIVISM in cognition. COMPUTATIONAL PSYCHOLINGUISTICS is concerned with modeling the complex processes involved in language use. In modern cultures that have achieved LITERACY with the introduction of written forms of language, the process of READING lies at the interface of psycholinguistics, perception, and memory retrieval. The intimate relationship between language and thought, and between language and human concepts, is widely recognized but still poorly understood. The use of METAPHOR in language is related to other symbolic processes in human cognition, particularly ANALOGY and CATEGORIZATION.

One of the most fundamental aspects of biological intelligence is the capacity to adaptively alter behavior. It has been clear at least from the time of William James that the adaptiveness of human behavior and the ability to achieve EXPERTISE in diverse domains is not generally the direct product of innate predispositions, but rather the result of adaptive problem solving and LEARNING SYSTEMS that operate over the lifespan. Both production systems and neural networks provide computational models of some aspects of learning, although no model has captured anything like the full range of human learning capacities. Humans as well as some other animals are able to learn by IMITATION, for example, translating visual information about the behavior of others into motor routines that allow the observer/imitator to produce comparable behavior. Many animal species are able to acquire expectancies about the environment and the consequences of the individual's actions on the basis of CONDITIONING, which enables learning of contingencies among events and actions.

Conditioning appears to be a primitive form of causal induction, the process by which humans and other animals learn about the cause-effect structure of the world. Both causal knowledge and similarity relations contribute to the process of categorization, which leads to the development of categories and concepts that serve to organize knowledge. People act as if they assume the external appearances of category members are caused by hidden (and often unknown) internal properties (e.g., the appearance of an individual dog may be attributed to its internal biology), an assumption sometimes termed psychological ESSENTIALISM.

There are important developmental influences that lead to CONCEPTUAL CHANGE over childhood. These developmental aspects of cognition are particularly important in understanding SCIENTIFIC THINKING AND ITS DEVELOPMENT. Without formal schooling, children and adults arrive at systematic beliefs that comprise NAIVE MATHEMATICS and NAIVE PHYSICS. Some of these beliefs provide the foundations for learning mathematics and physics in formal EDUCATION, but some are misconceptions that can impede learning these topics in school (see also AI AND EDUCATION). Young children are prone to ANIMISM, attributing properties of people and other animals to plants and nonliving things. Rather than being an aberrant form of early thought, animism may be an early manifestation of the use of ANALOGY to make inferences and learn new cognitive structures. Analogy is the process used to find systematic structural correspondences between a familiar, well-understood situation and an unfamiliar, poorly understood one, and then using the correspondences to draw plausible inferences about the less familiar case. Analogy, along with hypothesis testing and evaluation of competing explanations, plays a role in the discovery of new regularities and theories in science.

In its more complex forms, learning is intimately connected to thinking and reasoning. Humans are not only able to think, but also to think *about* their own cognitive processes, resulting in METACOGNITION. They can also form higher-level representations, termed METAREPRESENTATION. There are major individual differences in intelligence as assessed by tasks that require abstract thinking. Similarly, people differ in their CREATIVITY in finding solutions to problems. Various neural disorders, such as forms of MENTAL RETARDATION and AUTISM, can impair or radically alter normal thinking abilities. Some aspects of thinking are vulnerable to disruption in later life due to the links between AGING AND COGNITION.

Until the last few decades, the psychology of DEDUCTIVE REASONING was dominated by the view that human thinking is governed by formal rules akin to those used

in LOGIC. Although some theorists continue to argue for a role for formal, content-free rules in reasoning, others have focused on the importance of content-specific rules. For example, people appear to have specialized procedures for reasoning about broad classes of pragmatically important tasks, such as understanding social relations or causal relations among events. Such pragmatic reasoning schemas (Cheng and Holyoak 1985) enable people to derive useful inferences in contexts related to important types of recurring goals. In addition, both deductive and inductive inferences may sometimes be made using various types of MENTAL MODELS, in which specific possible cases are represented and manipulated (see also CASE-BASED REASONING AND ANALOGY).

Much of human inference depends not on deduction, but on inductive PROBABILISTIC REASONING under conditions of UNCERTAINTY. Work by researchers such as AMOS TVERSKY and Daniel Kahneman has shown that everyday inductive reasoning and decision making is often based on simple JUDGMENT HEURISTICS related to ease of memory retrieval (the *availability* heuristic) and degree of similarity (the *representativeness* heuristic). Although judgment heuristics are often able to produce fast and accurate responses, they can sometimes lead to errors of prediction (e.g., conflating the subjective ease of remembering instances of a class of events with their objective frequency in the world).

More generally, the impressive power of human information processing has apparent limits. People all too often take actions that will not achieve their intended ends, and pursue short-term goals that defeat their own long-term interests. Some of these mistakes arise from motivational biases, and others from computational limitations that constrain human attention, memory, and reasoning processes. Although human cognition is fundamentally adaptive, we have no reason to suppose that "all's for the best in this best of all possible minds."

Neurosciences

Thomas D. Albright and Helen J. Neville

1   Cognitive Neuroscience

The term alone suggests a field of study that is pregnant and full of promise. It is a large field of study, uniting concepts and techniques from many disciplines, and its boundaries are rangy and often loosely defined. At the heart of cognitive neuroscience, however, lies the fundamental question of knowledge and its representation by the brain—a relationship characterized not inappropriately by WILLIAM JAMES (1842–1910) as "the most mysterious thing in the world" (James 1890 vol. 1, 216). Cognitive neuroscience is thus a science of information processing. Viewed as such, one can identify key experimental questions and classical areas of study: How is information acquired (sensation), interpreted to confer meaning (perception and recognition), stored or modified (learning and memory), used to ruminate (thinking and consciousness), to predict the future state of the environment and the consequences of action (decision making), to guide behavior (motor control), and to communicate (language)? These questions are, of course, foundational in cognitive science generally, and it is instructive to consider what distinguishes cognitive neuroscience from cognitive science and psychology, on the one hand, and the larger field of neuroscience, on the other.

The former distinction is perhaps the fuzzier, depending heavily as it does upon how one defines cognitive science. A neurobiologist might adopt the progressive (or naive) view that the workings of the brain are the subject matter of both, and the distinction is therefore moot. But this view evidently has not prevailed (witness the fact that neuroscience is but one of the subdivisions of this volume); indeed the field of cognitive science was founded upon and continues to press the distinction between software (the content of cognition) and hardware (the physical stuff, for example, the brain) upon which cognitive processes are implemented. Much has been written on this topic, and one who pokes at the distinction too hard is likely to unshelve as much dusty political discourse as true science. In any case, for present purposes, we will consider both the biological hardware and the extent to which it constrains the software, and in doing so we will discuss answers to the questions of cognitive science that are rooted in the elements of biological systems.

The relationship between cognitive neuroscience and the umbrella of modern neuroscience is more straightforward and less embattled. While the former is clearly a subdivision of the latter, the questions of cognitive neuroscience lie at the root of much of neuroscience's turf. Where distinctions are often made, they arise from the fact that cognitive neuroscience is a functional neuroscience—particular structures and signals of the nervous system are of interest inasmuch as they can be used to explain cognitive functions.

There being many levels of explanation in biological systems—ranging from cellular and molecular events to complex behavior—a key challenge of the field of cognitive neuroscience has been to identify the relationships between different levels and the train of causality. In certain limited domains, this challenge has met with spectacular success; in others, it is clear that the relevant concepts have only begun to take shape and the necessary experimental tools are far behind. Using examples drawn from well-developed areas of research, such as vision, memory, and language, we illustrate concepts, experimental approaches, and general principles that have emerged—and, more specifically, how the work has answered many of the information processing questions identified above. Our contemporary view of cognitive neuroscience owes much to the heights attained by our predecessors; to appreciate the state of this field fully, it is useful to begin with a consideration of how we reached this vantage point.

2   *Origins of Cognitive Neuroscience*

Legend has it that the term "cognitive neuroscience" was coined by George A. Miller—the father of modern cognitive psychology—in the late 1970s over cocktails with Michael Gazzaniga at the Rockefeller University Faculty Club. That engaging tidbit of folklore nevertheless belies the ancient history of this pursuit. Indeed, identification of the biological structures and events that account for our ability to acquire, store, and utilize knowledge of the world was one of the earliest goals of empirical science. The emergence of the interdisciplinary field of cognitive neuroscience that we know today, which lies squarely at the heart of twentieth-century neuroscience, can thus be traced from a common stream in antiquity, with many tributaries converging in time as new concepts and techniques have evolved (Boring 1950).

Localization of Function

The focal point of the earliest debates on the subject—and a topic that has remained a centerpiece of cognitive neuroscience to the present day—is localization of the material source of psychological functions. With Aristotle as a notable exception (he thought the heart more important), scholars of antiquity rightly identified the brain as the seat of intellect. Relatively little effort was made to localize *specific* mental functions to *particular* brain regions until the latter part of the eighteenth century, when the anatomist Franz Josef Gall (1758–1828) unleashed the science of phrenology. Although flawed in its premises, and touted by charlatans, phrenology focused attention on the CEREBRAL CORTEX and brought the topic of localization of function to the forefront of an emerging nineteenth century physiology and psychology of mind (Zola-Morgan 1995). The subsequent HISTORY OF CORTICAL LOCALIZATION of function (Gross 1994a) is filled with colorful figures and weighty confrontations between localizationists and functional holists (antilocalizationists). Among the longest shadows is that cast by PAUL BROCA (1824–1880), who in 1861 reported that damage to a "speech center" in the left frontal lobe resulted in loss of speech function, and was thus responsible for the first widely cited evidence for localization of function in the cerebral cortex. An important development of a quite different nature came in the form of the Bell-Magendie law, discovered independently in the early nineteenth century by the physiologists Sir Charles Bell (1774–1842) and François Magendie (1783–1855). This law identified the fact that sensory and motor nerve fibers course through different roots (dorsal and ventral, respectively) of the spinal cord. Although far from the heavily contested turf of the cerebral cortex, the concept of nerve specificity paved the way for the publication in 1838 by Johannes Muller (1801–1858) of the law of specific nerve energies, which included among its principles the proposal that nerves carrying different types of sensory information terminate in distinct brain loci, perhaps in the cerebral cortex.

Persuasive though the accumulated evidence seemed at the dawn of the twentieth century, the debate between localizationists and antilocalizationists raged on for another three decades. By this time the chief experimental tool had become the "lesion method," through which the functions of specific brain regions are inferred from the behavioral or psychological consequences of loss of the tissue in question (either by clinical causes or deliberate experimental intervention). A central player during this period was the psychologist KARL SPENCER LASHLEY (1890–1958)—often inaccurately characterized as professing strong antilocalizationist beliefs, but best known for the concept of equipotentiality and the law of mass action of brain function. Lashley's descendants include several generations of flag bearers for the localizationist front—Carlyle Jacobsen, John Fulton, Karl Pribram, Mortimer Mishkin, Lawrence Weiskrantz, and Charles Gross, among others—who established footholds for our present understanding of the cognitive functions of the frontal and temporal lobes.

These later efforts to localize cognitive functions using the lesion method were complemented by studies of the effects of electrical stimulation of the human brain on psychological states. The use of stimulation as a probe for cognitive function followed

its more pragmatic application as a functional brain mapping procedure executed in preparation for surgical treatment of intractable epilepsy. The neurosurgeon WILDER PENFIELD (1891–1976) pioneered this approach in the 1930s at the legendary Montreal Neurological Institute and, with colleagues Herbert Jasper and Brenda Milner, subsequently began to identify specific cortical substrates of language, memory, emotion, and perception.

The years of the mid-twentieth century were quarrelsome times for the expanding field of psychology, which up until that time had provided a home for much of the work on localization of brain function. It was from this fractious environment, with inspiration from the many successful experimental applications of the lesion method and a growing link to wartime clinical populations, that the field of neuropsychology emerged—and with it the wagons were drawn up around the first science explicitly devoted to the relationship between brain and cognitive function. Early practitioners included the great Russian neuropsychologist ALEKSANDR ROMANOVICH LURIA (1902–1977) and the American behavioral neurologist NORMAN GESCHWIND (1926–1984), both of whom promoted the localizationist cause with human case studies and focused attention on the role of connections between functionally specific brain regions. Also among the legendary figures of the early days of neuropsychology was HANS-LUKAS TEUBER (1916–1977). Renowned scientifically for his systematization of clinical neuropsychology, Teuber is perhaps best remembered for having laid the cradle of modern cognitive neuroscience in the 1960s MIT Psychology Department, through his inspired recruitment of an interdisciplinary faculty with a common interest in brain structure and function, and its relationship to complex behavior (Gross 1994b).

Neuron Doctrine

Although the earliest antecedents of modern cognitive neuroscience focused by necessity on the macroscopic relationship between brain and psychological function, the last 50 years have seen a shift of focus, with major emphasis placed upon local neuronal circuits and the causal link between the activity of individual cells and behavior. The payoff has been astonishing, but one often takes for granted the resolution of much hotly debated turf. The debates in question focused on the elemental units of nervous system structure and function. We accept these matter-of-factly to be specialized cells known as NEURONS, but prior to the development of techniques to visualize cellular processes, their existence was mere conjecture. Thus the two opposing views of the nineteenth century were reticular theory, which held that the tissue of the brain was composed of a vast anastomosing reticulum, and neuron theory, which postulated neurons as differentiated cell types and the fundamental unit of nervous system function. The ideological chasm between these camps ran deep and wide, reinforced by ties to functional holism in the case of reticular theory, and localizationism in the case of neuron theory. The deadlock broke in 1873 when CAMILLO GOLGI (1843–1926) introduced a method for selective staining of individual neurons using silver nitrate, which permitted their visualization for the first time. (Though this event followed the discovery of the microscope by approximately two centuries, it was the Golgi method's complete staining of a minority of neurons that enabled them to be distinguished from one another.) In consequence, the neuron doctrine was cast, and a grand stage was set for studies of differential cellular morphology, patterns of connectivity between different brain regions, biochemical analysis, and, ultimately, electrophysiological characterization of the behavior of individual neurons, their synaptic interactions, and relationship to cognition.

Undisputedly, the most creative and prolific applicant of the Golgi technique was the Spanish anatomist SANTIAGO RAMÓN Y CAJAL (1852–1934), who used this new method to characterize the fine structure of the nervous system in exquisite detail. Cajal's efforts yielded a wealth of data pointing to the existence of discrete neuronal

elements. He soon emerged as a leading proponent of the neuron doctrine and subsequently shared the 1906 Nobel Prize in physiology and medicine with Camillo Golgi. (Ironically, Golgi held vociferously to the reticular theory throughout his career.)

Discovery of the existence of independent neurons led naturally to investigations of their means of communication. The fine-scale stereotyped contacts between neurons were evident to Ramón y Cajal, but it was Sir Charles Scott Sherrington (1857–1952) who, at the turn of the century, applied the term "synapses" to label them. The transmission of information across synapses by chemical means was demonstrated experimentally by Otto Loewi (1873–1961) in 1921. The next several decades saw an explosion of research on the nature of chemical synaptic transmission, including the discovery of countless putative NEUROTRANSMITTERS and their mechanisms of action through receptor activation, as well as a host of revelations regarding the molecular events that are responsible for and consequences of neurotransmitter release. These findings have provided a rich foundation for our present understanding of how neurons compute and store information about the world (see COMPUTING IN SINGLE NEURONS).

The ability to label neurons facilitated two other noteworthy developments bearing on the functional organization of the brain: (1) cytoarchitectonics, which is the use of coherent regional patterns of cellular morphology in the cerebral cortex to identify candidates for functional specificity; and (2) neuroanatomical tract tracing, by which the patterns of connections between and within different brain regions are established. The practice of cytoarchitectonics began at the turn of the century and its utility was espoused most effectively by the anatomists Oscar Vogt (1870–1950), Cecile Vogt (1875–1962), and Korbinian Brodmann (1868–1918). Cytoarchitectonics never fully achieved the functional parcellation that it promised, but clear histological differences across the cerebral cortex, such as those distinguishing primary visual and motor cortices from surrounding tissues, added considerable reinforcement to the localizationist camp.

By contrast, the tracing of neuronal connections between different regions of the brain, which became possible in the late nineteenth century with the development of a variety of specialized histological staining techniques, has been an indispensable source of knowledge regarding the flow of information through the brain and the hierarchy of processing stages. Recent years have seen the emergence of some remarkable new methods for tracing individual neuronal processes and for identifying the physiological efficacy of specific anatomical connections (Callaway 1998), the value of which is evidenced most beautifully by studies of the CELL TYPES AND CONNECTIONS IN THE VISUAL CORTEX.

The neuron doctrine also paved the way for an understanding of the information represented by neurons via their electrical properties, which has become a cornerstone of cognitive neuroscience in the latter half of the twentieth century. The electrical nature of nervous tissue was well known (yet highly debated) by the beginning of the nineteenth century, following advancement of the theory of "animal electricity" by Luigi Galvani (1737–1798) in 1791. Subsequent work by Emil du Bois-Reymond (1818–1896), Carlo Matteucci (1811–1862), and HERMANN LUDWIG FERDINAND VON HELMHOLTZ (1821–1894) established the spreading nature of electrical potentials in nervous tissue (nerve conduction), the role of the nerve membrane in maintaining and propagating an electrical charge ("wave of negativity"), and the velocity of nervous conduction. It was in the 1920s that Lord Edgar Douglas Adrian (1889–1977), using new cathode ray tube and amplification technology, developed the means to record "action potentials" from single neurons. Through this means, Adrian discovered the "all-or-nothing property" of nerve conduction via action potentials and demonstrated that action potential *frequency* is the currency of information transfer by neurons. Because of the fundamental importance of these discoveries, Adrian shared the 1932 Nobel Prize in physiology and medicine with Sherrington. Not long afterward, the Finnish physiologist Ragnar Granit developed techniques for recording neuronal activity using electrodes placed on the surface of the skin (Granit discovered the electroretinogram, or ERG, which reflects large-scale neuronal activity in the RETINA). These techniques became the foundation for non-invasive measurements of brain

activity (see ELECTROPHYSIOLOGY, ELECTRIC AND MAGNETIC EVOKED FIELDS), which have played a central role in human cognitive neuroscience over the past 50 years.

With technology for SINGLE-NEURON RECORDING and large-scale electrophysiology safely in hand, the mid-twentieth century saw a rapid proliferation of studies of physiological response properties in the central nervous system. Sensory processing and motor control emerged as natural targets for investigation, and major emphasis was placed on understanding (1) the topographic mapping of the sensory or motor field onto central target zones (such as the retinotopic mapping in primary visual cortex), and (2) the specific sensory or motor events associated with changes in frequency of action potentials. Although some of the earliest and most elegant research was directed at the peripheral auditory system—culminating with Georg von Bekesy's (1889–1972) physical model of cochlear function and an understanding of its influence on AUDITORY PHYSIOLOGY—it is the visual system that has become the model for physiological investigations of information processing by neurons.

The great era of single-neuron studies of visual processing began in the 1930s with the work of Haldan Keffer Hartline (1903–1983), whose recordings from the eye of the horseshoe crab (*Limulus*) led to the discovery of neurons that respond when stimulated by light and detect differences in the patterns of illumination (i.e., contrast; Hartline, Wagner, and MacNichol 1952). It was for this revolutionary advance that Hartline became a corecipient of the 1967 Nobel Prize in physiology and medicine (together with Ragnar Granit and George Wald). Single-neuron studies of the mammalian visual system followed in the 1950s, with the work of Steven Kuffler (1913–1980) and Horace Barlow, who recorded from retinal ganglion cells. This research led to the development of the concept of the center-surround receptive field and highlighted the key role of spatial contrast detection in early vision (Kuffler 1953). Subsequent experiments by Barlow and Jerome Lettvin, among others, led to the discovery of neuronal FEATURE DETECTORS for behaviorally significant sensory inputs. This set the stage for the seminal work of David Hubel and Torsten Wiesel, whose physiological investigations of visual cortex, beginning in the late 1950s, profoundly shaped our understanding of the relationship between neuronal and sensory events (Hubel and Wiesel 1977).

Sensation, Association, Perception, and Meaning

The rise of neuroscience from its fledgling origins in the nineteenth century was paralleled by the growth of experimental psychology and its embrace of sensation and perception as primary subject matter. The origins of experimental psychology as a scientific discipline coincided, in turn, with the convergence and refinement of views on the nature of the difference between sensation and perception. These views, which began to take their modern shape with the concept of "associationism" in the empiricist philosophy of John Locke (1632–1704), served to focus attention on the extraction of meaning from sensory events and, not surprisingly, lie at the core of much twentieth century cognitive neuroscience.

The proposition that things perceived cannot reflect directly the material of the external world, but rather depend upon the states of the sense organs and the intermediary nerves, is as old as rational empiricism itself. Locke's contribution to this topic was simply that *meaning*—knowledge of the world, functional relations between sensations, nee *perception*—is born from an association of "ideas," of which sensation was the primary source. The concept was developed further by George Berkeley (1685–1753) in his "theory of objects," according to which a sensation has meaning— that is, a reference to an external material source—only via the context of its relationship to other sensations. This associationism was a principal undercurrent of Scottish and English philosophy for the next two centuries, the concepts refined and the debate

further fueled by the writings of James Mill and, most particularly, John Stuart Mill. It was the latter who defined the "laws of association" between elemental sensations, and offered the useful dictum that perception is the belief in the "permanent possibilities of sensation." By so doing, Mill bridged the gulf between the ephemeral quality of sensations and the permanence of objects and our experience of them: it is the link between present sensations and those known to be possible (from past experience) that allows us to perceive the enduring structural and relational qualities of the external world.

In the mid-nineteenth century the banner of associationism was passed from philosophy of mind to the emerging German school of experimental psychology, which numbered among its masters Gustav Fechner (1801–1887), Helmholtz, WILHELM WUNDT (1832–1920), and the English-American disciple of that tradition Edward Titchener (1867–1927). Fechner's principal contribution in this domain was the introduction of a systematic scientific methodology to a topic that had before that been solely the province of philosophers and a target of introspection. Fechner's *Elements of Psychophysics,* published in 1860, founded an "exact science of the functional relationship . . . between body and mind," based on the assumption that the relationship between brain and perception could be measured experimentally as the relationship between a stimulus and the sensation it gives rise to. PSYCHOPHYSICS thus provided the new nineteenth-century psychology with tools of a rigorous science and has subsequently become a mainstay of modern cognitive neuroscience. It was during this move toward quantification and systematization that Helmholtz upheld the prevailing associationist view of objects as sensations bound together through experience and memory, and he advanced the concept of *unconscious inference* to account for the attribution of perceptions to specific environmental causes. Wundt pressed further with the objectification and deconstruction of psychological reality by spelling out the concept—implicit in the manifestoes of his associationist predecessors—of elementism. Although Wundt surely believed that the meaning of sensory events lay in the relationship between them, elementism held that any complex association of sensations—any perception—was reducible to the sensory elements themselves. Titchener echoed the Wundtian view and elaborated upon the critical role of context in the associative extraction of meaning from sensation.

It was largely in response to this doctrine of elementism, its spreading influence, and its corrupt reductionistic account of perceptual experience that GESTALT PSYCHOLOGY was born in the late nineteenth century. In simplest terms, the Gestalt theorists, led by the venerable trio of Max Wertheimer (1880–1943), Wolfgang Kohler (1887–1967), and Kurt Koffka (1886–1941), insisted—and backed up their insistence with innumerable compelling demonstrations—that our phenomenal experience of objects, which includes an appreciation of their meanings and functions, is not generally reducible to a set of elemental sensations and the relationships between them. Moreover, rather than accepting the received wisdom that perception amounts to an inference about the world drawn from the associations between sensations, the Gestalt theorists held the converse to be true: perception is native experience and efforts to identify the underlying sensory elements are necessarily inferential (Koffka 1935). In spite of other flaws and peculiarities of the broad-ranging Gestalt psychology, this holistic view of perception, its distinction from sensation, and the nature of meaning, has become a central theme of modern cognitive neuroscience.

At the time the early associationist doctrine was being formed, there emerged a physiological counterpart in the form of Johannes Muller's (1801–1858) law of specific nerve energies, which gave rise in turn to the concept of specific fiber energies, and, ultimately, our twentieth-century receptive fields and feature detectors. Muller's law followed, intellectually as well as temporally, the Bell-Magendie law of distinct sensory and motor spinal roots, which set a precedent for the concept of specificity of nerve action. Muller's law was published in his 1838 *Handbook of Physiology* and consisted of several principles, those most familiar being the specificity of the sensory information (Muller identified five kinds) carried by different nerves and the specificity of the site of termination in the brain (a principle warmly embraced by functional localizationists of the era). For present discussion, the essential principle is that "the

immediate objects of the perception of our senses are merely particular states induced in the nerves, and felt as sensations either by the nerves themselves or by the sensorium" (Boring 1950). Muller thus sidestepped the ancient problem of the mind's access to the external world by observing that all it can hope to access is the state of its sensory nerves. Accordingly, perception of the external world is a consequence of the stable relationship between external stimuli and nerve activation, and—tailing the associationist philosophers—meaning is granted by the associative interactions between nerves carrying different types of information. The concept was elaborated further by Helmholtz and others to address the different submodalities (e.g., color vs. visual distance) and qualities (e.g., red vs. green) of information carried by different fibers, and is a tenet of contemporary sensory neurobiology and cognitive neuroscience. The further implications of associationism for an understanding of the neuronal basis of perception—or, more precisely, of functional knowledge of the world—are profound and, as we shall see, many of the nineteenth-century debates on the topic are being replayed in the courts of modern single-neuron physiology.

3   *Cognitive Neuroscience Today*

And so it was from these ancient but rapidly converging lines of inquiry, with the blush still on the cheek of a young cognitive science, that the modern era of cognitive neuroscience began. The field continues to ride a groundswell of optimism borne by new experimental tools and concepts—particularly single-cell electrophysiology, functional brain imaging, molecular genetic manipulations, and neuronal computation—and the access they have offered to neuronal operations underlying cognition. The current state of the field and its promise of riches untapped can be summarized through a survey of the processes involved in the acquisition, storage, and use of information by the nervous system: sensation, perception, decision formation, motor control, memory, language, emotions, and consciousness.

Sensation

We acquire knowledge of the world through our senses. Not surprisingly, sensory processes are among the most thoroughly studied in cognitive neuroscience. Systematic explorations of these processes originated in two domains. The first consisted of investigations of the physical nature of the sensory stimuli in question, such as the wave nature of light and sound. Sir Isaac Newton's (1642–1727) *Optiks* is an exemplar of this approach. The second involved studies of the anatomy of the peripheral sense organs, with attention given to the manner in which anatomical features prepared the physical stimulus for sensory transduction. Von Bekesy's beautiful studies of the structural features of the cochlea and the relation of those features to the neuronal frequency coding of sound is a classic example (for which he was awarded the 1961 Nobel Prize in physiology and medicine). Our present understanding of the neuronal bases of sensation was further enabled by three major developments: (1) establishment of the neuron doctrine, with attendant anatomical and physiological studies of neurons; (2) systematization of behavioral studies of sensation, made possible through the development of psychophysics; and (3) advancement of sophisticated theories of neuronal function, as embodied by the discipline of COMPUTATIONAL NEUROSCIENCE. For a variety of reasons, vision has emerged as the model for studies of sensory processing, although many fundamental principles of sensory processing are conserved across modalities.

Initial acquisition of information about the world, by all sensory modalities, begins with a process known as transduction, by which forms of physical energy (e.g., photons) alter the electrical state of a sensory neuron. In the case of vision, phototransduction occurs in the RETINA, which is a specialized sheet-like neural network with a regular repeating structure. In addition to its role in transduction, the retina also functions in the initial detection of spatial and temporal contrast (Enroth-Cugell and Robson 1966; Kaplan and Shapley 1986) and contains specialized neurons that subserve

COLOR VISION (see also COLOR, NEUROPHYSIOLOGY OF). The outputs of the retina are carried by a variety of ganglion cell types to several distinct termination sites in the central nervous system. One of the largest projections forms the "geniculostriate" pathway, which is known to be critical for normal visual function in primates. This pathway ascends to the cerebral cortex by way of the lateral geniculate nucleus of the THALAMUS.

The cerebral cortex itself has been a major focus of study during the past forty years of vision research (and sensory research of all types). The entry point for ascending visual information is via primary visual cortex, otherwise known as striate cortex or area V1, which lies on the posterior pole (the occipital lobe) of the cerebral cortex in primates. The pioneering studies of V1 by Hubel and Wiesel (1977) established the form in which visual information is represented by the activity of single neurons and the spatial arrangement of these representations within the cortical mantle ("functional architecture"). With the development of increasingly sophisticated techniques, our understanding of cortical VISUAL ANATOMY AND PHYSIOLOGY, and their relationships to sensory experience, has been refined considerably. Several general principles have emerged:

Receptive Field   This is an operationally defined attribute of a sensory neuron, originally offered by the physiologist Haldan Keffer Hartline, which refers to the portion of the sensory field that, when stimulated, elicits a change in the electrical state of the cell. More generally, the receptive field is a characterization of the filter properties of a sensory neuron, which are commonly multidimensional and include selectivity for parameters such as spatial position, intensity, and frequency of the physical stimulus. Receptive field characteristics thus contribute to an understanding of the information represented by the brain, and are often cited as evidence for the role of a neuron in specific perceptual and cognitive functions.

Contrast Detection   The elemental sensory operation, that is, one carried out by all receptive fields—is detection of spatial or temporal variation in the incoming signal. It goes without saying that if there are no environmental changes over space and time, then nothing in the input is worthy of detection. Indeed, under such constant conditions sensory neurons quickly adapt. The result is a demonstrable loss of sensation—such as "snow blindness"—that occurs even though there may be energy continually impinging on the receptor surface. On the other hand, contrast along some sensory dimension indicates a change in the environment, which may in turn be a call for action. All sensory modalities have evolved mechanisms for detection of such changes.

Topographic Organization   Representation of spatial patterns of activation within a sensory field is a key feature of visual, auditory, and tactile senses, which serves the behavioral goals of locomotor navigation and object recognition. Such representations are achieved for these modalities, in part, by topographically organized neuronal maps. In the visual system, for example, the retinal projection onto the lateral geniculate nucleus of the thalamus possesses a high degree of spatial order, such that neurons with spatially adjacent receptive fields lie adjacent to one another in the brain. Similar visuotopic maps are seen in primary visual cortex and in several successively higher levels of processing (e.g., Gattass, Sousa, and Covey 1985). These maps are commonly distorted relative to the sensory field, such that, in the case of vision, the numbers of neurons representing the central portion of the visual field greatly exceed those representing the visual periphery. These variations in "magnification factor" coincide with (and presumably underlie) variations in the observer's resolving power and sensitivity.

Modular and Columnar Organization   The proposal that COLUMNS AND MODULES form the basis for functional organization in the sensory neocortex is a natural extension of the nineteenth-century concept of localization of function. The 1970s and 1980s saw a dramatic rise in the use of electrophysiological and anatomical tools to subdivide sensory cortices—particularly visual cortex—into distinct functional mod-

ules. At the present time, evidence indicates that the visual cortex of monkeys is composed of over thirty such regions, including the well-known and heavily studied areas V1, V2, V3, V4, MT, and IT, as well as some rather more obscure and equivocal designations (Felleman and Van Essen 1991). These efforts to reveal order in heterogeneity have been reinforced by the appealing computational view (e.g., Marr 1982) that larger operations (such as seeing) can be subdivided and assigned to dedicated task-specific modules (such as ones devoted to visual motion or color processing, for example). The latter argument also dovetails nicely with the nineteenth-century concept of elementism, the coincidence of which inspired a fevered effort to identify visual areas that process specific sensory "elements." Although this view appears to be supported by physiological evidence for specialized response properties in some visual areas—such as a preponderance of motion-sensitive neurons in area MT (Albright 1993) and color-sensitive neurons in area V4 (Schein and Desimone 1990)—the truth is that very little is yet known of the unique contributions of most other cortical visual areas.

Modular organization of sensory cortex also occurs at a finer spatial scale, in the form of regional variations in neuronal response properties and anatomical connections, which are commonly referred to as columns, patches, blobs, and stripes. The existence of a column-like anatomical substructure in the cerebral cortex has been known since the early twentieth century, following the work of Ramón y Cajal, Constantin von Economo (1876–1931), and Rafael Lorente de Nó. It was the latter who first suggested that this characteristic structure may have some functional significance (Lorento de Nó 1938). The concept of modular functional organization was later expanded upon by the physiologist Vernon B. Mountcastle (1957), who obtained the first evidence for columnar function through his investigations of the primate somatosensory system, and offered this as a general principle of cortical organization. The most well known examples of modular organization of the sort predicted by Mountcastle are the columnar systems for contour orientation and ocular dominance discovered in primary visual cortex in the 1960s by David Hubel and Torsten Wiesel (1968). Additional evidence for functional columns and for the veracity of Mountcastle's dictum has come from studies of higher visual areas, such as area MT (Albright, Desimone, and Gross 1984) and the inferior temporal cortex (Tanaka 1997). Other investigations have demonstrated that modular representations are not limited to strict columnar forms (Born and Tootell 1993; Livingstone and Hubel 1984) and can exist as relatively large cortical zones in which there is a common feature to the neuronal representation of sensory information (such as clusters of cells that exhibit a greater degree of selectivity for color, for example).

The high incidence of columnar structures leads one to wonder why they exist. One line of argument, implicit in Mountcastle's original hypothesis, is based on the need for adequate "coverage"—that is, nesting the representation of one variable (such as preferred orientation of a visual contour) across changes in another (such as the topographic representation of the visual field)—which makes good computational sense and has received considerable empirical support (Hubel and Wiesel 1977). Other arguments include those based on developmental constraints (Swindale 1980; Miller 1994; Goodhill 1997) and computational advantages afforded by representation of sensory features in a regular periodic structure (see COMPUTATIONAL NEUROANATOMY; Schwartz 1980).

Hierarchical Processing A consistent organizational feature of sensory systems is the presence of multiple hierarchically organized processing stages, through which incoming sensory information is represented in increasingly complex or abstract forms. The existence of multiple stages has been demonstrated by anatomical studies, and the nature of the representation at each stage has commonly been revealed through electrophysiological analysis of sensory response properties. As we have seen for the visual system, the first stage of processing beyond transduction of the physical stimulus is one in which a simple abstraction of light intensity is rendered, namely a representation of luminance contrast. Likewise, the outcome of processing in primary visual cortex is, in part, a representation of image contours—formed, it is believed, by

a convergence of inputs from contrast-detecting neurons at earlier stages (Hubel and Wiesel 1962). At successively higher stages of processing, information is combined to form representations of even greater complexity, such that, for example, at the pinnacle of the pathway for visual pattern processing—a visual area known as inferior temporal (IT) cortex—individual neurons encode complex, behaviorally significant objects, such as faces (see FACE RECOGNITION).

Parallel Processing   In addition to multiple serial processing stages, the visual system is known to be organized in parallel streams. Incoming information of different types is channeled through a variety of VISUAL PROCESSING STREAMS, such that the output of each serves a unique function. This type of channeling occurs on several scales, the grossest of which is manifested as multiple retinal projections (typically six) to different brain regions. As we have noted, it is the geniculostriate projection that serves pattern vision in mammals. The similarly massive retinal projection to the midbrain superior colliculus (the "tectofugal" pathway) is known to play a role in orienting responses, OCULOMOTOR CONTROL, and MULTISENSORY INTEGRATION. Other pathways include a retinal projection to the hypothalamus, which contributes to the entrainment of circadian rhythms by natural light cycles.

Finer scale channeling of visual information is also known to exist, particularly in the case of the geniculostriate pathway (Shapley 1990). Both anatomical and physiological evidence (Perry, Oehler, and Cowey 1984; Kaplan and Shapley 1986) from early stages of visual processing support the existence of at least three subdivisions of this pathway, known as parvocellular, magnocellular, and the more recently identified koniocellular (Hendry and Yoshioka 1994). Each of these subdivisions is known to convey a unique spectrum of retinal image information and to maintain that information in a largely segregated form at least as far into the system as primary visual cortex (Livingstone and Hubel 1988).

Beyond V1, the ascending anatomical projections fall into two distinct streams, one of which descends ventrally into the temporal lobe, while the other courses dorsally to the parietal lobe. Analyses of the behavioral effects of lesions, as well as electrophysiological studies of neuronal response properties, have led to the hypothesis (Ungerleider and Mishkin 1982) that the ventral stream represents information about form and the properties of visual surfaces (such as their color or TEXTURE)—and is thus termed the "what" pathway—while the dorsal stream represents information regarding motion, distance, and the spatial relations between environmental surfaces—the so-called "where" pathway. The precise relationship, if any, between the early-stage channels (magno, parvo, and konio) and these higher cortical streams has been a rich source of debate and controversy over the past decade, and the answers remain far from clear (Livingstone and Hubel 1988; Merigan and Maunsell 1993).

Perception

Perception reflects the ability to derive meaning from sensory experience, in the form of information about structure and causality in the perceiver's environment, and of the sort necessary to guide behavior. Operationally, we can distinguish sensation from perception by the nature of the internal representations: the former encode the physical properties of the proximal sensory stimulus (the retinal image, in the case of vision), and the latter reflect the world that likely gave rise to the sensory stimulus (the visual scene). Because the mapping between sensory and perceptual events is never unique—multiple scenes can cause the same retinal image—perception is necessarily an inference about the probable causes of sensation.

As we have seen, the standard approach to understanding the information represented by sensory neurons, which has evolved over the past fifty years, is to measure

the correlation between a feature of the neuronal response (typically magnitude) and some physical parameter of a sensory stimulus (such as the wavelength of light or the orientation of a contour). Because the perceptual interpretation of a sensory event is necessarily context-dependent, this approach alone is capable of revealing little, if anything, about the relationship between neuronal events and perceptual state. There are, however, some basic variations on this approach that have led to increased understanding of the neuronal bases of perception.

Experimental Approaches to the Neuronal Bases of Perception

Origins of a Neuron Doctrine for Perceptual Psychology   The first strategy involves evaluation of neuronal responses to visual stimuli that consist of complex objects of behavioral significance. The logic behind this approach is that if neurons are found to be selective for such stimuli, they may be best viewed as representing something of perceptual meaning rather than merely coincidentally selective for the collection of sensory features. The early studies of "bug detectors" in the frog visual system by Lettvin and colleagues (Lettvin, Maturana, MCCULLOCH, and PITTS 1959) exemplify this approach and have led to fully articulated views on the subject, including the concept of the "gnostic unit" advanced by Jerzy Konorski (1967) and the "cardinal cell" hypothesis from Barlow's (1972) classic "Neuron Doctrine for Perceptual Psychology." Additional evidence in support of this concept came from the work of Charles Gross in the 1960s and 1970s, in the extraordinary form of cortical cells selective for faces and hands (Gross, Bender, and Rocha-Miranda 1969; Desimone et al. 1984). Although the suggestion that perceptual experience may be rooted in the activity of single neurons or small neuronal ensembles has been decried, in part, on the grounds that the number of possible percepts greatly exceeds the number of available neurons, and is often ridiculed as the "grandmother-cell" hypothesis, the evidence supporting neuronal representations for visual patterns of paramount behavioral significance, such as faces, is now considerable (Desimone 1991; Rolls 1992).

Although a step in the right direction, the problem with this general approach is that it relies heavily upon assumptions about how the represented information is used. If a cell is activated by a face, and only a face, then it seems likely that the cell contributes directly to the perceptually meaningful experience of face recognition rather than simply representing a collection of sensory features (Desimone et al. 1984). To some, that distinction is unsatisfactorily vague, and it is, in any case, impossible to prove that a cell *only* responds to a face. An alternative approach that has proved quite successful in recent years is one in which an effort is made to directly relate neuronal and perceptual events.

Neuronal Discriminability Predicts Perceptual Discriminability   In the last quarter of the twentieth century, the marriage of single-neuron recording with visual psychophysics has yielded one of the dominant experimental paradigms of cognitive neuroscience, through which it has become possible to explain behavioral performance on a perceptual task in terms of the discriminative capacity of sensory neurons. The earliest effort of this type was a study of tactile discrimination conducted by Vernon Mountcastle in the 1960s (Mountcastle et al. 1967). In this study, thresholds for behavioral discrimination performance were directly compared to neuronal thresholds for the same stimulus set. A later study by Tolhurst, Movshon, and Dean (1983) introduced techniques from SIGNAL DETECTION THEORY that allowed more rigorous quantification of the discriminative capacity of neurons and thus facilitated neuronal-perceptual comparisons. Several other studies over the past ten years have significantly advanced this cause (e.g., Dobkins and Albright 1995), but the most direct approach has been that adopted by William Newsome and colleagues (e.g., Newsome, Britten, and Movshon 1989). In this paradigm, behavioral and neuronal events are measured simultaneously in response to a sensory stimulus, yielding by brute force some of the strongest evidence to date for neural substrates of perceptual discriminability.

Decoupling Sensation and Perception   A somewhat subtler approach has been forged by exploiting the natural ambiguity between sensory events and perceptual experience (see ILLUSIONS). This ambiguity is manifested in two general forms: (1) single sensory events that elicit multiple distinct percepts, a phenomenon commonly known as "perceptual metastability," and (2) multiple sensory events—"sensory synonyms"—that elicit the same perceptual state. Both of these situations, which are ubiquitous in normal experience, afford opportunities to experimentally decouple sensation and perception.

The first form of sensory-perceptual ambiguity (perceptual metastability) is a natural consequence of the indeterminate mapping between a sensory signal and the physical events that gave rise to it. A classic and familiar example is the Necker Cube, in which the three-dimensional interpretation—the observer's inference about visual scene structure—periodically reverses despite the fact that the retinal image remains unchanged. Logothetis and colleagues (Logothetis and Schall 1989) have used a form of perceptual metastability known as binocular rivalry to demonstrate the existence of classes of cortical neurons that parallel changes in perceptual state in the face of constant retinal inputs.

The second type of sensory-perceptual ambiguity, in which multiple sensory images give rise to the same percept, is perhaps the more common. Such effects are termed perceptual constancies, and they reflect efforts by sensory systems to reconstruct behaviorally significant attributes of the world in the face of variation along irrelevant sensory dimensions. Size constancy—the invariance of perceived size of an object across different retinal sizes—and brightness or color constancy—the invariance of perceived reflectance or color of a surface in the presence of illumination changes—are classic examples. These perceptual constancies suggest an underlying neuronal invariance across specific image changes. Several examples of neuronal constancies have been reported, including invariant representations of direction of motion and shape across different cues for form (Albright 1992; Sary et al. 1995).

Contextual Influences on Perception and its Neuronal Bases   One of the most promising new approaches to the neuronal bases of perception is founded on the use of contextual manipulations to influence the perceptual interpretation of an image feature. As we have seen, the contextual dependence of perception is scarcely a new finding, but contextual manipulations have been explicitly avoided in traditional physiological approaches to sensory coding. As a consequence, most existing data do not reveal whether and to what extent the neuronal representation of an image feature is context dependent. Gene Stoner, Thomas Albright, and colleagues have pioneered the use of contextual manipulations in studies of the neuronal basis of the PERCEPTION OF MOTION (e.g., Stoner and Albright 1992, 1993). The results of these studies demonstrate that context can alter neuronal filter properties in a manner that predictably parallels its influence on perception.

Stages of Perceptual Representation
Several lines of evidence suggest that there may be multiple steps along the path to extracting meaning from sensory signals. These steps are best illustrated by examples drawn from studies of visual processing. Sensation itself is commonly identified with "early" or "low-level vision." Additional steps are as follows.

Mid-Level Vision   This step involves a reconstruction of the spatial relationships between environmental surfaces. It is implicit in the accounts of the perceptual psychologist JAMES JEROME GIBSON (1904–1979), present in the computational approach of DAVID MARR (1945–1980), and encompassed by what has recently come to be known as MID-LEVEL VISION. Essential features of this processing stage include a dependence upon proximal sensory context to establish surface relationships (see SURFACE PERCEPTION) and a relative lack of dependence upon prior experience. By establishing environmental STRUCTURE FROM VISUAL INFORMATION SOURCES, mid-level vision thus invests sensory events with some measure of meaning. A clear exam-

ple of this type of visual processing is found in the phenomenon of perceptual TRANS-PARENCY (Metelli 1974) and the related topic of LIGHTNESS PERCEPTION. Physiological studies of the response properties of neurons at mid-levels of the cortical hierarchy have yielded results consistent with a mid-level representation (e.g., Stoner and Albright 1992).

High-Level Vision   HIGH-LEVEL VISION is a loosely defined processing stage, but one that includes a broad leap in the assignment of meaning to sensory events—namely identification and classification on the basis of previous experience with the world. It is through this process that recognition of objects occurs (see OBJECT RECOGNITION, HUMAN NEUROPSYCHOLOGY; OBJECT RECOGNITION, ANIMAL STUDIES; and VISUAL OBJECT RECOGNITION, AI), as well as assignment of affect and semantic categorization. This stage thus constitutes a bridge between sensory processing and MEMORY. Physiological and neuropsychological studies of the primate temporal lobe have demonstrated an essential contribution of this region to object recognition (Gross 1973; Gross et al. 1985).

Sensory-Perceptual Plasticity

The processes by which information is acquired and interpreted by the brain are modifiable throughout life and on many time scales. Although plasticity of the sort that occurs during brain development and that which underlies changes in the sensitivity of mature sensory systems may arise from similar mechanisms, it is convenient to consider them separately.

Developmental Changes
The development of the mammalian nervous system is a complex, multistaged process that extends from embryogenesis through early postnatal life. This process begins with determination of the fate of precursor cells such that a subset becomes neurons. This is followed by cell division and proliferation, and by differentiation of cells into different types of neurons. The patterned brain then begins to take shape as cells migrate to destinations appropriate for their assigned functions. Finally, neurons begin to extend processes and to make synaptic connections with one another. These connections are sculpted and pruned over a lengthy postnatal period. A central tenet of modern neuroscience is that these final stages of NEURAL DEVELOPMENT correspond to specific stages of COGNITIVE DEVELOPMENT. These stages are known as "critical periods," and they are characterized by an extraordinary degree of plasticity in the formation of connections and cognitive functions.

   Although critical periods for development are known to exist for a wide range of cognitive functions such as sensory processing, motor control, and language, they have been studied most intensively in the context of the mammalian visual system. These studies have included investigations of the timing, necessary conditions for, and mechanisms of (1) PERCEPTUAL DEVELOPMENT (e.g., Teller 1997), (2) formation of appropriate anatomical connections (e.g., Katz and Shatz 1996), and (3) neuronal representations of sensory stimuli (e.g., Hubel, Wiesel, and LeVay 1977). The general view that has emerged is that the newborn brain possesses a considerable degree of order, but that sensory experience is *essential* during critical periods to maintain that order and to fine-tune it to achieve optimal performance in adulthood. These principles obviously have profound implications for clinical practice and social policy. Efforts to further understand the cellular mechanisms of developmental plasticity, their relevance to other facets of cognitive function, the relative contributions of genes and experience, and routes of

clinical intervention, are all among the most important topics for the future of cognitive neuroscience.

Dynamic Control of Sensitivity in the Mature Brain
Mature sensory systems have limited information processing capacities. An exciting area of research in recent years has been that addressing the conditions under which processing capacity is dynamically reallocated, resulting in fluctuations in sensitivity to sensory stimuli. The characteristics of sensitivity changes are many and varied, but all serve to optimize acquisition of information in a world in which environmental features and behavioral goals are constantly in flux. The form of these changes may be broad in scope or highly stimulus-specific and task-dependent. Changes may be nearly instantaneous, or they may come about gradually through exposure to specific environmental features. Finally, sensitivity changes differ greatly in the degree to which they are influenced by stored information about the environment and the degree to which they are under voluntary control.

Studies of the visual system reveal at least three types of sensitivity changes represented by the phenomena of (1) contrast gain control, (2) attention, and (3) perceptual learning. All can be viewed as recalibration of incoming signals to compensate for changes in the environment, the fidelity of signal detection (such as that associated with normal aging or trauma to the sensory periphery), and behavioral goals.

Generally speaking, neuronal gain control is the process by which the sensitivity of a neuron (or neural system) to its inputs is dynamically controlled. In that sense, all of the forms of adult plasticity discussed below are examples of gain control, although they have different dynamics and serve different functions.

Contrast Gain Control   A well-studied example of gain control is the invariance of perceptual sensitivity to the features of the visual world over an enormous range of lighting conditions. Evidence indicates that the limited dynamic range of responsivity of individual neurons in visual cortex is adjusted in an illumination-dependent manner (Shapley and Victor 1979), the consequence of which is a neuronal invariance that can account for the sensory invariance. It has been suggested that this scaling of neuronal sensitivity as a function of lighting conditions may be achieved by response "normalization," in which the output of a cortical neuron is effectively divided by the pooled activity of a large number of other cells of the same type (Carandini, Heeger, and Movshon 1997).

Attention   Visual ATTENTION is, by definition, a rapidly occurring change in visual sensitivity that is selective for a specific location in space or specific stimulus features. The stimulus and mnemonic factors that influence attentional allocation have been studied for over a century (James 1890), and the underlying brain structures and events are beginning to be understood (Desimone and Duncan 1995). Much of our understanding comes from analysis of ATTENTION IN THE HUMAN BRAIN—particularly the effects of cortical lesions, which can selectively interfere with attentional allocation (VISUAL NEGLECT), and through electrical and magnetic recording (ERP, MEG) and imaging studies—POSITRON EMISSION TOMOGRAPHY (PET) and functional MAGNETIC RESONANCE IMAGING (fMRI). In addition, studies of ATTENTION IN THE ANIMAL BRAIN have revealed that attentional shifts are correlated with changes in the sensitivity of single neurons to sensory stimuli (Moran and Desimone 1985; Bushnell, Goldberg, and Robinson 1981; see also AUDITORY ATTENTION). Although attentional phenomena differ from contrast gain control in that they can be influenced by feedback WORKING MEMORY as well as feedforward (sensory) signals, attentional effects can also be characterized as an expansion of the dynamic range of sensitivity, but in a manner that is selective for the attended stimuli.

Perceptual Learning   Both contrast gain control and visual attention are rapidly occurring and short-lived sensitivity changes. Other experiments have targeted neuronal events that parallel visual sensitivity changes occurring over a longer time scale,

such as those associated with the phenomenon of perceptual learning. Perceptual learning refers to improvements in discriminability along any of a variety of sensory dimensions that come with practice. Although it has long been known that the sensitivity of the visual system is refined in this manner during critical periods of neuronal development, recent experiments have provided tantalizing evidence of improvements in the sensitivity of neurons at early stages of processing, which parallel perceptual learning in adults (Recanzone, Schreiner, and Merzenich 1993; Gilbert 1996).

Forming a Decision to Act

The meaning of many sensations can be found solely in their symbolic and experience-dependent mapping onto actions (e.g., green = go, red = stop). These mappings are commonly many-to-one or one-to-many (a whistle and a green light can both be signals to "go"; conversely, a whistle may be either a signal to "go" or a call to attention, depending upon the context). The selection of a particular action from those possible at any point in time is thus a context-dependent transition between sensory processing and motor control. This transition is commonly termed the decision stage, and it has become a focus of recent electrophysiological studies of the cerebral cortex (e.g., Shadlen and Newsome 1996). Because of the nonunique mappings, neurons involved in making such decisions should be distinguishable from those representing sensory events by a tendency to generalize across specific features of the sensory signal. Similarly, the representation of the neuronal decision should be distinguishable from a motor control signal by generalization across specific motor actions. In addition, the strength of the neuronal decision signal should increase with duration of exposure to the sensory stimulus (integration time), in parallel with increasing decision confidence on the part of the observer. New data in support of some of these predictions suggests that this may be a valuable new paradigm for accessing the neuronal substrates of internal cognitive states, and for bridging studies of sensory or perceptual processing, memory, and motor control.

Motor Control

Incoming sensory information ultimately leads to action, and actions, in turn, are often initiated in order to acquire additional sensory information. Although MOTOR CONTROL systems have often been studied in relative isolation from sensory processes, this sensory-motor loop suggests that they are best viewed as different phases of a processing continuum. This integrated view, which seeks to understand how the nature of sensory representations influences movements, and vice-versa, is rapidly gaining acceptance. The oculomotor control system has become the model for the study of motor processes at behavioral and neuronal levels.

Important research topics that have emerged from consideration of the transition from sensory processing to motor control include (1) the process by which representations of space (see SPATIAL PERCEPTION) are transformed from the coordinate system of the sensory field (e.g., retinal space) to a coordinate system for action (e.g., Graziano and Gross 1998) and (2) the processes by which the neuronal links between sensation and action are modifiable (Raymond, Lisberger, and Mauk 1996), as needed to permit MOTOR LEARNING and to compensate for degenerative sensory changes or structural changes in the motor apparatus.

The brain structures involved in motor control include portions of the cerebral cortex, which are thought to contribute to fine voluntary motor control, as well as the BASAL GANGLIA and CEREBELLUM, which play important roles in motor learning; the superior colliculus, which is involved in sensorimotor integration, orienting responses, and oculomotor control; and a variety of brainstem motor nuclei, which convey motor signals to the appropriate effectors.

See also BASAL GANGLIA; CEREBELLUM; MOTOR CONTROL; MOTOR LEARNING; SPATIAL PERCEPTION

Learning and Memory

Studies of the neuronal mechanisms that enable information about the world to be stored and retrieved for later use have a long and rich history—being, as they were, a central part of the agenda of the early functional localizationists—and now lie at the core of our modern cognitive neuroscience. Indeed, memory serves as the linchpin that binds and shapes nearly every aspect of information processing by brains, including perception, decision making, motor control, emotion, and consciousness. Memory also exists in various forms, which have been classified on the basis of their relation to other cognitive functions, the degree to which they are explicitly encoded and available for use in a broad range of contexts, and their longevity. (We have already considered some forms of nonexplicit memory, such as those associated with perceptual and motor learning.) Taxonomies based upon these criteria have been reviewed in detail elsewhere (e.g., Squire, Knowlton, and Musen 1993). The phenomenological and functional differences among different forms of memory suggest the existence of a variety of different brain substrates. Localization of these substrates is a major goal of modern cognitive neuroscience. Research is also clarifying the mechanisms underlying the oft-noted role of affective or emotional responses in memory consolidation (see MEMORY STORAGE, MODULATION OF; AMYGDALA, PRIMATE), and the loss of memory that occurs with aging (see AGING, MEMORY, AND THE BRAIN).

Three current approaches (broadly defined and overlapping) to memory are among the most promising for the future of cognitive neuroscience: (1) neuropsychological and neurophysiological studies of the neuronal substrates of explicit memory in primates, (2) studies of the relationship between phenomena of synaptic facilitation or depression and behavioral manifestations of learning and memory, and (3) molecular genetic studies that enable highly selective disruption of cellular structures and events thought to be involved in learning and memory.

Brain Substrates of Explicit Memory in Primates
The current approach to this topic has its origins in the early studies of Karl Lashley and colleagues, in which the lesion method was used to infer the contributions of specific brain regions to a variety of cognitive functions, including memory. The field took a giant step forward in the 1950s with the discovery by Brenda Milner and colleagues of the devastating effects of damage to the human temporal lobe—particularly the HIPPOCAMPUS—on human memory formation (see MEMORY, HUMAN NEUROPSYCHOLOGY). Following that discovery, Mortimer Mishkin and colleagues began to use the lesion technique to develop an animal model of amnesia. More recently, using a similar approach, Stuart Zola, Larry Squire, and colleagues have further localized the neuronal substrates of memory consolidation in the primate temporal lobe (see MEMORY, ANIMAL STUDIES).

Electrophysiological studies of the contributions of individual cortical neurons to memory began in the 1970s with the work of Charles Gross and Joaquin Fuster. The logic behind this approach is that by examining neuronal responses of an animal engaged in a standard memory task (e.g., match-to-sample: determine whether a sample stimulus corresponds to a previously viewed cue stimulus), one can distinguish the components of the response that reflect memory from those that are sensory in nature. Subsequent electrophysiological studies by Robert Desimone and Patricia Goldman-Rakic, among others, have provided some of the strongest evidence for single-cell substrates of working memory in the primate temporal and frontal lobes. These traditional approaches to explicit memory formation in primates are now being complemented by brain imaging studies in humans.

Do Synaptic Changes Mediate Memory Formation?
The phenomenon of LONG-TERM POTENTIATION (LTP), originally discovered in the 1970s—and the related phenomenon of long-term depression—consists of physiologically measurable changes in the strength of synaptic connections between neurons.

LTP is commonly produced in the laboratory by coincident activation of pre- and post-synaptic neurons, in a manner consistent with the predictions of DONALD O. HEBB (1904–1985), and it is often dependent upon activation of the postsynaptic NMDA glutamate receptor. Because a change in synaptic efficacy could, in principle, underlie behavioral manifestations of learning and memory, and because LTP is commonly seen in brain structures that have been implicated in memory formation (such as the hippocampus, cerebellum, and cerebral cortex) by other evidence, it is considered a likely mechanism for memory formation. Attempts to test that hypothesis have led to one of the most exciting new approaches to memory.

From Genes to Behavior: A Molecular Genetic Approach to Memory
The knowledge that the NMDA receptor is responsible for many forms of LTP, in conjunction with the hypothesis that LTP underlies memory formation, led to the prediction that memory formation should be disrupted by elimination of NMDA receptors. The latter can be accomplished in mice by engineering genetic mutations that selectively knock out the NMDA receptor, although this technique has been problematic because it has been difficult to constrain the effects to specific brain regions and over specific periods of time. Matthew Wilson and Susumu Tonegawa have recently overcome these obstacles by production of a knockout in which NMDA receptors are disrupted only in a subregion of the hippocampus (the CA1 layer), and only after the brain has matured. In accordance with the NMDA-mediated synaptic plasticity hypothesis, these animals were deficient on both behavioral and physiological assays of memory formation (Tonegawa et al. 1996). Further developments along these lines will surely involve the ability to selectively disrupt action potential generation in specific cell populations, as well as genetic manipulations in other animals (such as monkeys).

Language

One of the first cognitive functions to be characterized from a biological perspective was language. Nineteenth-century physicians, including Broca, observed the effects of damage to different brain regions and described the asymmetrical roles of the left and right hemispheres in language production and comprehension (see HEMISPHERIC SPECIALIZATION; APHASIA; LANGUAGE, NEURAL BASIS OF). Investigators since then have discovered that different aspects of language, including the PHONOLOGY, SYNTAX, and LEXICON, each rely on different and specific neural structures (see PHONOLOGY, NEURAL BASIS OF; GRAMMAR, NEURAL BASIS OF; LEXICON, NEURAL BASIS OF). Modern neuroimaging techniques, including ERPs, PET, and fMRI, have confirmed the role of the classically defined language areas and point to the contribution of several other areas as well. Such studies have also identified "modality neutral" areas that are active when language is processed through any modality: auditory, written, and even sign language (see SIGN LANGUAGE AND THE BRAIN). Studies describing the effects of lesions on language can identify neural tissue that is necessary and sufficient for processing. An important additional perspective can be obtained from neuroimaging studies of healthy neural tissue, which can reveal all the activity associated with language production and comprehension. Taken together the currently available evidence reveals a strong bias for areas within the left hemisphere to mediate language if learned early in childhood, independently of its form or modality. However, the nature of the language learned and the age of acquisition have effects on the configuration of the language systems of the brain (see BILINGUALISM AND THE BRAIN).

Developmental disorders of language (see LANGUAGE IMPAIRMENT, DEVELOPMENTAL; DYSLEXIA) can occur in isolation or in association with other disorders and can result from deficits within any of the several different skills that are central to the perception and modulation of language.

Consciousness

Rediscovery of the phenomena of perception and memory without awareness has renewed research and debate on issues concerning the neural basis of CONSCIOUSNESS (see CONSCIOUSNESS, NEUROBIOLOGY OF). Some patients with cortical lesions that have rendered them blind can nonetheless indicate (by nonverbal methods) accurate perception of stimuli presented to the blind portion of the visual field (see BLINDSIGHT). Similarly, some patients who report no memory for specific training events nonetheless demonstrate normal learning of those skills.

Systematic study of visual consciousness employing several neuroimaging tools within human and nonhuman primates is being conducted to determine whether consciousness emerges as a property of a large collection of interacting neurons or whether it arises as a function of unique neuronal characteristics possessed by some neurons or by an activity pattern temporarily occurring within a subset of neurons (see BINDING BY NEURAL SYNCHRONY).

Powerful insights into systems and cellular and molecular events critical in cognition and awareness, judgment and action have come from human and animal studies of SLEEP and DREAMING. Distinct neuromodulatory effects of cholenergic and aminergic systems permit the panoply of conscious cognitive processing, evaluation, and planning during waking states and decouple cognition, emotional, and mnemonic functions during sleep. Detailed knowledge of the neurobiology of sleep and dreaming presents an important opportunity for future studies of cognition and consciousness.

See also BINDING BY NEURAL SYNCHRONY; BLINDSIGHT; CONSCIOUSNESS; CONSCIOUSNESS, NEUROBIOLOGY OF; DREAMING; SLEEP

Emotions

Closely related to questions about consciousness are issues of EMOTIONS and feelings that have, until very recently, been ignored in cognitive science. Emotions sit at the interface between incoming events and preparation to respond, however, and recent studies have placed the study of emotion more centrally in the field. Animal models have provided detailed anatomical and physiological descriptions of fear responses (Armony and LeDoux 1997) and highlight the role of the amygdala and LIMBIC SYSTEM as well as different inputs to this system (see EMOTION AND THE ANIMAL BRAIN). Studies of human patients suggest specific roles for different neural systems in the perception of potentially emotional stimuli (Adolphs et al. 1994; Hamann et al. 1996), in their appraisal, and in organizing appropriate responses to them (see EMOTION AND THE HUMAN BRAIN; PAIN). An important area for future research is to characterize the neurochemistry of emotions. The multiple physiological responses to real or imagined threats (i.e., STRESS) have been elucidated in both animal and human studies. Several of the systems most affected by stress play central roles in emotional and cognitive functions (see NEUROENDOCRINOLOGY). Early pre- and postnatal experiences play a significant role in shaping the activity of these systems and in their rate of aging. The profound role of the stress-related hormones on memory-related brain structures, including the hippocampus, and their role in regulating neural damage following strokes and seizures and in aging, make them a central object for future research in cognitive neuroscience (see AGING AND COGNITION).

4   *Cognitive Neuroscience: A Promise for the Future*

A glance at the neuroscience entries for this volume reveals that we are amassing detailed knowledge of the highly specialized neural systems that mediate different and

specific cognitive functions. Many questions remain unanswered, however, and the applications of new experimental techniques have often raised more questions than they have answered. But such are the expansion pains of a thriving science.

Among the major research goals of the next century will be to elucidate how these highly differentiated cognitive systems arise in ontogeny, the degree to which they are maturationally constrained, and the nature and the timing of the role of input from the environment in NEURAL DEVELOPMENT. This is an area where research has just begun. It is evident that there exist strong genetic constraints on the overall patterning of different domains within the developing nervous system. Moreover, the same class of genes specify the rough segmentation of the nervous systems of both vertebrates and invertebrates. However, the information required to specify the fine differentiation and connectivity within the cortex exceeds that available in the genome. Instead, a process of selective stabilization of transiently redundant connections permits individual differences in activity and experience to organize developing cortical systems. Some brain circuits display redundant connectivity and pruning under experience only during a limited time period in development ("critical period"). These time periods are different for different species and for different functional brain systems within a species. Other brain circuits retain the ability to change under external stimulation throughout life, and this capability, which now appears more ubiquitous and long lasting than initially imagined, is surely a substrate for adult learning, recovery of function after brain damage, and PHANTOM LIMB phenomena (see also AUDITORY PLASTICITY; NEURAL PLASTICITY). A major challenge for future generations of cognitive neuroscientists will be to characterize and account for the markedly different extents and timecourses of biological constraints and experience-dependent modifiability of the developing human brain.

Though the pursuit may be ancient, consider these the halcyon days of cognitive neuroscience. As we cross the threshold of the millenium, look closely as the last veil begins to fall. And bear in mind that if cognitive neuroscience fulfills its grand promise, later editions of this volume may contain a section on history, into which all of the nonneuro cognitive science discussion will be swept.

Computational Intelligence

Michael I. Jordan and Stuart Russell

There are two complementary views of artificial intelligence (AI): one as an engineering discipline concerned with the creation of intelligent machines, the other as an empirical science concerned with the computational modeling of human intelligence. When the field was young, these two views were seldom distinguished. Since then, a substantial divide has opened up, with the former view dominating modern AI and the latter view characterizing much of modern cognitive science. For this reason, we have adopted the more neutral term "computational intelligence" as the title of this article—both communities are attacking the problem of understanding intelligence in computational terms.

It is our belief that the differences between the engineering models and the cognitively inspired models are small compared to the vast gulf in competence between these models and human levels of intelligence. For humans are, to a first approximation, *intelligent*; they can perceive, act, learn, reason, and communicate *successfully* despite the enormous difficulty of these tasks. Indeed, we expect that as further progress is made in trying to emulate this success, the engineering and cognitive models will become more similar. Already, the traditionally antagonistic "connectionist" and "symbolic" camps are finding common ground, particularly in their understanding of reasoning under uncertainty and learning. This sort of cross-fertilization was a central aspect of the early vision of cognitive science as an interdisciplinary enterprise.

1 Machines and Cognition

The conceptual precursors of AI can be traced back many centuries. LOGIC, the formal theory of deductive reasoning, was studied in ancient Greece, as were ALGORITHMS for mathematical computations. In the late seventeenth century, Wilhelm Leibniz actually constructed simple "conceptual calculators," but their representational and combinatorial powers were far too limited. In the nineteenth century, Charles Babbage designed (but did not build) a device capable of universal computation, and his collaborator Ada Lovelace speculated that the machine might one day be programmed to play chess or compose music. Fundamental work by ALAN TURING in the 1930s formalized the notion of universal computation; the famous CHURCH-TURING THESIS proposed that all sufficiently powerful computing devices were essentially identical in the sense that any one device could emulate the operations of any other. From here it was a small step to the bold hypothesis that human cognition was a form of COMPUTATION in exactly this sense, and could therefore be emulated by computers.

By this time, neurophysiology had already established that the brain consisted largely of a vast interconnected network of NEURONS that used some form of electrical signalling mechanism. The first mathematical model relating computation and the brain appeared in a seminal paper entitled "A logical calculus of the ideas immanent in nervous activity," by WARREN MCCULLOCH and WALTER PITTS (1943). The paper proposed an abstract model of neurons as linear threshold units—logical "gates" that output a signal if the weighted sum of their inputs exceeds a threshold value (see COMPUTING IN SINGLE NEURONS). It was shown that a network of such gates could represent any logical function, and, with suitable delay components to implement memory, would be capable of universal computation. Together with HEBB's model of learning in networks of neurons, this work can be seen as a precursor of modern NEURAL NETWORKS and connectionist cognitive modeling. Its stress on the representation of logical concepts by neurons also provided impetus to the "logicist" view of AI.

The emergence of AI proper as a recognizable field required the availability of usable computers; this resulted from the wartime efforts led by Turing in Britain and by JOHN VON NEUMANN in the United States. It also required a banner to be raised;

this was done with relish by Turing's (1950) paper "Computing Machinery and Intelligence," wherein an operational definition for intelligence was proposed (the Turing test) and many future developments were sketched out.

One should not underestimate the level of controversy surrounding AI's initial phase. The popular press was only too ready to ascribe intelligence to the new "electronic super-brains," but many academics refused to contemplate the idea of intelligent computers. In his 1950 paper, Turing went to great lengths to catalogue and refute many of their objections. Ironically, one objection already voiced by Kurt Gödel, and repeated up to the present day in various forms, rested on the ideas of incompleteness and undecidability in formal systems to which Turing himself had contributed (see GÖDEL'S THEOREMS and FORMAL SYSTEMS, PROPERTIES OF). Other objectors denied the possibility of CONSCIOUSNESS in computers, and with it the possibility of intelligence. Turing explicitly sought to separate the two, focusing on the objective question of intelligent *behavior* while admitting that consciousness might remain a mystery—as indeed it has.

The next step in the emergence of AI was the formation of a research community; this was achieved at the 1956 Dartmouth meeting convened by John McCarthy. Perhaps the most advanced work presented at this meeting was that of ALLEN NEWELL and Herb Simon, whose program of research in symbolic cognitive modeling was one of the principal influences on cognitive psychology and information-processing psychology. Newell and Simon's IPL languages were the first symbolic programming languages and among the first high-level languages of any kind. McCarthy's LISP language, developed slightly later, soon became the standard programming language of the AI community and in many ways remains unsurpassed even today.

Contemporaneous developments in other fields also led to a dramatic increase in the precision and complexity of the models that could be proposed and analyzed. In linguistics, for example, work by Chomsky (1957) on formal grammars opened up new avenues for the mathematical modeling of mental structures. NORBERT WIENER developed the field of cybernetics (see CONTROL THEORY and MOTOR CONTROL) to provide mathematical tools for the analysis and synthesis of physical control systems. The theory of optimal control in particular has many parallels with the theory of rational agents (see below), but within this tradition no model of internal representation was ever developed.

As might be expected from so young a field with so broad a mandate that draws on so many traditions, the history of AI has been marked by substantial changes in fashion and opinion. Its early days might be described as the "Look, Ma, no hands!" era, when the emphasis was on showing a doubting world that computers *could* play chess, learn, see, and do all the other things thought to be impossible. A wide variety of methods was tried, ranging from general-purpose symbolic problem solvers to simple neural networks. By the late 1960s, a number of practical and theoretical setbacks had convinced most AI researchers that there would be no simple "magic bullet." The general-purpose methods that had initially seemed so promising came to be called *weak methods* because their reliance on extensive combinatorial search and first-principles knowledge could not overcome the complexity barriers that were, by that time, seen as unavoidable. The 1970s saw the rise of an alternative approach based on the application of large amounts of domain-specific knowledge, expressed in forms that were close enough to the explicit solution as to require little additional computation. Ed Feigenbaum's gnomic dictum, "Knowledge is power," was the watchword of the boom in industrial and commercial application of *expert systems* in the early 1980s.

When the first generation of expert system technology turned out to be too fragile for widespread use, a so-called AI Winter set in—government funding of AI and public perception of its promise both withered in the late 1980s. At the same time, a revival of interest in neural network approaches led to the same kind of optimism as had characterized "traditional" AI in the early 1980s. Since that time, substantial progress has been made in a number of areas within AI, leading to renewed commercial interest in fields such as *data mining* (applied machine learning) and a new wave of expert system technology based on probabilistic inference. The 1990s may in fact come to be seen as the decade of probability. Besides expert systems, the so-called

Bayesian approach (named after the Reverend Thomas Bayes, eighteenth-century author of the fundamental rule for probabilistic reasoning) has led to new methods in planning, natural language understanding, and learning. Indeed, it seems likely that work on the latter topic will lead to a reconciliation of symbolic and connectionist views of intelligence.

2   *Artificial Intelligence: What's the Problem?*

The consensus apparent in modern textbooks (Russell and Norvig 1995; Poole, Mackworth, and Goebel 1997; Nilsson 1998) is that AI is about the design of intelligent *agents*. An agent is an entity that can be understood as perceiving and acting on its environment. An agent is *rational* to the extent that its actions can be expected to achieve its goals, given the information available from its perceptual processes. Whereas the Turing test defined only an informal notion of intelligence as emulation of humans, the theory of RATIONAL AGENCY (see also RATIONAL CHOICE THEORY) provides a first pass at a *formal specification* for intelligent agents, with the possibility of a constructive theory to satisfy this specification. Although the last section of this introduction argues that this specification needs a radical rethinking, the idea of RATIONAL DECISION MAKING has nonetheless been the foundation for most of the current research trends in AI.

The focus on AI as the design of intelligent agents is a fairly recent preoccupation. Until the mid-1980s, most research in "core AI" (that is, AI excluding the areas of robotics and computer vision) concentrated on isolated reasoning tasks, the inputs of which were provided by humans and the outputs of which were interpreted by humans. Mathematical theorem-proving systems, English question-answering systems, and medical expert systems all had this flavor—none of them took actions in any meaningful sense. The so-called situated movement in AI (see SITUATEDNESS/ EMBEDDEDNESS) stressed the point that reasoning is not an end in itself, but serves the purpose of enabling the selection of actions that will affect the reasoner's environment in desirable ways. Thus, reasoning always occurs in a specific context for specific goals. By removing context and taking responsibility for action selection, AI researchers were in danger of defining a subtask that, although useful, actually had no role in the design of a complete intelligent system. For example, some early medical expert systems were constructed in such a way as to accept as input a complete list of symptoms and to output the most likely diagnosis. This might seem like a useful tool, but it ignores several key aspects of medicine: the crucial role of hypothesis-directed *gathering* of information, the very complex task of interpreting sensory data to obtain suggestive and uncertain indicators of symptoms, and the overriding goal of *curing* the patient, which may involve treatments aimed at less likely but potentially dangerous conditions rather than more likely but harmless ones. A second example occurred in robotics. Much research was done on motion planning under the assumption that the locations and shapes of all objects in the environment were known exactly; yet no feasible vision system can, or should, be designed to obtain this information.

When one thinks about building intelligent agents, it quickly becomes obvious that the task environment in which the agent will operate is a primary determiner of the appropriate design. For example, if all relevant aspects of the environment are immediately available to the agent's perceptual apparatus—as, for example, when playing backgammon—then the environment is said to be *fully observable* and the agent need maintain no internal model of the world at all. Backgammon is also *discrete* as opposed to *continuous*—that is, there is a finite set of distinct backgammon board states, whereas tennis, say, requires real-valued variables and changes continuously over time. Backgammon is *stochastic* as opposed to *deterministic*, because it includes dice rolls and unpredictable opponents; hence an agent may need to make contingency

plans for many possible outcomes. Backgammon, unlike tennis, is also *static* rather than *dynamic*, in that nothing much happens while the agent is deciding what move to make. Finally, the "physical laws" of the backgammon universe—what the legal moves are and what effect they have—are known rather than unknown. These distinctions alone (and there are many more) define thirty-two substantially different kinds of task environment. This variety of tasks, rather than any true conceptual differences, may be responsible for the variety of computational approaches to intelligence that, on the surface, seem so philosophically incompatible.

3   Architectures of Cognition

Any computational theory of intelligence must propose, at least implicitly, an INTELLI-GENT AGENT ARCHITECTURE. Such an architecture defines the underlying organization of the cognitive processes comprising intelligence, and forms the computational substrate upon which domain-specific capabilities are built. For example, an architecture may provide a generic capability for learning the "physical laws" of the environment, for combining inputs from multiple sensors, or for deliberating about actions by envisioning and evaluating their effects.

There is, as yet, no satisfactory theory that defines the range of possible architectures for intelligent systems, or identifies the optimal architecture for a given task environment, or provides a reasonable specification of what is required for an architecture to support "general-purpose" intelligence, either in machines or humans. Some researchers see the observed variety of intelligent behaviors as a consequence of the operation of a unified, general-purpose problem-solving architecture (Newell 1990). Others propose a functional division of the architecture with modules for perception, learning, reasoning, communication, locomotion, and so on (see MODULAR-ITY OF MIND). Evidence from neuroscience (for example, lesion studies) is often interpreted as showing that the brain is divided into areas, each of which performs some function in this sense; yet the functional descriptions (e.g., "language," "face recognition," etc.) are often subjective and informal and the nature of the connections among the components remains obscure. In the absence of deeper theory, such generalizations from scanty evidence must remain highly suspect. That is, the basic organizational principles of intelligence are still up for grabs.

Proposed architectures vary along a number of dimensions. Perhaps the most commonly cited distinction is between "symbolic" and "connectionist" approaches. These approaches are often thought to be based on fundamentally irreconcilable philosophical foundations. We will argue that, to a large extent, they are complementary; where comparable, they form a continuum.

Roughly speaking, a *symbol* is an object, part of the internal state of an agent, that has two properties: it can be compared to other symbols to test for equality, and it can be combined with other symbols to form *symbol structures*. The symbolic approach to AI, in its purest form, is embodied in the physical symbol system (PSS) hypothesis (Newell and Simon 1972), which proposes that algorithmic manipulation of symbol structures is necessary and sufficient for general intelligence (see also COMPUTA-TIONAL THEORY OF MIND.)

The PSS hypothesis, if taken to its extreme, is identical to the view that cognition can be understood as COMPUTATION. Symbol systems can emulate any Turing machine; in particular, they can carry out finite-precision numerical operations and thereby implement neural networks. Most AI researchers interpret the PSS hypothesis more narrowly, ruling out primitive numerical quantities that are manipulated as *magnitudes* rather than simply tested for (in)equality. The Soar architecture (Newell 1990), which uses PROBLEM SOLVING as its underlying formalism, is the most well developed instantiation of the pure symbolic approach to cognition (see COGNITIVE MODELING, SYMBOLIC).

The symbolic tradition also encompasses approaches to AI that are based on logic. The symbols in the logical languages are used to represent objects and relations

among objects, and symbol structures called *sentences* are used to represent facts that the agent knows. Sentences are manipulated according to certain rules to generate new sentences that follow logically from the original sentences. The details of logical agent design are given in the section on knowledge-based systems; what is relevant here is the use of symbol structures as direct representations of the world. For example, if the agent sees John sitting on the fence, it might construct an internal representation from symbols that represent John, the fence, and the sitting-on relation. If Mary is on the fence instead, the symbol structure would be the same except for the use of a symbol for Mary instead of John.

This kind of compositionality of representations is characteristic of symbolic approaches. A more restricted kind of compositionality can occur even in much simpler systems. For example, in the network of logical gates proposed by McCulloch and Pitts, we might have a neuron J that is "on" whenever the agent sees John on the fence; and another neuron M that is "on" when Mary is on the fence. Then the proposition "either John or Mary is on the fence" can be represented by a neuron that is connected to J and M with the appropriate connection strengths. We call this kind of representation *propositional*, because the fundamental elements are propositions rather than symbols, denoting objects and relations. In the words of McCulloch and Pitts (1943), the state of a neuron was conceived of as "factually equivalent to a proposition which proposed its adequate stimulus." We will also extend the standard sense of "propositional" to cover neural networks comprised of neurons with continuous real-valued activations, rather than the 1/0 activations in the original McCulloch-Pitts threshold neurons.

It is clear that, in this sense, the raw sensory data available to an agent are propositional. For example, the elements of visual perception are "pixels" whose propositional content is, for example, "this area of my retina is receiving bright red light." This observation leads to the first difficulty for the symbolic approach: how to move from sensory data to symbolic representations. This so-called symbol grounding problem has been deemed insoluble by some philosophers (see CONCEPTS), thereby dooming the symbolic approach to oblivion. On the other hand, existence proofs of its solubility abound. For example, Shakey, the first substantial robotics project in AI, used symbolic (logical) reasoning for its deliberations, but interacted with the world quite happily (albeit slowly) through video cameras and wheels (see Raphael 1976).

A related problem for purely symbolic approaches is that sensory information about the physical world is usually thought of as numerical—light intensities, forces, strains, frequencies, and so on. Thus, there must at least be a layer of nonsymbolic computation between the real world and the realm of pure symbols. Neither the theory nor the practice of symbolic AI argues against the existence of such a layer, but its existence does open up the possibility that some substantial part of cognition occurs therein without ever reaching the symbolic level.

A deeper problem for the narrow PSS hypothesis is UNCERTAINTY—the unavoidable fact that unreliable and partial sensory information, combined with unreliable and partial theories of how the world works, must leave an agent with some doubt as to the truth of virtually all propositions of interest. For example, the stock market may soon recover this week's losses, or it may not. Whether to buy, sell, or hold depends on one's assessment of the prospects. Similarly, a person spotted across a crowded, smoky night club may or may not be an old friend. Whether to wave in greeting depends on how certain one is (and on one's sensitivity to embarrassment due to waving at complete strangers). Although many decisions under uncertainty can be made without reference to numerical degrees of belief (Wellman 1990), one has a lingering sense that degrees of belief in propositions may be a fundamental component of our mental representations. Accounts of such phenomena based on probability theory are now widely accepted within AI as an *augmentation* of the purely symbolic view; in particular, probabilistic models are a natural generalization of the logical approach. Recent work has also shown that some connectionist representations (e.g., Boltzmann machines) are essentially identical to probabilistic network models developed in AI (see NEURAL NETWORKS).

The three issues raised in the preceding paragraphs—sensorimotor connections to the external world, handling real-valued inputs and outputs, and robust handling of noisy and uncertain information—are primary motivations for the connectionist approach to cognition. (The existence of networks of neurons in the brain is obviously another.) Neural network models show promise for many low-level tasks such as visual pattern recognition and speech recognition. The most obvious drawback of the connectionist approach is the difficulty of envisaging a means to model higher levels of cognition (see BINDING PROBLEM and COGNITIVE MODELING, CONNECTIONIST), particularly when compared to the ability of symbol systems to generate an unbounded variety of structures from a finite set of symbols (see COMPOSITIONALITY). Some solutions have been proposed (see, for example, BINDING BY NEURAL SYNCHRONY); these solutions provide a plausible neural *implementation* of symbolic models of cognition, rather than an *alternative*.

Another problem for connectionist and other propositional approaches is the modeling of *temporally extended* behavior. Unless the external environment is completely observable by the agent's sensors, such behavior requires the agent to maintain some internal state information that reflects properties of the external world that are not directly observable. In the symbolic or logical approach, sentences such as "My car is parked at the corner of Columbus and Union" can be stored in "working memory" or in a "temporal knowledge base" and updated as appropriate. In connectionist models, internal states require the use of RECURRENT NETWORKS, which are as yet poorly understood.

In summary, the symbolic and connectionist approaches seem not antithetical but complementary—connectionist models may handle low-level cognition and may (or rather *must*, in some form) provide a substrate for higher-level symbolic processes. Probabilistic approaches to representation and reasoning may unify the symbolic and connectionist traditions. It seems that the more relevant distinction is between propositional and more expressive forms of representation.

Related to the symbolic-connectionist debate is the distinction between *deliberative* and *reactive* models of cognition. Most AI researchers view intelligent behavior as resulting, at least in part, from deliberation over possible courses of action based on the agent's knowledge of the world and of the expected results of its actions. This seems self-evident to the average person in the street, but it has always been a controversial hypothesis—according to BEHAVIORISM, it is meaningless. With the development of KNOWLEDGE-BASED SYSTEMS, starting from the famous "Advice Taker" paper by McCarthy (1958), the deliberative model could be put to the test. The core of a knowledge-based agent is the knowledge base and its associated reasoning procedures; the rest of the design follows straightforwardly. First, we need some way of acquiring the necessary knowledge. This could be from experience through MACHINE LEARNING methods, from humans and books through NATURAL LANGUAGE PROCESSING, by direct programming, or through perceptual processes such as MACHINE VISION. Given knowledge of its environment and of its objectives, an agent can reason that certain actions will achieve those objectives and should be executed. At this point, if we are dealing with a physical environment, robotics takes over, handling the mechanical and geometric aspects of motion and manipulation.

The following sections deal with each of these areas in turn. It should be noted, however, that the story in the preceding paragraph is a gross idealization. It is, in fact, close to the view caricatured as good old-fashioned AI (GOFAI) by John Haugeland (1985) and Hubert Dreyfus (1992). In the five decades since Turing's paper, AI researchers have discovered that attaining real competence is not so simple—the principle barrier being COMPUTATIONAL COMPLEXITY. The idea of *reactive systems* (see also AUTOMATA) is to implement direct mappings from perception to action that avoid the expensive intermediate steps of representation and reasoning. This observation was made within the first month of the Shakey project (Raphael 1976) and given new life in the field of BEHAVIOR-BASED ROBOTICS (Brooks 1991). Direct mappings of this kind can be learned from experience or can be compiled from the results of deliberation within a knowledge-based architecture (see EXPLANATION-BASED LEARNING). Most current models propose a *hybrid* agent design incorporating a vari-

ety of decision-making mechanisms, perhaps with capabilities for METAREASONING to control and integrate these mechanisms. Some have even proposed that intelligent systems should be constructed from large numbers of separate agents, each with percepts, actions, and goals of its own (Minsky 1986)—much as a nation's economy is made up of lots of separate humans. The theory of MULTIAGENT SYSTEMS explains how, in some cases, the goals of the whole agent can be achieved even when each sub-agent pursues its own ends.

4   *Knowledge-Based Systems*

The *procedural-declarative controversy*, which raged in AI through most of the 1970s, was about which way to build AI systems (see, for example, Boden 1977). The procedural view held that systems could be constructed by encoding expertise in domain-specific algorithms—for example, a procedure for diagnosing migraines by asking specific sequences of questions. The declarative view, on the other hand, held that systems should be *knowledge-based*, that is, composed from domain-specific *knowledge*—for example, the symptoms typically associated with various ailments—combined with a general-purpose reasoning system. The procedural view stressed efficiency, whereas the declarative view stressed the fact that the overall internal representation can be decomposed into separate *sentences*, each of which has an identifiable meaning. Advocates of knowledge-based systems often cited the following advantages:

Ease of construction: knowledge-based systems can be constructed simply by encoding domain knowledge extracted from an expert; the system builder need not construct and encode a *solution* to the problems in the domain.

Flexibility: the same knowledge can be used to answer a variety of questions and as a component in a variety of systems; the same reasoning mechanism can be used for all domains.

Modularity: each piece of knowledge can be identified, encoded, and debugged independently of the other pieces.

Learnability: various learning methods exist that can be used to extract the required knowledge from data, whereas it is very hard to construct programs by automatic means.

Explainability: a knowledge-based system can *explain* its decisions by reference to the explicit knowledge it contains.

With arguments such as these, the declarative view prevailed and led to the boom in expert systems in the late 1970s and early 1980s.

Unfortunately for the field, the early knowledge-based systems were seldom equal to the challenges of the real world, and since then there has been a great deal of research to remedy these failings. The area of KNOWLEDGE REPRESENTATION deals with methods for encoding knowledge in a form that can be processed by a computer to derive consequences. Formal logic is used in various forms to represent definite knowledge. To handle areas where definite knowledge is not available (for example, medical diagnosis), methods have been developed for representation and reasoning under uncertainty, including the extension of logic to so-called NONMONOTONIC LOGICS. All knowledge representation systems need some process for KNOWLEDGE ACQUISITION, and much has been done to automate this process through better interface tools, machine learning methods, and, most recently, extraction from natural language texts. Finally, substantial progress has been made on the question of the computational complexity of reasoning.

See also KNOWLEDGE ACQUISITION; KNOWLEDGE REPRESENTATION; NONMONO-
TONIC LOGICS

5   Logical Representation and Reasoning

Logical reasoning is appropriate when the available knowledge is definite. McCarthy's (1958) "Advice Taker" paper proposed first-order logic (FOL) as a formal language for the representation of commonsense knowledge in AI systems. FOL has sufficient expressive power for most purposes, including the representation of objects, relations among objects, and universally quantified statements about sets of objects.

Thanks to work by a long line of philosophers and mathematicians, who were also interested in a formal language for representing general (as well as mathematical) knowledge, FOL came with a well-defined syntax and semantics, as well as the powerful guarantee of *completeness:* there exists a computational procedure such that, if the answer to a question is entailed by the available knowledge, then the procedure will find that answer (see GÖDEL'S THEOREMS). More expressive languages than FOL generally do not allow completeness—roughly put, there exist theorems in these languages that cannot be proved.

The first complete logical reasoning system for FOL, the resolution method, was devised by Robinson (1965). An intense period of activity followed in which LOGICAL REASONING SYSTEMS were applied to mathematics, automatic programming, planning, and general-knowledge question answering. Theorem-proving systems for full FOL have proved new theorems in mathematics and have found widespread application in areas such as program verification, which spun off from mainstream AI in the early 1970s.

Despite these early successes, AI researchers soon realized that the computational complexity of general-purpose reasoning with full FOL is prohibitive; such systems could not scale up to handle large knowledge bases. A great deal of attention has therefore been given to more restricted languages. *Database systems*, which have long been distinct from AI, are essentially logical question-answering systems the knowledge bases of which are restricted to very simple sentences about specific objects. *Propositional* languages avoid objects altogether, representing the world by the discrete values of a fixed set of propositional variables and by logical combinations thereof. (Most neural network models fall into this category also.) Propositional reasoning methods based on CONSTRAINT SATISFACTION and GREEDY LOCAL SEARCH have been very successful in real-world applications, but the restricted expressive power of propositional languages severely limits their scope. Much closer to the expressive power of FOL are the languages used in LOGIC PROGRAMMING. Although still allowing most kinds of knowledge to be expressed very naturally, logic programming systems such as Prolog provide much more efficient reasoning and can work with extremely large knowledge bases.

Reasoning systems must have content with which to reason. Researchers in knowledge representation study methods for codifying and reasoning with particular kinds of knowledge. For example, McCarthy (1963) proposed the SITUATION CALCULUS as a way to represent states of the world and the effects of actions within first-order logic. Early versions of the situation calculus suffered from the infamous FRAME PROBLEM—the apparent need to specify sentences in the knowledge base for all the *noneffects* of actions. Some philosophers see the frame problem as evidence of the impossibility of the formal, knowledge-based approach to AI, but simple technical advances have resolved the original issues.

Situation calculus is perhaps the simplest form of TEMPORAL REASONING; other formalisms have been developed that provide substantially more general frameworks for handling time and extended events. Reasoning about knowledge itself is important particularly when dealing with other agents, and is usually handled by MODAL LOGIC, an extension of FOL. Other topics studied include reasoning about ownership and transactions, reasoning about substances (as distinct from objects), and reasoning about physical representations of information. A general *ontology*—literally, a description of existence—ties all these areas together into a unified taxonomic hierarchy of catego-

ries. FRAME-BASED SYSTEMS are often used to represent such hierarchies, and use specialized reasoning methods based on *inheritance* of properties in the hierarchy.

6   *Logical Decision Making*

An agent's job is to make *decisions*, that is, to commit to particular actions. The connection between logical reasoning and decision making is simple: the agent must conclude, based on its knowledge, that a certain action is best. In philosophy, this is known as *practical reasoning*. There are many routes to such conclusions. The simplest leads to a reactive system using *condition-action rules* of the form "If P then do A." Somewhat more complex reasoning is required when the agent has explicitly represented *goals*. A goal "G" is a description of a desired state of affairs—for example, one might have the goal "On vacation in the Seychelles." The *practical syllogism*, first expounded by Aristotle, says that if G is a goal, and A achieves G, then A should be done. Obviously, this rule is open to many objections: it does not specify which of many eligible As should be done, nor does it account for possibly disastrous side-effects of A. Nonetheless, it underlies most forms of decision making in the logical context.

Often, there will be no single action A that achieves the goal G, but a solution may exist in the form of a *sequence* of actions. Finding such a sequence is called PROBLEM SOLVING, where the word "problem" refers to a task defined by a set of actions, an initial state, a goal, and a set of reachable states. Much of the early cognitive modeling work of Newell and Simon (1972) focused on problem solving, which was seen as a quintessentially intelligent activity. A great deal of research has been done on efficient algorithms for problem solving in the areas of HEURISTIC SEARCH and GAME-PLAYING SYSTEMS. The "cognitive structure" of such systems is very simple, and problem-solving competence is often achieved by means of searching through huge numbers of possibilities. For example, the Deep Blue chess program, which defeated human world champion Gary Kasparov, often examined over a billion positions prior to each move. Human competence is not thought to involve such computations (see CHESS, PSYCHOLOGY OF).

Most problem-solving algorithms treat the states of the world as atomic—that is, the internal structure of the state representation is not accessible to the algorithm as it considers the possible sequences of actions. This fails to take advantage of two very important sources of power for intelligent systems: the ability to *decompose* complex problems into subproblems and the ability to identify relevant actions from explicit goal descriptions. For example, an intelligent system should be able decompose the goal "have groceries and a clean car" into the subgoals "have groceries" and "have a clean car." Furthermore, it should immediately consider buying groceries and washing the car. Most search algorithms, on the other hand, may consider a variety of action sequences—sitting down, standing up, going to sleep, and so on—before happening on some actions that are relevant.

In principle, a logical reasoning system using McCarthy's situation calculus can generate the kinds of reasoning behaviors necessary for decomposing complex goals and selecting relevant actions. For reasons of computational efficiency, however, special-purpose PLANNING systems have been developed, originating with the STRIPS planner used by Shakey the Robot (Fikes and Nilsson 1971). Modern planners have been applied to logistical problems that are, in some cases, too complex for humans to handle effectively.

See also CHESS, PSYCHOLOGY OF; GAME-PLAYING SYSTEMS; HEURISTIC SEARCH; PLANNING; PROBLEM-SOLVING

7   *Representation and Reasoning under Uncertainty*

In many areas to which one might wish to apply knowledge-based systems, the available knowledge is far from definite. For example, a person who experiences recurrent

headaches may suffer from migraines or a brain tumor. A logical reasoning system can represent this sort of disjunctive information, but cannot represent or reason with the belief that migraine is a *more likely* explanation. Such reasoning is obviously essential for diagnosis, and has turned out to be central for expert systems in almost all areas. The theory of *probability* (see PROBABILITY, FOUNDATIONS OF) is now widely accepted as the basic calculus for reasoning under uncertainty (but see FUZZY LOGIC for a complementary view). Questions remain as to whether it is a good model for human reasoning (see TVERSKY and PROBABILISTIC REASONING), but within AI many of the computational and representational problems that deterred early researchers have been resolved. The adoption of a probabilistic approach has also created rich connections with statistics and control theory.

Standard probability theory views the world as comprised of a set of interrelated random variables the values of which are initially unknown. Knowledge comes in the form of *prior* probability distributions over the possible assignments of values to subsets of the random variables. Then, when evidence is obtained about the values of some of the variables, inference algorithms can infer *posterior* probabilities for the remaining unknown variables. Early attempts to use probabilistic reasoning in AI came up against complexity barriers very soon, because the number of probabilities that make up the prior probability distribution can grow exponentially in the number of variables considered.

Starting in the early 1980s, researchers in AI, decision analysis, and statistics developed what are now known as BAYESIAN NETWORKS (Pearl 1988). These networks give structure to probabilistic knowledge bases by expressing *conditional independence* relationships among the variables. For example, given the actual temperature, the temperature measurements of two thermometers are independent. In this way, Bayesian networks capture our intuitive notions of the causal structure of the domain of application. In most cases, the number of probabilities that must be specified in a Bayesian network grows only linearly with the number of variables. Such systems can therefore handle quite large problems, and applications are very widespread. Moreover, methods exist for *learning* Bayesian networks from raw data (see BAYESIAN LEARNING), making them a natural bridge between the symbolic and neural-network approaches to AI.

In earlier sections, we have stressed the importance of the distinction between propositional and first-order languages. So far, probability theory has been limited to essentially propositional representations; this prevents its application to the more complex forms of cognition addressed by first-order methods. The attempt to unify probability theory and first-order logic, two of the most fundamental developments in the history of mathematics and philosophy, is among the more important topics in current AI research.

See also BAYESIAN LEARNING; BAYESIAN NETWORKS; FUZZY LOGIC; PROBABILISTIC REASONING; PROBABILITY, FOUNDATIONS OF; TVERSKY, AMOS

8   Decision Making under Uncertainty

Just as logical reasoning is connected to action through goals, probabilistic reasoning is connected to action through *utilities*, which describe an agent's preferences for some states over others. It is a fundamental result of UTILITY THEORY (see also RATIONAL CHOICE THEORY) that an agent whose preferences obey certain rationality constraints, such as transitivity, can be modeled as possessing a *utility function* that assigns a numerical value to each possible state. Furthermore, RATIONAL DECISION MAKING consists of selecting an action to maximize the expected utility of outcome states. An agent that makes rational decisions will, on average, do better than an agent that does not—at least as far as satisfying its own preferences is concerned.

In addition to their fundamental contributions to utility theory, von Neumann and Morgenstern (1944) also developed GAME THEORY to handle the case where the environment contains other agents, which must be modeled as independent utility maximizers. In some game-theoretic situations, it can be shown that optimal behavior must be *randomized*. Additional complexities arise when dealing with so-called *sequential*

decision problems, which are analogous to planning problems in the logical case. DYNAMIC PROGRAMMING algorithms, developed in the field of operations research, can generate optimal behavior for such problems. (See also the discussion of REINFORCEMENT LEARNING in segment 12—Learning.)

In a sense, the theory of rational decision making provides a zeroth-order theory of intelligence, because it provides an operational definition of what an agent *ought* to do in any situation. Virtually every problem an agent faces, including such problems as how to gather information and how to update its beliefs given that information, can be formulated within the theory and, in principle, solved. What the theory ignores is the question of complexity, which we discuss in the final section of this introduction.

See also DYNAMIC PROGRAMMING; GAME THEORY; RATIONAL CHOICE THEORY; RATIONAL DECISION MAKING; REINFORCEMENT LEARNING; UTILITY THEORY

9   *Learning*

LEARNING has been a central aspect of AI from its earliest days. It is immediately apparent that learning is a vital characteristic of any intelligent system that has to deal with changing environments. Learning may also be the only way in which complex and competent systems can be constructed—a proposal stated clearly by Turing (1950), who devoted a quarter of his paper to the topic. Perhaps the first major public success for AI was Arthur Samuel's (1959) checker-playing system, which learned to play checkers to a level far superior to its creator's abilities and attracted substantial television coverage. State-of-the-art systems in almost all areas of AI now use learning to avoid the need for the system designer to have to anticipate and provide knowledge to handle every possible contingency. In some cases, for example speech recognition, humans are simply incapable of providing the necessary knowledge accurately.

The discipline of machine learning has become perhaps the largest subfield of AI as well as a meeting point between AI and various other engineering disciplines concerned with the design of autonomous, robust systems. An enormous variety of learning systems has been studied in the AI literature, but once superficial differences are stripped away, there seem to be a few core principles at work. To reveal these principles it helps to classify a given learning system along a number of dimensions: (1) the type of feedback available, (2) the component of the agent to be improved, (3) how that component is represented, and (4) the role of prior knowledge. It is also important to be aware that there is a tradeoff between learning and inference and different systems rely more on one than on the other.

The type of feedback available is perhaps the most useful categorizer of learning algorithms. Broadly speaking, learning algorithms fall into the categories of *supervised learning*, *unsupervised learning*, and *reinforcement learning*. Supervised learning algorithms (see, e.g., DECISION TREES and SUPERVISED LEARNING IN MULTILAYER NEURAL NETWORKS) require that a target output is available for every input, an assumption that is natural in some situations (e.g., categorization problems with labeled data, imitation problems, and prediction problems, in which the present can be used as a target for a prediction based on the past). UNSUPERVISED LEARNING algorithms simply find structure in an ensemble of data, whether or not this structure is useful for a particular classification or prediction (examples include clustering algorithms, dimensionality-reducing algorithms, and algorithms that find independent components). REINFORCEMENT LEARNING algorithms require an evaluation signal that gives some measure of progress without necessarily providing an example of correct behavior. Reinforcement learning research has had a particular focus on temporal learning problems, in which the evaluation arrives after a sequence of responses.

The different components of an agent generally have different kinds of representational and inferential requirements. Sensory and motor systems must interface with the physical world and therefore generally require continuous representations and smooth input-output behavior. In such situations, neural networks have provided a useful class of architectures, as have probabilistic systems such as HIDDEN MARKOV MODELS and Bayesian networks. The latter models also are generally characterized by

a clear propositional semantics, and as such have been exploited for elementary cognitive processing. Decision trees are also propositional systems that are appropriate for simple cognitive tasks. There are variants of decision trees that utilize continuous representations, and these have close links with neural networks, as well as variants of decision trees that utilize relational machinery, making a connection with INDUCTIVE LOGIC PROGRAMMING. The latter class of architecture provides the full power of first-order logic and the capability of learning complex symbolic theories.

Prior knowledge is an important component of essentially all modern learning architectures, particularly so in architectures that involve expressive representations. Indeed, the spirit of inductive logic programming is to use the power of logical inference to bootstrap background knowledge and to interpret new data in the light of that knowledge. This approach is carried to what is perhaps its (logical) extreme in the case of EXPLANATION-BASED LEARNING (EBL), in which the system uses its current theory to *explain* a new observation, and extracts from that explanation a useful rule for future use. EBL can be viewed as a form of generalized caching, also called *speedup learning*. CASE-BASED REASONING AND ANALOGY provides an alternate route to the same end through the solution of problems by reference to previous experience instead of first principles.

Underlying all research on learning is a version of the general problem of INDUCTION; in particular, on what basis can we expect that a system that performs well on past "training" data should also perform well on future "test" data? The theory of learning (see COMPUTATIONAL LEARNING THEORY and STATISTICAL LEARNING THEORY) attacks this problem by assuming that the data provided to a learner is obtained from a fixed but unknown probability distribution. The theory yields a notion of *sample complexity*, which quantifies the amount of data that a learner must see in order to expect—with high probability—to perform (nearly) as well in the future as in the past. The theory also provides support for the intuitive notion of Ockham's razor—the idea that if a simple hypothesis performs as well as a complex hypothesis, one should prefer the simple hypothesis (see PARSIMONY AND SIMPLICITY).

General ideas from probability theory in the form of Bayesian learning, as well as related ideas from INFORMATION THEORY in the form of the MINIMUM DESCRIPTION LENGTH approach provide a link between learning theory and learning practice. In particular, Bayesian learning, which views learning as the updating of probabilistic beliefs in hypotheses given evidence, naturally embodies a form of Ockham's razor. Bayesian methods have been applied to neural networks, Bayesian networks, decision trees, and many other learning architectures.

We have seen that learning has strong relationships to knowledge representation and to the study of uncertainty. There are also important connections between learning and search. In particular, most learning algorithms involve some form of search through the hypothesis space to find hypotheses that are consistent (or nearly so) with the data and with prior expectations. Standard heuristic search algorithms are often invoked—either explicitly or implicitly—to perform this search. EVOLUTIONARY COMPUTATION also treats learning as a search process, in which the "hypothesis" is an entire agent, and learning takes place by "mutation" and "natural selection" of agents that perform well (see also ARTIFICIAL LIFE). There are also interesting links between learning and planning; in particular, it is possible to view reinforcement learning as a form of "on-line" planning.

Finally, it is worth noting that learning has been a particularly successful branch of AI research in terms of its applications to real-world problems in specific fields; see for example the articles on PATTERN RECOGNITION AND FEEDFORWARD NETWORKS, STATISTICAL TECHNIQUES IN NATURAL LANGUAGE PROCESSING, VISION AND LEARNING, and ROBOTICS AND LEARNING.

ING; VISION AND LEARNING

10   Language

NATURAL LANGUAGE PROCESSING, or NLP—the ability to perceive, understand, and
generate language—is an essential part of HUMAN-COMPUTER INTERACTION as well as
the most obvious task to be solved in passing the Turing test. As with logical reason-
ing, AI researchers have benefited from a pre-existing intellectual tradition. The field
of linguistics (see also LINGUISTICS, PHILOSOPHICAL ISSUES) has produced formal
notions of SYNTAX and SEMANTICS, the view of utterances as *speech acts,* and very
careful philosophical analyses of the meanings of various constructs in natural lan-
guage. The field of COMPUTATIONAL LINGUISTICS has grown up since the 1960s as a
fertile union of ideas from AI, cognitive science, and linguistics.

As soon as programs were written to process natural language, it became obvious
that the problem was much harder than had been anticipated. In the United States sub-
stantial effort was devoted to Russian-English translation from 1957 onward, but in
1966 a government report concluded that "there has been no machine translation of
general scientific text, and none is in immediate prospect." Successful MACHINE
TRANSLATION appeared to require an *understanding* of the content of the text; the bar-
riers included massive ambiguity (both syntactic and semantic), a huge variety of
word senses, and the vast numbers of idiosyncratic ways of using words to convey
meanings. Overcoming these barriers seems to require the use of large amounts of
commonsense knowledge and the ability to reason with it—in other words, solving a
large fraction of the AI problem. For this reason, Robert Wilensky has described natu-
ral language processing as an "AI-complete" problem (see also MODULARITY AND
LANGUAGE).

Research in NLP has uncovered a great deal of new information about language.
There is a better appreciation of the *actual* syntax of natural language—as opposed to
the vastly oversimplified models that held sway before computational investigation
was possible. Several new families of FORMAL GRAMMARS have been proposed as a
result. In the area of semantics, dozens of interesting phenomena have surfaced—for
example, the surprising range of semantic relationships in noun-noun pairs such as
"alligator shoes" and "baby shoes." In the area of DISCOURSE understanding, research-
ers have found that grammaticality is sometimes thrown out of the window, leading
some to propose that grammar itself is not a useful construct for NLP.

One consequence of the richness of natural language is that it is very difficult to
build by hand a system capable of handling anything close to the full range of phe-
nomena. Most systems constructed prior to the 1990s functioned only in predefined
and highly circumscribed domains. Stimulated in part by the availability of large
online text corpora, the use of STATISTICAL TECHNIQUES IN NATURAL LANGUAGE PRO-
CESSING has created something of a revolution. Instead of building complex grammars
by hand, these techniques train very large but very simple probabilistic grammars and
semantic models from millions of words of text. These techniques have reached the
point where they can be usefully applied to extract information from general newspa-
per articles.

Few researchers expect simple probability models to yield human-level under-
standing. On the other hand, the view of language entailed by this approach—that the
text is a form of *evidence* from which higher-level facts can be inferred by a process of
probabilistic inference—may prove crucial for further progress in NLP. A probabilis-
tic framework allows the smooth integration of the multiple "cues" required for NLP,
such as syntax, semantics, discourse conventions, and prior expectations.

In contrast to the general problem of natural language understanding, the problem
of SPEECH RECOGNITION IN MACHINES may be feasible without recourse to general
knowledge and reasoning capabilities. The statistical approach was taken much ear-
lier in the speech field, beginning in the mid-1970s. Together with improvements in
the signal processing methods used to extract acoustic features, this has led to steady
improvements in performance, to the point where commercial systems can handle

dictated speech with over 95 percent accuracy. The combination of speech recognition and SPEECH SYNTHESIS (see also NATURAL LANGUAGE GENERATION) promises to make interaction with computers much more natural for humans. Unfortunately, accuracy rates for natural dialogue seldom exceed 75 percent; possibly, speech systems will have to rely on knowledge-based expectations and real understanding to make further progress.

11   Vision

The study of vision presents a number of advantages—visual processing systems are present across a wide variety of species, they are reasonably accessible experimentally (psychophysically, neuropsychologically, and neurophysiologically), and a wide variety of artificial imaging systems are available that are sufficiently similar to their natural counterparts so as to make research in machine vision highly relevant to research in natural vision. An integrated view of the problem has emerged, linking research in COMPUTATIONAL VISION, which is concerned with the development of explicit theories of human and animal vision, with MACHINE VISION, which is concerned with the development of an engineering science of vision.

Computational approaches to vision, including the influential theoretical framework of MARR, generally involve a succession of processes that begin with localized numeric operations on images (so-called early vision) and proceed toward the high-level abstractions thought to be involved in OBJECT RECOGNITION. The current view is that the interpretation of complex scenes involves inference in both the bottom-up and top-down directions (see also TOP-DOWN PROCESSING IN VISION).

High-level object recognition is not the only purpose of vision. Representations at intermediate levels can also be an end unto themselves, directly subserving control processes of orienting, locomotion, reaching, and grasping. Visual analysis at all levels can be viewed as a process of recovering aspects of the visual scene from its projection onto a 2-D image. Visual properties such as shape and TEXTURE behave in lawful ways under the geometry of perspective projection, and understanding this geometry has been a focus of research. Related geometrical issues have been studied in STEREO AND MOTION PERCEPTION, where the issue of finding correspondences between multiple images also arises. In all of these cases, localized spatial and temporal cues are generally highly ambiguous with respect to the aspects of the scene from which they arise, and algorithms that recover such aspects generally involve some form of spatial or temporal integration.

It is also important to prevent integrative processes from wrongly smoothing across discontinuities that correspond to visually meaningful boundaries. Thus, visual processing also requires segmentation. Various algorithms have been studied for the segmentation of image data. Again, an understanding of projective geometry has been a guide for the development of such algorithms. Integration and segmentation are also required at higher levels of visual processing, where more abstract principles (such as those studied by GESTALT PSYCHOLOGY; see GESTALT PERCEPTION) are needed to group visual elements.

Finally, in many cases the goal of visual processing is to detect or recognize objects in the visual scene. A number of difficult issues arise in VISUAL OBJECT RECOGNITION, including the issue of what kinds of features should be used (2-D or 3-D, edge-based or filter-based), how to deal with missing features (e.g., due to occlusion or shadows), how to represent flexible objects (such as humans), and how to deal with variations in pose and lighting. Methods based on learning (cf. VISION AND LEARNING) have played an increasingly important role in addressing some of these issues.

CESSING IN VISION; VISION AND LEARNING; VISUAL OBJECT RECOGNITION, AI

12   Robotics

Robotics is the control of physical effectors to achieve physical tasks such as naviga-
tion and assembly of complex objects. Effectors include grippers and arms to perform
MANIPULATION AND GRASPING and wheels and legs for MOBILE ROBOTS and WALKING
AND RUNNING MACHINES.

The need to interact directly with a physical environment, which is generally only
partially known and partially controllable, brings certain issues to the fore in robotics
that are often skirted in other areas in AI. One important set of issues arises from the
fact that environments are generally dynamical systems, characterizable by a large
(perhaps infinite) collection of real-valued state variables, whose values are not gener-
ally directly observable by the robot (i.e., they are "hidden"). The presence of the
robot control algorithm itself as a feedback loop in the environment introduces addi-
tional dynamics. The robot designer must be concerned with the issue of *stability* in
such a situation. Achieving stability not only prevents disasters but it also simplifies
the dynamics, providing a degree of predictability that is essential for the success of
planning algorithms.

Stability is a key issue in manipulation and grasping, where the robot must impart a
distributed pattern of forces and torques to an object so as to maintain a desired posi-
tion and orientation in the presence of external disturbances (such as gravity).
Research has tended to focus on static stability (ignoring the dynamics of the grasped
object). Static stability is also of concern in the design of walking and running robots,
although rather more pertinent is the problem of dynamic stability, in which a moving
robot is stabilized by taking advantage of its inertial dynamics.

Another important set of issues in robotics has to do with uncertainty. Robots are
generally equipped with a limited set of sensors and these sensors are generally noisy
and inherently ambiguous. To a certain extent the issue is the same as that treated in
the preceding discussion of vision, and the solutions, involving algorithms for integra-
tion and smoothing, are often essentially the same. In robotics, however, the sensory
analysis is generally used to subserve a control law and the exigencies of feedback
control introduce new problems (cf. CONTROL THEORY). Processing time must be held
to a minimum and the system must focus on obtaining only that information needed
for control. These objectives can be difficult to meet, and recent research in robotics
has focused on minimizing the need for feedback, designing sequences of control
actions that are guaranteed to bring objects into desired positions and orientations
regardless of the initial conditions.

Uncertainty is due not only to noisy sensors and hidden states, but also to igno-
rance about the structure of the environment. Many robot systems actively model the
environment, using system identification techniques from control theory, as well as
more general supervised and unsupervised methods from machine learning. Special-
ized representations are often used to represent obstacles ("configuration space") and
location in space (graphs and grids). Probabilistic approaches are often used to explic-
itly represent and manipulate uncertainty within these formalisms.

In classical robotic control methodology, the system attempts to recover as much of
the state of the environment as possible, operates on the internal representation of the
state using general planning and reasoning algorithms, and chooses a sequence of
control actions to implement the selected plan. The sheer complexity of designing this
kind of architecture has led researchers to investigate simpler architectures that make
do with minimal internal state. BEHAVIOR-BASED ROBOTICS approaches the problem
via an interacting set of elemental processes called "behaviors," each of which is a
simplified control law relating sensations and actions. REINFORCEMENT LEARNING has
provided algorithms that utilize simplified evaluation signals to guide a search for
improved laws; over time these algorithms approach the optimal plans that are derived
(with more computational effort) from explicit planning algorithms (see ROBOTICS
AND LEARNING).

13   Complexity, Rationality, and Intelligence

We have observed at several points in this introduction that COMPUTATIONAL COMPLEXITY is a major problem for intelligent agents. To the extent that they can be analyzed, most of the problems of perceiving, learning, reasoning, and decision making are believed to have a worst-case complexity that is at least exponential in the size of the problem description. Exponential complexity means that, for example, a problem of size 100 would take 10 billion years to solve on the fastest available computers. Given that humans face much larger problems than this all the time—we receive as input several billion bytes of information every second—one wonders how we manage at all.

Of course, there are a number of mitigating factors: an intelligent agent must deal largely with the typical case, not the worst case, and accumulated experience with similar problems can greatly reduce the difficulty of new problems. The fact remains, however, that humans cannot even come close to achieving perfectly rational behavior—most of us do fairly poorly even on problems such as chess, which is an *infinitesimal* subset of the real world. What, then, is the right thing for an agent to do, if it cannot possibly compute the right thing to do?

In practical applications of AI, one possibility is to restrict the allowable set of problems to those that are efficiently soluble. For example, deductive database systems use restricted subsets of logic that allow for polynomial-time inference. Such research has given us a much deeper understanding of the sources of complexity in reasoning, but does not seem directly applicable to the problem of general intelligence. Somehow, we must face up to the inevitable compromises that must be made in the quality of decisions that an intelligent agent can make. Descriptive theories of such compromises—for example, Herbert Simon's work on *satisficing*—appeared soon after the development of formal theories of rationality. Normative theories of BOUNDED RATIONALITY address the question at the end of the preceding paragraph by examining what is achievable with fixed computational resources. One promising approach is to devote some of those resources to METAREASONING (see also METACOGNITION), that is, reasoning about what reasoning to do. The technique of EXPLANATION-BASED LEARNING (a formalization of the common psychological concept of *chunking* or *knowledge compilation*) helps an agent cope with complexity by caching efficient solutions to common problems. Reinforcement learning methods enable an agent to learn effective (if not perfect) behaviors in complex environments without the need for extended problem-solving computations.

What is interesting about all these aspects of intelligence is that without the need for effective use of limited computational resources, they make no sense. That is, computational complexity may be responsible for many, perhaps most, of the aspects of cognition that make intelligence an interesting subject of study. In contrast, the cognitive structure of an infinitely powerful computational device could be very straightforward indeed.

14   Additional Sources

Early AI work is covered in Feigenbaum and Feldman's (1963) *Computers and Thought,* Minsky's (1968) *Semantic Information Processing,* and the *Machine Intelligence* series edited by Donald Michie. A large number of influential papers are collected in *Readings in Artificial Intelligence* (Webber and Nilsson 1981). Early papers on neural networks are collected in *Neurocomputing* (Anderson and Rosenfeld 1988). The *Encyclopedia of AI* (Shapiro 1992) contains survey articles on almost every topic in AI. The four-volume *Handbook of Artificial Intelligence* (Barr and Feigenbaum

1981) contains descriptions of almost every major AI system published before 1981. Standard texts on AI include *Artificial Intelligence: A Modern Approach* (Russell and Norvig 1995) and *Artificial Intelligence: A New Synthesis* (Nilsson 1998). Historical surveys include Kurzweil (1990) and Crevier (1993).

The most recent work appears in the proceedings of the major AI conferences: the biennial International Joint Conference on AI (IJCAI); the annual National Conference on AI, more often known as AAAI after its sponsoring organization; and the European Conference on AI (ECAI). The major journals for general AI are *Artificial Intelligence, Computational Intelligence,* the IEEE *Transactions on Pattern Analysis and Machine Intelligence,* and the electronic *Journal of Artificial Intelligence Research*. There are also many journals devoted to specific areas, some of which are listed in the relevant articles. The main professional societies for AI are the American Association for Artificial Intelligence (AAAI), the ACM Special Interest Group in Artificial Intelligence (SIGART), and the Society for Artificial Intelligence and Simulation of Behaviour (AISB). AAAI's *AI Magazine* and the *SIGART Bulletin* contain many topical and tutorial articles as well as announcements of conferences and workshops.

Linguistics and Language

Gennaro Chierchia

1 Language and Cognition

Why is the study of language central to cognition? The answer lies in the key properties of language as they manifest themselves in the way speakers use it. The best way to get a sense of the centrality of language in understanding cognitive phenomena is through some examples. In the rest of this introduction I illustrate some features of language that display surprising regularities. Among the many ways in which an efficient communication code could be designed, natural languages seem to choose quite peculiar ones. The question is why. We consider some of the answers that modern linguistics gives to this question, which lead us into a scenic (if necessarily brief) tour of its main problematics. In particular, section 2 is devoted to language structure and its main articulations. Section 3 is devoted to language use, its interplay with language structure, and the various disciplines that deal with these matters. We then close, in section 4, with a few short remarks on the place of linguistics within cognitive science.

Languages are made of words. How many words do we know? This is something that can be estimated quite accurately (see Pinker 1994: 149 ff.). To set a base line, consider that Shakespeare in his works uses roughly 15,000 different words. One would think that the vocabulary of, say, a high school student, is considerably poorer. Instead, it turns out that a high school senior reliably understands roughly 45,000 words out of a lexicon of 88,500 unrelated words. It might be worth mentioning how one arrives at this estimate. One samples randomly the target corpus of words and performs simple comprehension tests on the sample. The results are then statistically projected to the whole corpus. Now, the size of the vocabulary of a high school senior entails that from when the child starts learning words at a few months of age until the age of eighteen, he or she must be learning roughly a word every hour and half when awake. We are talking here of learning arbitrary associations of sound patterns with meanings. Compare this with the effort it takes to learn an even short poem by heart, or the names of a handful of basketball players. The contrast is striking. We get to understand 45,000 words with incomparably less effort, to the point of not even being aware of it. This makes no sense without the assumption that our mind must be especially equipped with something, a cognitive device of some sort, that makes us so successful at the task of learning words. This cognitive device must be quite specialized for such a task, as we are not as good at learning poems or the names of basketball players (cf. WORD MEANING, ACQUISITION OF)

The world of sounds that make up words is similarly complex. We all find the sounds of our native language easy to distinguish. For example, to a native English speaker the i-sounds in "leave" and "live" are clearly different. And unless that person is in especially unfavorable conditions, he or she will not take one for the other. To a native English speaker, the difficulty that an Italian learning English (as an adult) encounters in mastering such distinctions looks a bit mysterious. Italians take revenge when English speakers try to learn the contrast between words like "*fato*" 'fate' vs. "*fatto*" 'fact.' The only difference between them is that the t-sound in *fatto* sounds to the Italian speaker slightly longer or tenser, a contrast that is difficult for a speaker of English to master. These observations are quite commonplace. The important point, however, is that a child exposed to the speech sounds of *any* language picks them up effortlessly. The clicks of Zulu (sounds similar to the "tsk-tsk" of disapproval) or the implosive sounds of Sindhi, spoken in India and Pakistan (sounds produced by sucking in air, rather than ejecting it—see ARTICULATION) are not harder for the child to acquire than the occlusives of English. Adults, in contrast, often fail to learn to produce sounds not in their native repertoire. Figuring out the banking laws or the foods of a different culture is generally much easier. One would like to understand why.

Behind its daily almost quaint appearance, language seems to host many remarkable regularities of the sort just illustrated. Here is yet another example taken from a different domain, that of pronouns and ANAPHORA. Consider the following sentence:

(1) John promised Bill to wash him.

Any native speaker of English will agree that the pronoun "him" in (1) can refer to "Bill" (the object—see GRAMMATICAL RELATIONS), but there is no way it can refer to "John" (the subject). If we want a pronoun that refers to "John" in a sentence like (1), we have to use a reflexive:

(2) John promised Bill to wash himself.

The reflexive "himself" in (2) refers to "John." It cannot refer to "Bill." Compare now (1) with (3):

(3) John persuaded Bill to wash him

Here "him" can refer to the *subject*, but not to the object. If we want a pronoun to refer to "Bill" we have to use

(4) John persuaded Bill to wash himself.

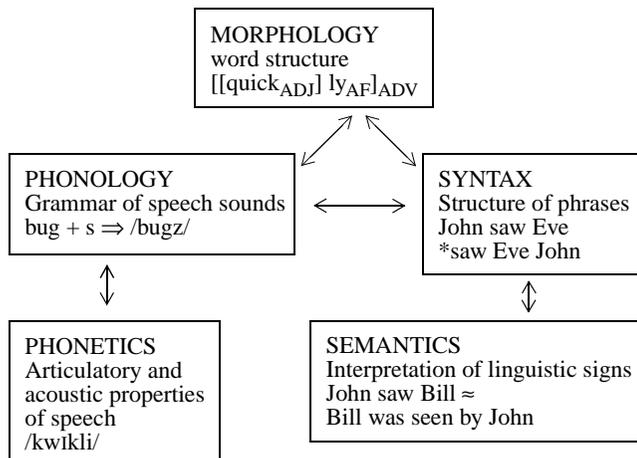
The reflexive "himself" in (4) must refer to the object. It cannot refer to the subject. By comparing (1) and (2) with (3) and (4), we see that the way pronouns work with verbs like "promise" appears to be the opposite of verbs like "persuade." Yet the structure of these sentences appears to be identical. There must be a form of specialized, unconscious knowledge we have that makes us say "Yes, 'him' can refer to the subject in (1) but not in (3)." A very peculiar intuition we have grown to have.

What is common to these different aspects of language is the fact that our linguistic behavior reveals striking and complex regularities. This is true throughout the languages of the worlds. In fact the TYPOLOGY of the world's languages reveals significant universal tendencies. For example, the patterns of word order are quite limited. The most common basic orders of the major sentence constituents are subject-verb-object (abbreviated as SVO) and SOV. Patterns in which the object precedes the subject are quite rare. Another language universal one might mention is that all languages have ways of using clauses to modify nouns (as in "the boy that you just met," where the relative clause "that you just met" modifies the noun "boy"). Now structural properties of this sort are not only common to all known spoken languages but in fact can be found even in SIGN LANGUAGES, that is, visual-gestural languages typically in use in populations with impaired verbal abilities (e.g., the deaf). It seems plausible to maintain that universal tendencies in language are grounded in the way we are; this must be so for speaking is a cognitive capacity, that capacity in virtue of which we say that we "know" our native language. We exercise such capacity in using language. A term often used in this connection is "linguistic competence." The way we put such competence to use in interacting with our environment and with each other is called "performance."

The necessity to hypothesize a linguistic competence can be seen also from another point of view. Language is a dynamic phenomenon, dynamic in many senses. It changes across time and space (cf. LANGUAGE VARIATION AND CHANGE). It varies along social and gender dimensions (cf. LANGUAGE AND GENDER; LANGUAGE AND CULTURE). It also varies in sometimes seemingly idiosyncratic ways from speaker to speaker. Another important aspect of the dynamic character of language is the fact that a speaker can produce and understand an indefinite number of sentences, while having finite cognitive resources (memory, attention span, etc.). How is this possible? We must assume that this happens by analogy with the way we, say, add two numbers we have never added before. We can do it because we have mastered a combinatorial device, an ALGORITHM. But the algorithm for adding we have learned through explicit training. The one for speaking appears to grow spontaneously in the child. Such an algorithm is constitutive of our linguistic competence.

The fact that linguistic competence does not develop through explicit training can be construed as an argument in favor of viewing it as a part of our genetic endowment

(cf. INNATENESS OF LANGUAGE). This becomes all the more plausible if one considers how specialized the knowledge of a language is and how quickly it develops in the child. In a way, the child should be in a situation analogous to that of somebody who is trying to break the mysteries of an unknown communication code. Such a code could have in principle very different features from that of a human language. It might lack a distinction between subjects and objects. Or it might lack the one between nouns and verbs. Many languages of practical use (e.g., many programming languages) are designed just that way. The range of possible communication systems is huge and highly differentiated. This is part of the reason why cracking a secret code is very hard—as hard as learning an unfamiliar language as an adult. Yet the child does it without effort and without formal training. This seems hard to make sense of without assuming that, in some way, the child knows what to look for and knows what properties of natural speech he or she should attend to in order to figure out its grammar. This argument, based on the observation that language learning constitutes a specialized skill acquired quickly through minimal input, is known as the POVERTY OF THE STIMULUS ARGUMENT. It suggests that linguistic competence is a relatively autonomous computational device that is part of the biological endowment of humans and guides them through the acquisition of language. This is one of the planks of what has come to be known as GENERATIVE GRAMMAR, a research program started in the late 1950s by Noam Chomsky, which has proven to be quite successful and influential.

It might be useful to contrast this view with another one that a priori might be regarded as equally plausible (see CONNECTIONIST APPROACHES TO LANGUAGE). Humans seem to be endowed with a powerful all-purpose computational device that is very good at extracting regularities from the environment. Given that, one might hypothesize that language is learned the way we learn any kind of algorithm: through trial and error. All that language learning amounts to is simply applying our high-level computational apparatus to linguistic input. According to this view, the child acquires language similarly to how she learns, say, doing division, the main difference being in the nature of the input. Learning division is of course riddled with all sorts of mistakes that the child goes through (typical ones involve keeping track of rests, misprocessing partial results, etc.). Consider, in this connection, the pattern of pronominalization in sentences (1) through (4). If we learn languages the way we learn division, the child ought to make mistakes in figuring out what can act as the antecedent of a reflexive and what cannot. In recent years there has been extensive empirical investigation of the behavior of pronominal elements in child language (see BINDING THEORY; SYNTAX, ACQUISITION OF; SEMANTICS, ACQUISITION OF). And this was not what was found. The evidence goes in the opposite direction. As soon as reflexives and nonreflexive pronouns make their appearance in the child's speech, they appear to be used in an adult-like manner (cf. Crain and McKee 1985; Chien and Wexler 1990; Grodzinsky and Reinhart 1993).


Many of the ideas we find in generative grammar have antecedents throughout the history of thought (cf. LINGUISTICS, PHILOSOPHICAL ISSUES). One finds important debates on the "conventional" versus "natural" origins of language already among the presocratic philosophers. And many ancient grammarians came up with quite sophisticated analyses of key phenomena. For example the Indian grammarian Panini (fourth to third century B.C.) proposed an analysis of argument structure in terms of THEMATIC ROLES (like *agent, patient,* etc.), quite close in spirit to current proposals. The scientific study of language had a great impulse in the nineteenth century, when the historical links among the languages of the Indo-European family, at least in their general setup, were unraveled. A further fundamental development in our century was the structuralist approach, that is the attempt to characterize in explicit terms language structure as it manifests itself in sound patterns and in distributional patterns. The structuralist movement started out in Europe, thanks to F. DE SAUSSURE and the Prague School (which included among it protagonists N. Trubeckoj and R. JAKOBSON) and developed, then, in somewhat different forms, in the United States through the work of L. BLOOMFIELD, E. SAPIR, Z. Harris (who was Chomsky's teacher), and others. Structuralism, besides leaving us with an accurate description of many important linguistic phenomena, constituted the breeding ground for a host of concepts (like "morpheme," "phoneme," etc.)

that have been taken up and developed further within the generative tradition. It is against this general background that recent developments should be assessed.

2   *Language Structure*

Our linguistic competence is made up of several components (or "modules," see MODULARITY AND LANGUAGE) that reflect the various facets of language, going from speech sounds to meaning. In this section we will review the main ones in a necessarily highly abbreviated from. Language can be thought of as a LEXICON and combinatiorial apparatus. The lexicon is constituted by the inventory of words (or morphemes) through which sentences and phrases are built up. The combinatorial apparatus is the set of rules and principles that enable us to put words together in well-formed strings, and to pronounce and interpret such strings. What we will see, as we go through the main branches of linguistics, is how the combinatorial machinery operates throughout the various components of grammar. Meanwhile, here is a rough road map of major modules that deal with language structure.

Words and Sounds

We already saw that the number of words we know is quite remarkable. But what do we mean by a "word"? Consider the verb "walk" and its past tense "walked." Are these two different words? And how about "walk" versus "walker"? We can clearly detect some inner regular components to words like "walked" namely the stem "walk" (which is identical to the infinitival form) and the ending "-ed," which signals "past." These components are called "morphemes;" they constitute the smallest elements with an identifiable meaning we can recognize in a word. The internal structure of words is the object of the branch of linguistics known as MORPHOLOGY. Just like sentences are formed by putting words together, so words themselves are formed by putting together morphemes. Within the word, that is, as well as between words, we see a combinatorial machinery at work. English has a fairly simple morphological structure. Languages like Chinese have even greater morphological simplicity, while languages like Turkish or Japanese have a very rich morphological structure. POLYSYNTHETIC LANGUAGES are perhaps the most extreme cases of morphological complexity. The

following, for example, is a single word of Mohawk, a polysynthetic North American Indian language (Baker 1996: 22):

(5) *ni-mic-tomi-maka*
    first person-second person-money-give
    'I'll give you the money.'

Another aspect of morphology is compounding, which enables one to form complex words by "glomming" them together. This strategy is quite productive in English, for example, *blackboard, blackboard design, blackboard design school*, and so on. Compounds can be distinguished from phrases on the basis of a variety of converging criteria. For example, the main stress on compounds like "blackboard" is on "black," while in the phrase "black board" it is on "board" (cf. STRESS, LINGUISTIC; METER AND POETRY). Moreover syntax treats compounds as units that cannot be separated by syntactic rules. Through morphological derivation and compounding the structure of the lexicon becomes quite rich.

So what is a word? At one level, it is what is stored in our mental lexicon and has to be memorized as such (a listeme). This is the sense in which we know 45,000 (unrelated) words. At another, it is what enters as a unit into syntactic processes. In this second sense (but not in the first) "walk" and "walked" count as two words. Words are formed by composing together smaller meaningful units (the morphemes) through specific rules and principles.

Morphemes are, in turn, constituted by sound units. Actually, speech forms a continuum not immediately analyzable into discrete units. When exposed to an unfamiliar language, we can not tell where, for example, the word boundaries are, and we have difficulty in identifying the sounds that are not in our native inventory. Yet speakers classify their speech sound stream into units, the phonemes. PHONETICS studies speech sounds from an acoustic and articulatory point of view. Among other things, it provides an alphabet to notate all of the sounds of the world's languages. PHONOLOGY studies how the range of speech sounds are exploited by the grammars of different languages and the universal laws of the grammar of sounds. For example, we know from phonetics that back vowels (produced by lifting the rear of the tongue towards the palate) can be rounded (as in "hot") or unrounded (as in "but") and that this is so also for front vowels (produced by lifting the tongue toward the front of the vocal tact). The i-sound in "feet" is a high, front, unrounded vowel; the sound of the corresponding German word "füsse" is also pronounced raising the tongue towards the front, but is rounded. If a language has rounded front vowels it also has rounded back vowels. To illustrate, Italian has back rounded vowels, but lacks altogether unrounded back vowels. English has both rounded and unrounded back vowels. Both English and Italian lack front rounded vowels. German and French, in contrast, have them. But there is no language that has in its sound inventory front rounded vowels without also having back rounded ones. This is the form that constraints on possible systems of phonemes often take.

As noted in section 1, the type of sounds one finds in the world's languages appear to be very varied. Some languages may have relatively small sound inventories constituted by a dozen phonemes (as, for example, Polynesian); others have quite large ones with about 140 units (Khoisan). And there are of course intermediate cases. One of the most important linguistic discoveries of this century has been that all of the wide variety of phonemes we observe can be described in terms of a small universal set of DISTINCTIVE FEATURES (i.e., properties like "front," "rounded," "voiced," etc.). For example, /p/ and /b/ (bilabial stops) have the same feature composition except for the fact that the former is voiceless (produced without vibration of the vocal cords) while the latter is voiced. By the same token, the phoneme /k/, as in "bake," and the final sound of the German word "Bach" are alike, except in one feature. In the former the air flux is completely interrupted (the sound is a *stop*) by lifting the back of the tongue up to the rear of the palate, while in the latter a small passage is left which results in a turbulent continuous sound (a *fricative,* notated in the phonetic alphabet as /x/). So all phonemes can be analyzed as feature structures.

There is also evidence that features are not just a convenient way to classify phonemes but are actually part of the implicit knowledge that speakers have of their

language. One famous experiment that provides evidence of this kind has to do with English plurals. In simplified terms, plurals are formed by adding a voiced alveolar fricative /z/ after a voiced sound (e.g., fad[z]) and its voiceless counterpart /s/ after a voiceless one (e.g., fat[s]). This is a form of *assimilation,* a very common phonological process (see PHONOLOGICAL RULES AND PROCESSES). If a monolingual English speaker is asked to form the plural of a word ending in a phoneme that is not part of his or her native inventory and has never been encountered before, that speaker will follow the rule just described; for example, the plural of the word "Bach" will be [baxs] not [baxz]. This means that in forming the plural speakers are actually accessing the featural make up of the phonemes and analyzing phonemes into voiced verus voiceless sets. They have not just memorized after which sounds /s/ goes and after which /z/ goes (see Akmajian et al. 1990: chapter 3 and references therein).

Thus we see that even within sound units we find smaller elements, the distinctive features, combined according to certain principles. Features, organized in phonemes, are manipulated by rule systems. Phonemes are in turn structured into larger prosodic constituents (see PROSODY AND INTONATION), which constitute the domains over which stress and TONE are determined. On the whole we see that the world of speech sounds is extremely rich in structure and its study has reached a level of remarkable theoretical sophistication (for recent important developments, see OPTIMALITY THEORY).

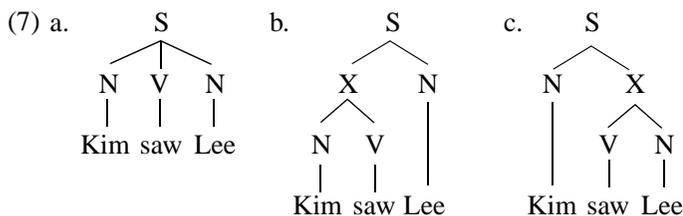
Phrases

The area where we perhaps most clearly see the power of the combinatorial machinery that operates in language is SYNTAX, the study of how words are composed into phrases. In constructing sentences, we don't merely put words into certain sequences, we actually build up a structure. Here is a simple illustration.

English is an SVO language, whose basic word order in simple sentences is the one in (6a).

(6) a. Kim saw Lee
    b. *saw Lee Kim   b'. Ha visto Lee Kim (Italian)
    c. *Kim Lee saw   c'. Kim-ga Lee-o mita (Japanese)

Alternative orders, such as those in (6b–c), are ungrammatical in English. They are grammatical in other languages; thus (6b'), the word-by-word Italian translation of (6b), is grammatical in Italian; and so is (6c'), the Japanese translation of (6c). A priori, the words in (6a) could be put together in a number of different ways, which can be represented by the following tree diagrams:

(7) a. tree with S dominating N V N → Kim saw Lee; b. S dominating X (→ N V: Kim saw) and N (Lee); c. S dominating N (Kim) and X (→ V N: saw Lee)


where: S = sentence, N = noun

The structure in (7a) simply says that "Kim," "Lee," and "saw" are put together all at once and that one cannot recognize any subunit within the clause. Structure (7b) says that there is a subunit within the clause constituted by the subject plus the verb; (7c) that the phrasing actually puts together the verb plus the object. The right analysis for English turns out to be (7c), where the verb and the object form a unit, a constituent called the verb phrase (VP), whose "center," or, in technical terms, whose "head" is the verb. Interestingly, such an analysis turns out to be right also for Japanese and Italian, and, it seems, universally. In all languages, the verb and the object form a unit.

There are various ways of seeing that it must be so. A simple one is the following: languages have proforms that is elements that lack an inherent meaning and get their semantic value from a linguistic antecedent (or, in some cases, the extralinguistic context). Personal pronouns like "he" or "him" are a typical example:

(8) A tall boy came in. Paul greeted him warmly.

Here the antecedent of "him" is most naturally construed as "a tall boy". "Him" is a noun phrase (NP), that is, it has the same behavior as things like "Kim" or "a tall boy," which can act as its antecedent. Now English, as many other languages, also has proforms that clearly stand for V+object sequences:

(9) Kim saw Lee. Mary swears that Paul did too

"Did" in (9) is understood as "saw Kim." This means that the antecedent of "did" in (9) is the verb+object sequence of the previous sentence. This makes sense if we assume that such sequences form a unit, the VP (just like "a tall boy" forms an NP).

   Notice that English does not have a proform that stands for the subject plus a transitive verb. There is no construction of the following sort:

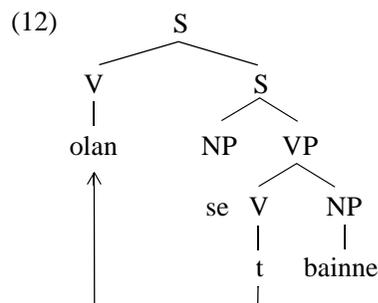
(10) Kim saw Lee. Mary swears that PROed John too.
      [meaning: "Mary swears that **Kim saw** John too"]

The hypothetical element "PROed" would be an overt morpheme standing for a subject+transitive verb sequence. From a logical point of view, a verb+subject proform doesn't look any more complex than a verb+object proform. From a practical point of view, such a proform could be as useful and as effective for communication as the proform "did." Yet there is nothing like "PROed," and not just in English. In no known language does such a proform appear. This makes sense if we assume that proforms must be constituents of some kind and that verb + object (in whatever order they come) forms a constituent. If, instead, the structure of the clause were (7a) there would be no reason to expect such asymmetry. And if the structure were (7b), we *would* expect proforms such as "PROed" to be attested.

   A particularly interesting case is constituted by VSO languages, such as Irish, Breton, and many African languages, etc. Here is an Irish example (Chung and McCloskey 1987: 218):

(11) Ni olan   se bainne ariamh
      Neg drink-PRES.   he milk   ever
      He never drinks milk.

In this type of language the V surfaces next to the subject, separated from the object. If simple linear adjacency is what counts, one might well expect to find in some language of this form a verbal proform that stands for the verb plus the subject. Yet no VSO language has such a proform. This peculiar insistence on banning a potentially useful item even where one would expect it to be readily available can be understood if we assume that VSO structures are obtained by moving the verbal head out of a canonical VP as indicated in what follows:

(12)


The process through which (11) is derived is called HEAD MOVEMENT and is analogous to what one observes in English alternations of the following kind:

(13) a. Kim has seen Lee.
     b. Has Kim seen Lee?

In English, yes-no questions are formed by fronting the auxiliary. This process that applies in English to questions applies in Irish more generally, and is what yields the main difference in basic word order between these languages (see Chung and McCloskey 1987 for evidence and references).

Summing up, there is evidence that in sentences like (6a) the verb and the object are tied together by an invisible knot. This abstract structure in constituents manifests itself in a number of phenomena, of which we have discussed one: the existence of VP proforms, in contrast with the absence of subject+verb proforms. The latter appears to be a universal property of languages and constitutes evidence in favor of the universality of the VP. Along the way, we have also seen how languages can vary and what mechanisms can be responsible for such variations (cf. X-BAR THEORY). Generally speaking, words are put together into larger phrases by a computational device that builds up structures on the basis of relatively simple principles (like: "put a head next to its complement" or "move a head to the front of the clause"). Aspects of this computational device are universal and are responsible for the general architecture that all languages share; others can vary (in a limited way) and are responsible for the final form of particular languages.

There is converging evidence that confirms the psychological reality of constituent structure, that is, the idea that speakers unconsciously assign a structure in constituents to sequences of words. A famous case that shows this is a series of experiments known as the "click" experiments (cf. Fodor, Bever, and Garret 1974). In these experiments, subjects were presented with a sentence through a headphone. At some stage during this process a click sound was produced in the headphone and subjects were then asked at which point of the presentation the click occurred. If the click occurred at major constituent breaks (such as the one between the subject and the VP) the subjects were accurate in recalling when it occurred. If, however, the click occurred within a constituent, subjects would make systematic mistakes in recalling the event. They would overwhelmingly displace the click to the closest constituent break. This behavior would be hard to explain if constituent structure were not actually computed by subjects in processing a sentence (see Clark and Clark 1977 for further discussion).

Thus, looking at the syntax of languages we discover a rich structure that reveals fundamental properties of the computational device that the speaker must be endowed with in order to be able to speak (and understand). There are significant disagreements as to the specifics of how these computational devices are structured. Some frameworks for syntactic analysis (e.g., CATEGORIAL GRAMMAR; HEAD-DRIVEN PHRASE STRUCTURE GRAMMAR; LEXICAL FUNCTIONAL GRAMMAR) emphasize the role of the lexicon in driving syntactic computations. Others, like MINIMALISM, put their emphasis on the economical design of the principles governing how sentences are built up (see also OPTIMALITY THEORY). Other kinds of disagreement concern the choice of primitives (e.g., RELATIONAL GRAMMAR and COGNITIVE LINGUISTICS). In spite of the liveliness of the debate and of the range of controversy, most, maybe all of these frameworks share a lot. For one thing, key empirical generalizations and discoveries can be translated from one framework to the next. For example, all frameworks encode a notion of constituency and ways of fleshing out the notion of "relation at a distance" (such as the one we have described above as head movement). All frameworks assign to grammar a universal structural core and dimensions along which particular languages may vary. Finally, all major modern frameworks share certain basic methodological tenets of formal explicitness, aimed at providing mathematical models of grammar (cf. FORMAL GRAMMARS).

Interfaces

Syntax interacts directly with all other major components of grammar. First, it draws from the lexicon the words to be put into phrases. The lexical properties of words (e.g.

whether they are verbs or nouns, whether and how many complements they need, etc.) will affect the kind of syntactic structures that a particular selection of words can enter into. For example, a sentence like "John cries Bill" is ungrammatical because "cry" is intransitive and takes no complement. Second, syntax feeds into phonology. At some point of the syntactic derivation we get the words in the order that we want to pronounce them. And third, syntax provides the input to semantic interpretation.

To illustrate these interfaces further, consider the following set of sentences:

(14) a. John ignores that Mary saw who.
    b. John ignores who Mary saw t.
    c. who does John ignore that Mary saw t.

Here we have three kinds of interrogative structures. Sentence (14a) is not acceptable as a genuine question. It is only acceptable as an "echo" question, for example in reaction to an utterance of the form "John ignores that Mary saw so and so" where we do not understand who "so and so" is. Sentence (14b) contains an embedded question. In it, the *wh*-pronoun appears in place of the complementizer "that;" in other terms, in (14b), the pronoun "who" has been dislocated to the beginning of the embedded clause and "t" marks the site that it was moved from. Finally, sentence (14c), with the *wh*-pronoun moved to the beginning, constitutes a canonical matrix question (see WH-MOVEMENT). Now, the interpretations of (14b) and (14c) can be given roughly as follows:

(15) a. John ignores (the answer to the question) for which x Mary saw x.
    b. (tell me the answer to the question) for which x John ignores that Mary saw x.

The interpretations in (15) are quite close in form to the overt structures of (14b) and (14c) respectively, while the "echo" question (14a) is interpreted roughly as (15b), modulo the special contexts to which it is limited. Thus it seems that the structure of English (non-echo) questions reflects quite closely its interpretation. *Wh*-pronouns are interpreted as question-forming operators. To make sense of such operators we need to know their scope (i.e., what is being asked). English marks the scope of *wh*-operators by putting them at the beginning of the clause on which they operate: the embedded clause in (14b), the matrix one in (14c). Now, it is quite telling to compare this with what happens in other languages. A particularly interesting case is that of Chinese (see, in particular, Huang 1982; Cheng 1991) where there is no visible *wh*-movement. Chinese only has the equivalent of (14a) (Huang 1992).

(16) Zhangsan xian-zhidao [Lisi kanjian shei]
    Zhangsan ignores [Lisi see who]

Sentence (16) in Chinese is ambiguous. It can either be interpreted as (15b) or as (15c). One way of making sense of this situation is along the following lines. *Wh*-pronouns must be assigned scope to be interpreted. One of the strategies that grammar makes available is placing the *wh*-pronoun at the beginning of the clause on which it operates. English uses such a strategy overtly. First the *wh*-word is fronted, then the result is fed to phonology (and hence pronounced) and to semantics (and hence interpreted). In Chinese, instead, one feeds to phonology the base structure (16); *then wh*-movement applies, as a step toward the computation of meaning. This gives rise to two abstract structures corresponding to (14b) and (14c) respectively:

(17) a. Zhangsan xian-zhidao shei [Lisi kanjian t]
    b. shei Zhangsan xian-zhidao [Lisi kanjian t]

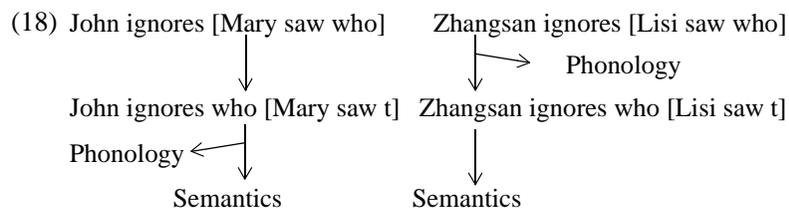
The structures in (17) are what is fed to semantic interpretation. The process just sketched can be schematized as follows:

(18) John ignores [Mary saw who]   Zhangsan ignores [Lisi saw who]

                                    → Phonology

John ignores who [Mary saw t] Zhangsan ignores who [Lisi saw t]

Phonology ←

        Semantics   Semantics


In rough terms, in Chinese one utters the sentence in its basic form (which is semantically ambiguous—see AMBIGUITY) then one does scoping mentally. In English, one first applies scoping (i.e., one marks what is being asked), then utters the result. This way of looking at things enables us to see question formation in languages as diverse as English and Chinese in terms of a uniform mechanism. The only difference lies in the level at which scoping applies. Scope marking takes place overtly in English (i.e., before the chosen sequence of words is pronounced). In Chinese, by contrast, it takes place covertly (i.e., after having pronounced the base form). This is why sentence (16) is ambiguous in Chinese.

There are other elements that need to be assigned a scope in order to be interpreted. A prime case is constituted by quantified NPs like "a student" or "every advisor" (see QUANTIFIERS). Consider (19):

(19) Kim introduced a new student to every advisor.

This sentence has roughly the following two interpretations:

(20) a. There is a student such that Kim introduced him to every advisor.
      b. Every advisor is such that Kim introduced a (possibly different) student to him.

With the help of variables, these interpretation can also be expressed as follows:

(21) a. There is some new student y such that for every advisor x, Kim introduced y to x.
      b. For every advisor x, there is some new student y such that Kim introduced y to x.

Now we have just seen that natural language marks scope in questions by overt or covert movement. If we assume that this is the strategy generally made available to us by grammar, then we are led to conclude that also in cases like (19) scope must be marked via movement. That is, in order to interpret (19), we must determine the scope of the quantifiers by putting them at the beginning of the clause they operate on. For (19), this can be done in two ways:

(22) a. [a new student$_i$ every advisor$_j$ [Kim introduced t$_i$ to t$_j$]]
      b. [every advisor$_j$ a new student$_i$ [Kim introduced t$_i$ to t$_j$]]

Both (22a) and (22b) are obtained out of (19). In (22a) we move "a new student" over "every advisor." In (22b) we do the opposite. These structures correspond to the interpretations in (21a) and (21b), respectively. In a more standard logical notation, they would be expressed as follows:

(23) a. [∃x$_i$ x$_i$ a new student][∀ x$_j$ x$_j$ an advisor] [Kim introduces x$_i$ to x$_j$]
      b. [∀ x$_j$ x$_j$ an advisor] [∃x$_i$ x$_i$ a new student] [Kim introduces x$_i$ to x$_j$]

So in the interpretation of sentences with quantified NPs, we apply scoping to such NPs. Scoping of quantifiers in English is a covert movement, part of the mental computation of MEANING, much like scoping of *wh*-words in Chinese. The result of scoping (i.e., the structures in [22], which are isomorphic to [23]) is what gets semantically interpreted and is called LOGICAL FORM.

What I just sketched in very rough terms constitutes one of several views currently being pursued. Much work has been devoted to the study of scope phenomena, in several frameworks. Such study has led to a considerable body of novel empirical generalizations. Some important principles that govern the behavior of scope in natural language have been identified (though we are far from a definitive understanding). Phenomena related to scope play an important role at the SYNTAX-SEMANTICS INTERFACE. In particular, according to the hypothesis sketched previously, surface syntactic representations are mapped onto an abstract syntactic structure as a first step toward being interpreted. Such an abstract structure, logical form, provides an explicit representation of scope, anaphoric links, and the relevant lexical information. These are all key factors in determining meaning. The hypothesis of a logical form onto which syntactic structure is mapped fits well with the idea that we are endowed with a LANGUAGE OF

THOUGHT, as our main medium for storing and retrieving information, reasoning, and so on. The reason why this is so is fairly apparent. Empirical features of languages lead linguists to detect the existence of a covert level of representation with the properties that the proponents of the language of thought hypothesis have argued for on the basis of independent considerations. It is highly tempting to speculate that logical form actually *is* the language of thought. This idea needs, of course, to be fleshed out much more. I put it forth here in this "naive" form as an illustration of the potential of interaction between linguistics and other disciplines that deal with cognition.

   See also AMBIGUITY; LANGUAGE OF THOUGHT; LOGICAL FORM, ORIGINS OF; LOGICAL FORM IN LINGUISTICS; MEANING; QUANTIFIERS; SYNTAX-SEMANTICS INTERFACE; WH-MOVEMENT

Meaning

What is meaning? What is it to interpret a symbolic structure of some kind? This is one of the hardest question across the whole history of thought and lies right at the center of the study of cognition. The particular form it takes within the picture we have so far is: How is logical form interpreted? A consideration that constrains the range of possible answers to these questions is that our knowledge of meaning enables us to interpret an indefinite number of sentences, including ones we have never encountered before. To explain this we must assume, it seems, that the interpretation procedure is compositional (see COMPOSITIONALITY). Given the syntactic structure to be interpreted, we start out by retrieving the meaning of words (or morphemes). Because the core of the lexicon is finite, we can memorize and store the meaning of the lexical entries. Then each mode of composing words together into phrases (i.e., each configuration in a syntactic analysis tree) corresponds to a mode of composing meanings. Thus, cycling through syntactic structure we arrive eventually at the meaning of the sentence. In general, meanings of complex structures are composed by putting together word (or morpheme) meanings through a finite set of semantic operations that are systematically linked to syntactic configurations. This accounts, in principle, for our capacity of understanding a potential infinity of sentences, in spite of the limits of our cognitive capacities.

   Figuring out what operations we use for putting together word meanings is one of the main task of SEMANTICS. To address it, one must say what the output of such operations is. For example, what is it that we get when we compose the meaning of the NP "Pavarotti" with the meaning of the VP "sings 'La Boheme' well"? More generally, what is the meaning of complex phrases and, in particular, what is the meaning of clauses? Although there is disagreement here (as on other important topics) on the ultimate correct answer, there is agreement on what it is that such an answer must afford us. In particular, to have the information that Pavarotti sings "La Boheme" well is to have also the following kind of information:

(24) a. Someone sings "La Boheme" well.
     b. Not everyone sings "La Boheme" poorly.
     c. It is not the case that nobody sings "La Boheme" well.

Barring performance errors or specific pathologies, we do not expect to find a competent speaker of English who sincerely affirms that Pavarotti sings "La Boheme" well and simultaneously denies that someone does (or denies any of the sentences in [24]). So sentence meaning must be something in virtue of which we can compute how the information associated with the sentence in question is related to the information of other sentences. Our knowledge of sentence meaning enables us to place sentences within a complex network of semantic relationships with other sentences.

   The relation between a sentence like "Pavarotti sings well" and "someone sings well" (or any of the sentences in [24]), is called "entailment". Its standard definition involves the concept of truth: A sentence A entails a sentence B if and only if whenever A is true, then B must also be true. This means that if we understand under what conditions a sentence is true, we also understand what its entailments are. Considerations such as these have lead to a program of semantic analysis based on truth conditions.

The task of the semantic component of grammar is viewed as that of recursively spelling out the truth conditions of sentences (via their logical form). The truth conditions of simple sentences like "Pavarotti sings" are given in terms of the reference of the words involved (cf. REFERENCE, THEORIES OF). Thus "Pavarotti sings" is true (in a certain moment t) if Pavarotti is in fact the agent of an action of singing (at t). Truth conditions of complex sentences (like "Pavarotti sings or Domingo sings") involve figuring out the contributions to truth conditions of words like "or." According to this program, giving the semantics of the logical form of natural language sentences is closely related to the way we figure out the semantics of any logical system.

Entailment, though not the only kind of important semantic relation, is certainly at the heart of a net of key phenomena. Consider for example the following pair:

(25) a. At least two students who read a book on linguistics by Chomsky were in the audience.
   b. At least two students who read a book by Chomsky were in the audience.

Clearly, (25a) entails (25b). It cannot be the case that (25a) is true while simultaneously (25b) is false. We simply know this a priori. And it is perfectly general: if "at least two As B" is the case and if the Cs form a superset of the As (as the books by Chomsky are a superset of the books on linguistics by Chomsky), then "at least two Cs B" must also be the case. This must be part of what "at least two" means. For "at most two" the opposite is the case:

(26) a. At most two students who read a book on linguistics by Chomsky were in the audience.
   b. At most two students who read a book by Chomsky were in the audience.

Here, (26a) does not entail (26b). It can well be the case that no more than two students read a book on linguistics by Chomsky, but more than two read books (on, say, politics) by Chomsky. What happens is that (26b) entails (26a). That is, if (26b) is the case, then (26a) cannot be false. Now there must be something in our head that enables us to converge on these judgments. That something must be constitutive of our knowledge of the meaning of the sentences in (25) and (26). Notice that our entailment judgment need not be immediate. To see that in fact (26b) entails (26a) requires some reflection. Yet any normal speaker of English will eventually converge in judging that in any situation in which (26b) is true, (26a) has also got to be.

The relevance of entailment for natural language is one of the main discoveries of modern semantics. I will illustrate it in what follows with one famous example, having to do with the distributional properties of words like "any" (cf. Ladusaw 1979, 1992 and references therein). A word like "any" has two main uses. The first is exemplified in (27a):

(27) a. You may pick any apple.
   b. A: Can I talk to John or is he busy with students now?
   c. B: No, wait. *He is talking to any student.
   c'. B: No, wait. He is talking to every student.
   c". B: Go ahead. He isn't talking to any student right now.

The use exemplified by (27a) is called free choice "any." It has a universal interpretation: sentence (27a) says that for every apple x, you are allowed to pick x. This kind of "any" seems to require a special modality of some kind (see e.g., Dayal 1998 and references therein). Such a requirement is brought out by the strangeness of sentences like (27c) (the asterisk indicates deviance), which, in the context of (27b), clearly describes an ongoing happening with no special modality attached. Free choice "any" seems incompatible with a plain descriptive mode (and contrasts in this with "every;" cf. [27c']). The other use of "any" is illustrated by (27c"). Even though this sentence, understood as a reply to (27b), reports on an ongoing happening, it is perfectly grammatical. What seems to play a crucial role is the presence of negation. Nonfree choice "any" seems to require a negative context of some kind and is therefore called a *negative polarity item*. It is part of a family of expressions that includes,

for example, things like "ever" or "give a damn":

(28) a. *John gives a damn about linguistics.
     b.   John doesn't give a damn about linguistics.
     c. *For a long time John ever ate chicken.
     d.   For a long time, John didn't ever eat chicken.

In English the free choice and the negative polarity senses of "any" are expressed by the same morphemes. But in many languages (e.g., most Romance languages) they are expressed by different words (for example, in Italian free choice "any" translates as "*qualunque,*" and negative polarity "any" translates as "*alcuno*"). Thus, while the two senses might well be related, it is useful to keep them apart in investigating the behavior of "any." In what follows, we will concentrate on negative polarity "any" (and thus the reader is asked to abstract away from imagining the following examples in contexts that would make the free choice interpretation possible).

    The main puzzle in the behavior of words like "any" is understanding what exactly constitutes a "negative" context. Consider for example the following set of sentences:

(29) a. *Yesterday John read any book.
     b.   Yesterday John didn't read any book.
     c. *A student who read any book by Chomsky will want to miss his talk.
     d.   No student who read any book by Chomsky will want to miss his talk.

In cases such as these, we can rely on morphology: we actually see there the negative morpheme "no" or some of its morphological derivatives. But what about the following cases?

(30) a. *At least two students who read any book by Chomsky were in the audience.
     b.   At most two students who read any book by Chomsky were in the audience.

In (30b), where "any" is acceptable, there is no negative morpheme or morphological derivative thereof. This might prompt us to look for a different way of defining the notion of negative context, maybe a semantic one. Here is a possibility: A logical property of negation is that of licensing entailments from sets to their subsets. Consider for example the days in which John read a book by Chomsky. They must be subsets of the days in which he read. This is reflected in the fact that (31a) entails (31b):

(31) a. It is not the case that yesterday John read a book.
     b. It is not the case that yesterday John read a book by Chomsky.

In (30) the entailment goes from a set (the set of days in which John read book) to its subsets (e.g., the set of days in which John read a book by Chomsky). Now this seems to be precisely what sentential negation, negative determiners like "no" and determiners like "at most n" have in common: they all license inferences from sets to subsets thereof. We have already seen that "at most" has precisely this property. To test whether our hypothesis is indeed correct and fully general, we should find something seemingly utterly "non-negative," which, however, has the property of licensing entailments from sets to subsets. The determiner "every" gives us what we need. Such a determiner does not appear to be in any reasonable sense "negative," yet, within a noun phrase headed by "every," the entailment clearly goes from sets to subsets:

(32) a. Every employee who smokes will be terminated.
     b. Every employee who smokes cigars will be terminated.

If (32a) is true, then (32b) must also be. And the set of cigar smokers is clearly a subset of the set of smokers. If "any" wants to be in an environment with these entailment properties, then it should be grammatical within an NP headed by "every." This is indeed so:

(33) Every student who read any book by Chomsky will want to come to his talk.

So the principle governing the distribution of "any" seems to be:

(34) "any" must occur in a context that licenses entailments from sets to their subsets.

Notice that within the VP in sentences like (32), the entailment to subsets does not hold.

(35) a. Every employee smokes.
     b. Every employee smokes cigars.

Sentence (35a) does not entail sentence (35b); in fact the opposite is the case. And sure enough, within the VP "any" is not licensed (I give also a sentence with "at most n" for contrast):

(36) a. *Every student came to any talk by Chomsky.
     b. At most two students came to any talk by Chomsky.

Surely no one explicitly taught us these facts. No one taught us that "any" is acceptable within an NP headed by "every," but not within a VP of which an "every"-headed NP is subject. Yet we come to have convergent intuitions on these matters. Again, something in our mental endowment must be responsible for such judgments. What is peculiar to the case at hand is that the overt distribution of a class of morphemes like "any" appears to be sensitive to the entailment properties of their context. In particular, it appears to be sensitive to a specific logical property, that of licensing inferences from sets to subsets, which "no," "at most n" and "every" share with sentential negation. It is worth noting that most languages have negative polarity items and their properties tend to be the same as "any," with minimal variations (corresponding to degrees of "strength" of negativity). This illustrates how there are specific architectural features of grammar that cannot be accounted for without a semantic theory of entailment for natural language. And it is difficult to see how to build such a theory without resorting to a compositional assignment of truth conditions to syntactic structures (or something that enables to derive the same effects—cf. DYNAMIC SEMANTICS). The case of negative polarity is by no means isolated. Many other phenomena could be used to illustrate this point (e.g. FOCUS; TENSE AND ASPECT). But the illustration just given will have to suffice for our present purposes. It is an old idea that we understand each other because our language, in spite of its VAGUENESS, has a logic. Now this idea is no longer just an intriguing hypothesis. The question on the table is no more whether this is true. The question is what the exact syntactic and semantic properties of this logic are.

3   Language Use

Ultimately, the goal of a theory of language is to explain how language is used in concrete communicative situations. So far we have formulated the hypothesis that at the basis of linguistic behavior there is a competence constituted by blocks of rules or systems of principles, responsible for sound structure, morphological structure, and so on. Each block constitutes a major *module* of our linguistic competence, which can in turn be articulated into further submodules. These rule systems are then put to use by the speakers in speech acts. In doing so, the linguistic systems interact in complex ways with other aspects of our cognitive apparatus as well as with features of the environment. We now turn to a consideration of these dimensions.

Language in Context

The study of the interaction of grammar with the CONTEXT of use is called PRAGMATICS. Pragmatics looks at sentences within both the extralinguistic situation and the DISCOURSE of which it is part. For example, one aspect of pragmatics is the study of INDEXICALS AND DEMONSTRATIVES (like "I," "here," "now," etc.) whose meaning is fixed by the grammar but whose reference varies with the context. Another important area is the study of PRESUPPOSITION, that is, what is taken for granted in uttering a sentence. Consider the difference between (37a) and (37b):

(37) a. John ate the cake.
     b. It is John that ate the cake.

How do they differ? Sentence (37a) entails that someone ate a cake. Sentence (37b), instead, *takes it for granted* that someone did and asserts that that someone is John. Thus, there are grammatical constructs such as clefting, exemplified in (37b), that appear to be specially linked to presupposition. Just like we have systematic intuitions about entailments, we do about presuppositions and how they are passed from simple sentences to more complex ones.

Yet another aspect of pragmatics is the study of how we virtually always go beyond what is literally said. In ordinary conversational exchanges, one and the same sentence, for example, "the dog is outside," can acquire the *illocutionary force* of a command ("go get it"), of a request ("can you bring it in?"), of an insult ("you are a servant; do your duty"), or can assume all sort of metaphorical or ironical colorings, and so on, depending on what the situation is, what is known to the illocutionary agents, and so on. A breakthrough in the study of these phenomena is due to the work of P. GRICE. Grice put on solid grounds the commonsense distinction between literal meaning, that is, the interpretation we assign to sentences in virtue of rules of grammar and linguistic conventions, and what is conveyed or *implicated*, as Grice puts it, beyond the literal meaning. Grice developed a theory of IMPLICATURE based on the idea that in our use of grammar we are guided by certain general conversational norms to which we spontaneously tend to conform. Such norms instruct us to be cooperative, truthful, orderly, and relevant (cf. RELEVANCE AND RELEVANCE THEORY). These are norms that can be ignored or even flouted. By exploiting both the norms and their violations systematically, thanks to the interaction of literal meaning and mutually shared information present in the context, the speaker can put the hearer in the position of inferring his communicative intentions (i.e., what is implicated). Some aspects of pragmatics (e.g., the study of deixis or presupposition) appear to involve grammar-specific rule systems, others, such as implicature, more general cognitive abilities. All of them appear to be rule governed.

Language in Flux

Use of language is an important factor in language variation. Certain forms of variation tend to be a constant and relatively stable part of our behavior. We all master a number of registers and styles; often a plurality of grammatical norms are present in the same speakers, as in the case of bilinguals. Such coexisting norms affect one another in interesting ways (see CODESWITCHING). These phenomena, as well as pragmatically induced deviations from a given grammatical norm, can also result in actual changes in the prevailing grammar. Speakers' creative uses can bring innovations about that become part of grammar. On a larger scale, languages enter in contact through a variety of historical events and social dynamics, again resulting in changes. Some such changes come about in a relatively abrupt manner and involve simultaneously many aspects of grammar. A case often quoted in this connection is the great vowel shift which radically changed the vowel space of English toward the end of the Middle English period. The important point is that the dynamic of linguistic change seems to take place within the boundaries of Universal Grammar as charted through synchronic theory (cf. LINGUISTIC UNIVERSALS AND UNIVERSAL GRAMMAR). In fact, it was precisely the discovery of the regularity of change (e.g., Grimm's laws) that led to the discovery of linguistic structure.

A particularly interesting vantage point on linguistic change is provided by the study of CREOLES (Bickerton 1975, 1981). Unlike most languages that evolve from a common ancestor (sometimes a hypothesized protolanguage, as in the case of the Indoeuropean family), Creoles arise from communities of speakers that *do not* share a native language. A typical situation is that of slaves or workers brought together by a dominating group that develop an impoverished quasi-language (a *pidgin*) in order to communicate with one another. Such quasi-languages typically have a small vocabulary drawn from several sources (the language of the dominating group or the native

languages of the speakers), no fixed word order, no inflection. The process of creolization takes place when such a language starts having its own native speakers, that is, speakers born to the relevant groups that start using the quasi-language of their parents as a native language. What typically happens is that all of a sudden the characteristics of a full-blown natural language come into being (morphological markers for agreement, case endings, modals, tense, grammaticized strategies for focusing, etc.). This process, which in a few lucky cases has been documented, takes place very rapidly, perhaps even within a single generation. This has led Bickerton to formulate an extremely interesting hypothesis, that of a "bioprogram," that is, a species-specific acquisition device, part of our genetic endowment, that supplies the necessary grammatical apparatus even when such an apparatus is not present in the input. This raises the question of how such a bioprogram has evolved in our species, a topic that has been at the center of much speculation (see EVOLUTION OF LANGUAGE). A much debated issue is the extent to which language has evolved through natural selection, in the ways complex organs like the eye have. Although not much is yet known or agreed upon on this score, progress in the understanding of our cognitive abilities and of the neurological basis of language is constant and is likely to lead to a better understanding of language evolution (also through comparisons of the communication systems of other species; see ANIMAL COMMUNICATION; PRIMATE LANGUAGE).

See also ANIMAL COMMUNICATION; CODESWITCHING; CREOLES; EVOLUTION OF LANGUAGE; LINGUISTIC UNIVERSALS AND UNIVERSAL GRAMMAR; PRIMATE LANGUAGE

Language in the Mind

The cognitive turn in linguistics has brought together in a particularly fruitful manner the study of grammar with the study of the psychological processes at its basis on the one hand and the study of other forms of cognition on the other. PSYCHOLINGUISTICS deals with how language is acquired (cf. LANGUAGE ACQUISITION) and processed in its everyday uses (cf. NATURAL LANGUAGE PROCESSING; SENTENCE PROCESSING). It also deals with language pathology, such as APHASIA and various kinds of developmental impairments (see LANGUAGE IMPAIRMENT, DEVELOPMENTAL).

With regard to acquisition, the available evidence points consistently in one direction. The kind of implicit knowledge at the basis of our linguistic behavior appears to be fairly specialized. Among all the possible ways to communicate and all the possible structures that a system of signs can have, those that are actualized in the languages of the world appear to be fairly specific. Languages exploit only some of the logically conceivable (and humanly possible) sound patterns, morphological markings, and syntactic and semantic devices. Here we could give just a taste of how remarkable the properties of natural languages are. And it is not obvious how such properties, so peculiar among possible semiotic systems, can be accounted for in terms of, say, pragmatic effectiveness or social conventions or cultural inventiveness (cf. SEMIOTICS AND COGNITION). In spite of this, the child masters the structures of her language without apparent effort or explicit training, and on the basis of an often very limited and impoverished input. This is clamorously so in the case of creolization, but it applies to a significant degree also to "normal" learning. An extensive literature documents this claim in all the relevant domains (see WORD MEANING, ACQUISITION OF; PHONOLOGY, ACQUISITION OF; SYNTAX, ACQUISITION OF; SEMANTICS, ACQUISITION OF). It appears that language "grows into the child," to put it in Chomsky's terms; or that the child "invents" it, to put it in Pinker's words. These considerations could not but set the debate on NATIVISM on a new and exciting standing. At the center of intense investigations there is the hypothesis that a specialized form of knowledge, Universal Grammar, is part of the genetic endowment of our species, and thus constitutes the initial state for the language learner. The key to learning, then, consists in fixing what Universal Grammar leaves open (see PARAMETER SETTING APPROACHES TO ACQUISITION, CREOLIZATION AND DIACHRONY). On the one hand, this involves setting the parameters of variation, the "switches" made available by Universal Grammar. On the other hand, it also involves exploiting, for various purposes such as segmenting the

stream of sound into words, generalized statistical abilities that we also seem to have (see Saffran, Aslin, and Newport 1996). The interesting problem is determining what device we use in what domain of LEARNING. The empirical investigation of child language proceeds in interaction with the study of the formal conditions under which acquisition is possible, which has also proven to be a useful tool in investigating these issues (cf. ACQUISITION, FORMAL THEORIES OF).

Turning now to processing, planning a sentence, building it up, and uttering it requires a remarkable amount of cognitive work (see LANGUAGE PRODUCTION). The same applies to going from the continuous stream of speech sounds (or, in the case of sign languages, gestures) to syntactic structure and from there to meaning (cf. PROSODY AND INTONATION, PROCESSING ISSUES; SPEECH PERCEPTION; SPOKEN WORD RECOGNITION; VISUAL WORD RECOGNITION). The measure of the difficulty of this task can in part be seen by how partial our progress is in programming machines to accomplish related tasks such as going from sounds to written words, or to analyze an actual text, even on a limited scale (cf. COMPUTATIONAL LINGUISTICS; COMPUTATIONAL LEXICONS). The actual use of sentences in an integrated discourse is an extremely complex set of phenomena. Although we are far from understanding it completely, significant discoveries have been made in the last decades, also thanks to the advances in linguistic theory. I will illustrate it with one well known issue in sentence processing.

As is well known, the recursive character of natural language syntax enables us to construct sentences of indefinite length and complexity:

(38) a. The boy saw the dog.
     b. The boy saw the dog that bit the cat.
     c. The boy saw the dog that bit the cat that ate the mouse.
     d. The boy saw the dog that bit the cat that ate the mouse that stole the cheese.

In sentence (38b), the object is modified by a relative clause. In (38c) the object of the first relative clause is modified by another relative clause. And we can keep doing that. The results are not particularly hard to process. Now, subjects can also be modified by relative clauses:

(39) The boy that the teacher called on saw the dog.

But try now modifying the subject of the relative clause. Here is what we get:

(40) The boy that the teacher that the principal hates called on saw the dog.

Sentence (40) is hard to grasp. It is formed through the same grammatical devices we used in building (39). Yet the decrease in intelligibility from (39) to (40) is quite dramatic. Only after taking the time to look at it carefully can we see that (40) makes sense. Adding a further layer of modification in the most embedded relative clause in (40) would make it virtually impossible to process. So there is an asymmetry between adding modifiers to the right (in English, the recursive side) and adding it to the center of a clause (*center embedding*). The phenomenon is very general. What makes it particularly interesting is that the oddity, if it can be called such, of sentences like (40) does not seem to be due to the violation of any known grammatical constraint. It must be linked to how we parse sentences, that is, how we attach to them a syntactic analysis as a prerequisite to semantic interpretation. Many theories of sentence processing address this issue in interesting ways. The phenomenon of center embedding illustrates well how related but autonomous devices (in this case, the design of grammar vis a vis the architecture of the parser) interact in determining our behavior.

4   Concluding Remarks

Language is important for many fairly obvious and widely known reasons. It can be put to an enormous range of uses; it is the main tool through which our thought gets expressed and our modes of reasoning become manifest. Its pathologies reveal important aspects of the functioning of the brain (cf. LANGUAGE, NEURAL BASIS OF); its use in HUMAN-COMPUTER INTERACTION is ever more a necessity (cf. SPEECH RECOGNITION IN MACHINES; SPEECH SYNTHESIS). These are all well established motivations for studying it. Yet, one of the most interesting things about language is in a way independent of them. What makes the study of language particularly exciting is the identification of regularities and the discovery of the laws that determine them. Often unexpectedly, we detect in our behavior, in our linguistic judgments or through experimentation, a pattern, a regularity. Typically, such regularities present themselves as intricate, they concern exotic data that are hidden in remote corners of our linguistic practice. Why do we have such solid intuitions about such exotic aspects of, say, the functioning of pronouns or the distribution of negative polarity items? How can we have acquired such intuitions? With luck, we discover that at the basis of these intricacies there are some relative simple (if fairly abstract) principles. Because speaking is a cognitive ability, whatever principles are responsible for the relevant pattern of behavior must be somehow implemented or realized in our head. Hence, they must grow in us, will be subject to pathologies, and so on. The cognitive turn in linguistics, through the advent of the generative paradigm, has not thrown away traditional linguistic inquiry. Linguists still collect and classify facts about the languages of the world, but in a new spirit (with arguably fairly old roots)—that of seeking out the mental mechanisms responsible for linguistic facts. Hypotheses on the nature of such mechanisms in turn lead to new empirical discoveries, make us see things we had previously missed, and so on through a new cycle. In full awareness of the limits of our current knowledge and of the disputes that cross the field, it seems impossible to deny that progress over the last 40 years has been quite remarkable. For one thing, we just know more facts (facts not documented in traditional grammars) about more languages. For another thing, the degree of theoretical sophistication is high, I believe higher than it ever was. Not only for the degree of formalization (which, in a field traditionally so prone to bad philosophizing, has its importance), but mainly for the interesting ways in which arrays of complex properties get reduced to ultimately simple axioms. Finally, the cross-disciplinary interaction on language is also a measure of the level the field is at. Abstract modeling of linguistic structure leads quite directly to psychological experimentation and to neurophysiological study and vice versa (see, e.g., GRAMMAR, NEURAL BASIS OF; LEXICON, NEURAL BASIS OF; BILINGUALISM AND THE BRAIN). As Chomsky puts it, language appears to be the first form of higher cognitive capacity that is beginning to yield. We have barely begun to reap the fruits of this fact for the study of cognition in general.

Culture, Cognition, and Evolution

Dan Sperber and Lawrence Hirschfeld

Most work in the cognitive sciences focuses on the manner in which an individual device—be it a mind, a brain, or a computer—processes various kinds of information. Cognitive psychology in particular is primarily concerned with individual thought and behavior. Individuals however belong to populations. This is true in two quite different senses. Individual organisms are members of species and share a genome and most phenotypic traits with the other members of the same species. Organisms essentially have the cognitive capacities characteristic of their species, with relatively superficial individual variations. In social species, individuals are also members of groups. An important part of their cognitive activity is directed toward other members of the group with whom they cooperate and compete. Among humans in particular, social life is richly cultural. Sociality and culture are made possible by cognitive capacities, contribute to the ontogenetic and phylogenetic development of these capacities, and provide specific inputs to cognitive processes.

Although population-level phenomena influence the development and implementation of cognition at the individual level, relevant research on these phenomena has not been systematically integrated within the cognitive sciences. In good part, this is due to the fact that these issues are approached by scholars from a wide range of disciplines, working within quite different research traditions. To the extent that researchers rely on methodological and theoretical practices that are sometimes difficult to harmonize (e.g., controlled laboratory versus naturalistic observations), the influence of these insights across disciplines and traditions of research is often unduly limited, even on scholars working on similar problems. Moreover, one of the basic notions that should bring together these researchers, the very notion of culture, is developed in radically different ways, and is, if anything, a source of profound disagreements.

The whole area reviewed in this chapter is fraught with polemics and misunderstandings. No one can claim an ecumenical point of view or even a thorough competence. We try to be fair to the many traditions of research we consider and to highlight those that seem to us most important or promising. We are very aware of the fact that the whole area could be reviewed no less fairly but from a different vantage point, yielding a significantly different picture. We hope, at least, to give some sense of the relevance of the issues, of the difficulty involved in studying them, and of the creativity of scholars who have attempted to do so.

To better appreciate the combined importance of work on population-level phenomena, we sort relevant research into three categories:

1. Cognition in a comparative and evolutionary perspective
2. Culture in an evolutionary and cognitive perspective
3. Cognition in an ecological, social, and cultural perspective

1   Cognition in a Comparative and Evolutionary Perspective

Humans spontaneously attribute to nonhuman animals mental states similar to their own, such as desires and beliefs. Nevertheless, it has been commonplace, grounded in Western religion and philosophy, to think of humans as radically different from other species, and as being unique in having a true mind and soul. Charles Darwin's theory of EVOLUTION based on natural selection challenged this classical dichotomy between "man and beast." In the controversies that erupted, anecdotal examples of animal intelligence were used by DARWIN and his followers to question the discontinuity between humans and other species. Since that time, the study of animal behavior has been pursued by zoologists working on specific species and using more and more rigorous methods of observation. However, until recently, and with some notable exceptions

such as the pioneering work of Wolfgang Köhler on chimpanzees (see GESTALT PSY-CHOLOGY), zoological observation had little impact on psychology.

Psychologists too were influenced by Darwin and espoused, in an even more radical form, the idea that fundamentally there is no difference between the psychology of humans and that of other animals. Drawing in particular on the work of Edward Thorndike and Ivan Pavlov on CONDITIONING, behaviorists developed the view that a single set of laws govern LEARNING in all animals. Whereas naturalists insisted that animal psychology was richer and more human-like than was generally recognized, behaviorist psychologists insisted that human psychology was poorer and much more animal-like than we would like to believe. In this perspective, the psychology of cats, rats, and pigeons was worth studying in order, not to understand better these individual species, but to discover universal psychological laws that apply to humans as well, in particular laws of learning. COMPARATIVE PSYCHOLOGY developed in this behavioristic tradition. It made significant contributions to the methodology of the experimental study of animal behavior, but it has come under heavy criticism for its neglect of what is now called ECOLOGICAL VALIDITY and for its narrow focus on quantitative rather than qualitative differences in performance across species. This lack of interest in natural ecologies or species-specific psychological adaptations, in fact, is profoundly anti-Darwinian.

For behaviorists, behavior is very much under the control of forces acting on the organism from without, such as external stimulations, as opposed to internal forces such as instincts. After 1940, biologically inspired students of animal behavior, under the influence of Konrad Lorenz, Karl von Frisch, and Niko Tinbergen, and under the label of ETHOLOGY, drew attention to the importance of instincts and species-specific "fixed action patterns." In the ongoing debate on innate versus acquired components of behavior, they stressed the innate side in a way that stirred much controversy, especially when Lorenz, in his book *On Aggression* (1966), argued that humans have strong innate dispositions to aggressive behavior. More innovatively, ethologists made clear that instinct and learning are not to be thought of as antithetic forces: various learning processes (such as "imprinting" or birds' learning of songs) are guided by an instinct to seek specific information in order to develop specific competencies.

By stressing the importance of species-specific psychological mechanisms, ethologists have shown every species (not just humans) to be, to some interesting extent, psychologically unique. This does not address the commonsense and philosophical interest (linked to the issue of the rights of animals) in the commonalties between human and other animals' psyche. Do other animals think? How intelligent are they? Do they have conscious experiences? Under the influence of Donald Griffin, researchers in COGNITIVE ETHOLOGY have tried to answer these questions (typically in the positive) by studying animals, preferably in their natural environment, through observation complemented by experimentation. This has meant accepting some of what more laboratory-oriented psychologists disparagingly call "anecdotal evidence" and has led to methodological controversies.

Work on PRIMATE COGNITION has been of special importance for obvious reasons: nonhuman primates are humans' closest relatives. The search for similarities between humans and other animals begins, quite appropriately, with apes and monkeys. Moreover, because these similarities are then linked to close phylogenetic relationships, they help situate human cognition in its evolutionary context. This phylogenetic approach has been popularized in works such as Desmond Morris's *The Naked Ape*. There have been more scientifically important efforts to link work on apes and on humans. For instance, the study of naïve psychology in humans owes its label, THEORY OF MIND, and part of its inspiration to Premack and Woodruff's famous article "Does the chimpanzee have a theory of mind?" (1978). As the long history of the study of apes' linguistic capacities illustrate, however, excessive focalization on continuities with the human case can, in the end, be counterproductive (see PRIMATE LANGUAGE). Primate psychology is rich and complex, and highly interesting in its own right.

Different species rely to different degrees and in diverse ways on their psychological capacities. Some types of behavior provide immediate evidence of highly special-

ized cognitive and motor abilities. ECHOLOCATION found in bats and in marine mammals is a striking example. A whole range of other examples of behavior based on specialized abilities is provided by various forms of ANIMAL COMMUNICATION. Communicating animals use a great variety of behaviors (e.g., vocal sounds, electric discharges, "dances," facial expressions) that rely on diverse sensory modalities, as signals conveying some informational content. These signals can be used altruistically to inform, or selfishly to manipulate. Emitting, receiving, and interpreting these signals rely on species-specific abilities. Only in the human case has it been suggested— in keeping with the notion of a radical dichotomy between humans and other animals—that the species' general intelligence provides all the cognitive capacities needed for verbal communication. This view of human linguistic competence has been strongly challenged, under the influence of Noam Chomsky, by modern approaches to LANGUAGE ACQUISITION.

Important aspects of animal psychology are manifested in social behavior. In many mammals and birds, for instance, animals recognize one another individually and have different types of interactions with different members of their group. These relationships are determined not only by the memory of past interactions, but also by kinship relations and hierarchical relationships within the group (see DOMINANCE IN ANIMAL SOCIAL GROUPS). All this presupposes the ability to discriminate individuals and, more abstractly, types of social relationships. In the case of primates, it has been hypothesized that their sophisticated cognitive processes are adaptations to their social rather than their natural environment. The MACHIAVELLIAN INTELLIGENCE HYPOTHESIS, so christened by Richard Byrne and Andrew Whiten (1988), offers an explanation not only of primate intelligence, but also of their ability to enter into strategic interactions with one another, an ability hyperdeveloped in humans, of course.

Many social abilities have fairly obvious functions and it is unsurprising, from a Darwinian point of view, that they should have evolved. (The adaptive value of SOCIAL PLAY BEHAVIOR is less evident and has given rise to interesting debates.) On the other hand, explaining the very existence of social life presents a major challenge to Darwinian theorizing, a challenge that has been at the center of important recent developments in evolutionary theory and in the relationship between the biological, the psychological, and the social sciences.

Social life implies COOPERATION AND COMPETITION. Competition among organisms plays a central role in classical Darwinism, and is therefore not at all puzzling; but the very existence of cooperation is harder to accommodate in a Darwinian framework. Of course, cooperation can be advantageous to the cooperators. Once cooperation is established, however, it seems that it would invariably be even more advantageous for any would-be cooperator to "defect," be a "free-rider," and benefit from the cooperative behavior of others without incurring the cost of being cooperative itself (a problem known in GAME THEORY and RATIONAL CHOICE THEORY as the "prisoner's dilemma"). Given this, it is surprising that cooperative behavior should ever stabilize in the evolution of a population subject to natural selection.

The puzzle presented by the existence of various forms of cooperation or ALTRUISM in living species has been resolved by W. D. Hamilton's (1964) work on kin selection and R. Trivers's (1971) work on reciprocal altruism. A gene for altruism causing an individual to pay a cost, or even to sacrifice itself for the benefit of his kin may thereby increase the number of copies of this gene in the next generation, not through the descendents of the self-sacrificing individual (who may thereby lose its chance of reproducing at all), but through the descendents of the altruist's kin who are likely to carry the very same gene. Even between unrelated individuals, ongoing reciprocal behavior may not only be advantageous to both, but, under some conditions, may be more advantageous than defecting. This may in particular be so if there are cheater-detection mechanisms that make cheating a costly choice. It is thus possible to predict, in some cases with remarkable precision, under which circumstances kin selection or reciprocal altruism are likely to evolve.

The study of such cases has been one of the achievements of SOCIOBIOLOGY. In general sociobiologists aim at explaining behavior, and in particular social behavior,

on the assumption that natural selection favors behaviors of an organism that tends to maximize the reproductive success of its genes. Sociobiology, especially as expounded in E. O. Wilson's book *Sociobiology: The New Synthesis* (1975) and in his *On Human Nature* (1978), has been the object of intense controversy. Although some social scientists have espoused a sociobiological approach, the majority have denounced the extension of sociobiological models to the study of human behavior as reductionist and naïve. Sociobiology has had less of an impact, whether positive or negative, on the cognitive sciences. This can probably be explained by the fact that sociobiologists relate behavior directly to biological fitness and are not primarily concerned with the psychological mechanisms that govern behavior.

It is through the development of EVOLUTIONARY PSYCHOLOGY that, in recent years, evolutionary theory has had an important impact on cognitive psychology (Barkow, Cosmides, and Tooby 1992). Unlike sociobiology, evolutionary psychology focuses on what Cosmides and Tooby (1987) have described as the "missing link" (missing, that is, from sociobiological accounts) between genes and behavior, namely the mind. Evolutionary psychologists view the mind as an organized set of mental devices, each having evolved as an adaptation to some specific challenge presented by the ancestral environment. There is, however, some confusion of labels, with some sociobiologists now claiming evolutionary psychology as a subdiscipline or even describing themselves as evolutionary psychologists.

This perspective may help discover discrete mental mechanisms, the existence of which is predicted by evolutionary considerations and may help explain the structure and function of known mental mechanisms. As an example of the first type of contribution, the evolutionary psychology of SEXUAL ATTRACTION has produced strong evidence of the existence of a special purpose adaptation for assessing the attractiveness of potential mates that uses subtle cues such as facial symmetry and waist-to-hips ratio (Symons 1979; Buss 1994). As an example of the second type of contribution, Steven Pinker has argued in *The Language Instinct* (1994) that the language faculty is an evolved adaptation, many aspects of which are best explained in evolutionary terms. Both types of contribution have stirred intense controversies.

Evolutionary psychology has important implications for the study of culture, significantly different from those of sociobiology. Sociobiologists tend to assume that the behaviors of humans in cultural environments are adaptive. They seek therefore to demonstrate the adaptiveness of cultural patterns of behavior and see such demonstrations as explanations of these cultural patterns. Evolutionary psychologists, on the other hand, consider that evolved adaptations, though of course adaptive in the ancestral environment in which they evolved, need not be equally adaptive in a later cultural environment. Slowly evolving adaptations may have neutral or even maladaptive behavioral effects in a rapidly changing cultural environment.

For instance, the evolved disposition to automatically pay attention to sudden loud noises was of adaptive value in the ancestral environment where such noises were rare and very often a sign of danger. This disposition has become a source of distraction, annoyance, and even pathology in a modern urban environment where such noises are extremely common, but a reliable sign of danger only in specific circumstances, such as when crossing a street. This disposition to pay attention to sudden loud noises is also culturally exploited in a way that is unlikely to significantly affect biological fitness, as when gongs, bells, or hand-clapping are used as conventional signals, or when musicians derive special effect from percussion instruments. Such nonadaptive effects of evolved adaptations may be of great cultural significance.

2 Culture in an Evolutionary and Cognitive Perspective

There are many species of social animals. In some of these species, social groups may share and maintain behaviorally transmitted information over generations. Examples of this are songs specific to local populations of some bird species or nut-cracking techniques among West African chimpanzees. Such populations can be said to have a "culture," even if in a very rudimentary form. Among human ancestors, the archaeological record shows the existence of tools from which the existence of a rudimentary technical culture can be inferred, for some two million years (see TECHNOLOGY AND HUMAN EVOLUTION), but the existence of complex cultures with rich CULTURAL SYMBOLISM manifested through ritual and art is well evidenced only in the last 40,000 years. COGNITIVE ARCHAEOLOGY aims in particular at explaining this sudden explosion of culture and at relating it to its cognitive causes and effects.

The study of culture is of relevance to cognitive science for two major reasons. The first is that the very existence of culture, for an essential part, is both an effect and a manifestation of human cognitive abilities. The second reason is that the human societies of today culturally frame every aspect of human life, and, in particular, of cognitive activity. This is true of all societies studied by anthropologists, from New Guinea to Silicon Valley. Human cognition takes place in a social and cultural context. It uses tools provided by culture: words, concepts, beliefs, books, microscopes and computers. Moreover, a great deal of cognition is about social and cultural phenomena.

Thus two possible perspectives, a cognitive perspective on culture and a cultural perspective on cognition, are both legitimate and should be complementary. Too often, however, these two perspectives are adopted by scholars with different training, very different theoretical commitments, and therefore a limited willingness and ability to interact fruitfully. In this section, we engage the first, cognitive perspective on culture and in the next the second, cultural perspective on cognition, trying to highlight both the difficulties and opportunities for greater integration.

Let us first underscore two points of general agreement: the recognition of cultural variety, and that of "psychic unity." The existence of extraordinary cultural variety, well documented by historians and ethnographers, is universally acknowledged. The full extent of this variety is more contentious. For instance, although some would deny the very existence of interesting HUMAN UNIVERSALS in matters cultural, others have worked at documenting them in detail (Brown 1991). Until the early twentieth century, this cultural variation was often attributed to supposed biological variation among human populations. Coupled with the idea of progress, this yielded the view that, as biological endowment progressed, so did cultural endowment, and that some populations (typically Christian whites) were biologically and culturally superior. This view was never universally embraced. Adolf Bastian and Edward Tylor, two of the founders of anthropology in the nineteenth century, insisted on the "psychic unity" of humankind. FRANZ BOAS, one of the founders of American anthropology, in a resolute challenge to scientific racism, argued that human cultural variations are learned and not inherited. Today, with a few undistinguished exceptions, it is generally agreed among cognitive and social scientists that cultural variation is the effect, not of biological variation, but of a common biological, and more specifically cognitive endowment that, given different historical and ecological conditions, makes this variability possible.

No one doubts that the biologically evolved capacities of humans play a role in their social and cultural life. For instance, humans are omnivorous and, sure enough, their diet varies greatly, both within and across cultures. Or to take another example, humans have poorly developed skills for tree climbing, and, not surprisingly, few human communities are tree-dwelling. But what are the human *cognitive* capacities actually relevant to understanding cultural variability and other social phenomena, and in which manner are they relevant?

In the social sciences, it has long been a standard assumption that human learning abilities are general and can be applied in the same way to any empirical domain, and that reasoning abilities are equally general and can be brought to bear on any problem, whatever its content. The human mind, so conceived, is viewed as the basis for an

extra somatic adaptation—culture—that has fundamentally changed the relationship between humans and their environment. Culture permits humans to transcend physical and cognitive limitations through the development and use of acquired skills and artifacts. Thus, humans can fly, scale trees, echolocate, and perform advanced mathematical calculus despite the fact that humans are not equipped with wings, claws, natural sonars, or advanced calculus abilities. Cultural adaptations trump cognitive ones in the sense that cultural skills and artifacts can achieve outcomes unpredicted by human cognitive architecture.

Many social scientists have concluded from this that psychology is essentially irrelevant to the social sciences and to the study of culture in particular. It is, however, possible to think of the mind as a relatively homogeneous general-purpose intelligence, and still attribute to it some interesting role in the shaping of culture. For instance, Lucien Lévy-Bruhl assumed that there was a primitive mentality obeying specific intellectual laws and shaping religious and magical beliefs. BRONISLAW MALINOWSKI sought to explain such beliefs, and culture in general, as a response to biological and psychological needs. CLAUDE LÉVI-STRAUSS explicitly tried to explain culture in terms of the structure of the human mind. He developed the idea that simple cognitive dispositions such as a preference for hierarchical classifications or for binary oppositions played an important role in shaping complex social systems such as kinship and complex cultural representations such as myth.

Most research done under the label COGNITIVE ANTHROPOLOGY (reviewed in D'Andrade 1995) accepts the idea that the human mind applies the same categorization and inference procedures to all cognitive domains. Early work in this field concentrated on classification and drew its conceptual tools more from semantics and semiotics (see SEMIOTICS AND COGNITION) than from a cognitive psychology (which, at the time, was in its infancy). More recently, building on Shank and Abelson's idea of scripts, cognitive anthropologists have begun to propose that larger knowledge structures—"cultural schema" or "cultural models"—guide action and belief, in part by activating other related cultural SCHEMATA or models, and as a whole encapsulate tenets of cultural belief. Some of this work has drawn on recent work on FIGURATIVE LANGUAGE, in particular, on METAPHOR (Lakoff and Johnson 1980; Lakoff 1987; Lakoff and Turner 1989) and has focused on cultural models structured in metaphorical terms (see METAPHOR AND CULTURE).

In an extended analysis, Quinn (1987), for instance, identifies a number of interconnecting metaphors for marriage in contemporary North America: marriage is enduring, marriage is mutually beneficial, marriage is unknown at the outset, marriage is difficult, marriage is effortful, marriage is joint, marriage may succeed or fail, marriage is risky. These conjoined metaphors—which together constitute a cultural model—in turn contain within them assumptions derived from models of other everyday domains: the folk physics of difficult activities, the folk social psychology of voluntary relationships, the folk theory of probability, and the folk psychology of human needs. Through this embedding, cultural schema or models provide a continuity and coherency in a given culture's systems of belief. Schema- and model-based analyses are intended to bridge psychological representations and cultural representations. They also provide a basis for relating MOTIVATION AND CULTURE. Not surprisingly, CONNECTIONISM, seen as a way to model the mind without attributing to it much internal structure, is now popular in this tradition of cognitive anthropology (Strauss and Quinn 1998).

Still, it is possible to acknowledge that culture has made the human condition profoundly different from that of any other animal species, and yet to question the image of the human mind as a general-purpose learning and problem-solving device. It is possible also to acknowledge the richness and diversity of human culture and yet to doubt that the role of human-evolved cognitive capacities has been merely to enable the development of culture and possibly shape the form of cultural representations, without exerting any influence on their contents. It is possible, in other terms, to reconcile the social sciences' awareness of the importance of culture with the cognitive sciences' growing awareness of the biological grounded complexity of the human mind.

For example, cognitive scientists have increasingly challenged the image of the human mind as essentially a general intelligence. Arguments and evidence from evolutionary theory, developmental psychology, linguistics, and one approach in cognitive anthropology render plausible a different picture. It is being argued that many human cognitive abilities are not domain-general but specialized to handle specific tasks or domains. This approach (described either under the rubric of MODULARITY or DOMAIN SPECIFICITY) seeks to investigate the nature and scope of these specific abilities, their evolutionary origin, their role in cognitive development, and their effect on culture.

The most important domain-specific abilities are evolved adaptations and are at work in every culture, though often with different effects. Some other domain-specific abilities are cases of socially developed, painstakingly acquired EXPERTISE, such as chess (see CHESS, PSYCHOLOGY OF), that is specific to some cultures. The relationship between evolved adaptations and acquired expertise has not been much studied but is of great interest, in particular for the articulation of the cognitive and the cultural perspective. For instance, writing—which is so important to cognitive and cultural development (see WRITING SYSTEMS and LITERACY)—is a form of expertise, although it has become so common that we may not immediately think of it as such. It would be of the utmost interest to find out to what extent this expertise is grounded in specific psychomotor evolved adaptations.

The first domain-specific mechanisms to be acknowledged in the cognitive literature were input modules and submodules (see Fodor 1982). Typical examples are linked to specific perceptual modality. They include devices that detect edges, surfaces, and whole objects in processing visual information; face recognition devices; and speech parsing devices; abilities to link specific outcomes (such as nausea and vomiting but not electric shock) to specific stimuli (such as eating but not light) through rapid, often single trial, learning.

More recently, there has been a growing body of evidence suggesting that central (i.e., conceptual) mechanisms, as well as input-output processes, may be domain-specific. It has been argued, for instance, that the ability to interpret human action in terms of beliefs and desires is governed by a naive psychology, a domain-specific ability, often referred to as THEORY OF MIND; that the capacity to partition and explain living things in terms of biological principles like growth, inheritance, and bodily function is similarly governed by a FOLK BIOLOGY; and that the capacity to form consistent predictions about the integrity and movements of inert objects is governed by a NAIVE PHYSICS. These devices are described as providing the basis for competencies that children use to think about complex phenomena in a coherent manner using abstract causal principles. Cultural competencies in these domains are seen as grounded in these genetically determined domain-specific dispositions, though they may involve some degree of CONCEPTUAL CHANGE.

The study of folk biology provides a good example of how different views of the mind yield different accounts of cultural knowledge. A great deal of work in classical cognitive anthropology has been devoted to the study of folk classification of plants and animals (Berlin, Breedlove, and Raven 1973; Berlin 1992; Ellen 1993). This work assumed that the difference in organization between these biological classifications and classifications of say, artifacts or kinship relations had to do with differences in the objects classified and that otherwise the mind approached these domains in exactly the same way. Scott Atran's (1990) cognitive anthropological work, drawing on developmental work such as that of Keil (1979), developed the view that folkbiological knowledge was based on a domain-specific approach to living things characterized by specific patterns of CATEGORIZATION and inference. This yields testable predictions regarding both the acquisition pattern and the cultural variability of folk biology. It predicts, for instance, that from the start (rather than through a lengthy learning process) children will classify animals and artifacts in quite different ways, will reason about them quite differently, and will do so in similar ways across cultures. Many of these predictions seem to be borne out (see Medin and Atran 1999).

Generally, each domain-specific competence represents a knowledge structure that identifies and interprets a class of phenomena assumed to share certain properties and

hence be of a distinct and general type. Each such knowledge structure provides the basis for a stable response to a set of recurring and complex cognitive or practical challenges. These responses involve largely unconscious dedicated perceptual, retrieval, and inferential processes. Evolutionary psychology interprets these domain-specific competencies as evolved adaptations to specific problems faced by our ancestral populations.

At first, there might seem to be a tension between the recognition of these evolved domain-specific competencies and the recognition of cultural variety. Genetically determined adaptations seem to imply a level of rigidity in cognitive performance that is contradicted by the extraordinary diversity of human achievements. In some domain, a relative degree of rigidity may exist. For example, the spontaneous expectations of not only infants but also adults about the unity, boundaries, and persistence of physical objects may be based on a rather rigid naïve physics. It is highly probable that these expectations vary little across populations, although at present hardly any research speaks to this possibility, which thus remains an open empirical question. After all, evidence does exist suggesting that other nonconscious perceptual processes, such as susceptibility to visual illusions, do vary across populations (Herskovits, Campbell, and Segall 1969).

Generally, however, it is a mistake to equate domain-specificity and rigidity. A genetically determined cognitive disposition may express itself in different ways (or not express itself at all) depending on the environmental conditions. For instance, even in a case such as fear of snakes and other predators, where a convincing argument can be made for the existence, in many species, of evolved mechanisms that trigger an appropriate self-protection response, the danger cues and the fear are not necessarily directly linked. Marks and Nesse (1994: 255), following Mineka et al. (1984), describe such a case in which fear does not emerge instinctively but only after a specific sort of learning experience: "Rhesus monkeys are born without snake fear. Enduring fear develops after a few observations of another rhesus monkey taking fright at a snake . . . Likewise, a fawn is not born with fear of a wolf, but lifelong panic is conditioned by seeing its mother flee just once from a wolf."

Thus, even low-level effects like primordial fears develop out of interactions between prepotentials for discriminating certain environmental conditions, a preparedness to fast learning, and actual environmental inputs. In general, domain-specific competencies emerge only after the competence's initial state comes into contact with a specific environment, and, in some cases, with displays of the competence by older conspecifics. As the environmental inputs vary so does the outcome (within certain limits, of course). This is obviously the case with higher-level conceptual dispositions: It goes without saying, for instance, that even if there is a domain-specific disposition to classify animals in the same way, local faunas differ, and so does people's involvement with this fauna.

There is another and deeper reason why domain-specific abilities are not just compatible with cultural diversity, but may even contribute to explaining it (see Sperber 1996: chap. 6). A domain-specific competence processes information that meets specific input conditions. Normally, these input conditions are satisfied by information belonging to the proper domain of the competence. For instance, the face recognition mechanism accepts as inputs visual patterns that in a natural environment are almost exclusively produced by actual faces. Humans, however, are not just receivers of information, they are also massive producers of information that they use (or seek to use) to influence one another in many ways, and for many different purposes. *A reliable way to get the attention of others is to produce information that meets the input conditions of their domain-specific competencies*. For instance, in a human cultural environment, the face recognition mechanism is stimulated not just by natural faces, but also by pictures of faces, by masks, and by actual faces with their features highlighted or hidden by means of make-up. The effectiveness of these typically cultural artifacts is in part to be explained by the fact that they rely on and exploit a natural disposition.

Although the natural inputs of a natural cognitive disposition may not vary greatly across environments, different cultures may produce widely different artificial inputs

that, nevertheless, meet the input conditions of the same natural competence. Hence not all societies have cosmetic make-up, pictures of faces, or masks, and those that do exhibit a remarkable level of diversity in these artifacts. But to explain the very existence of these artifacts and the range of their variability, it is important to understand that they all rely on the same natural mechanism. In the same way, the postulation of a domain-specific competence suggests the existence of a diversified range of possible exploitations of this competence. Of course these exploitations can also be enhancements: portraitists and make-up technicians contribute to culturally differentiated and enhanced capacities for face recognition (and aesthetic appraisal).

Let us give three more illustrations of the relationship between a domain-specific competence and a cultural domain: *color classification, mathematics, and social classifications*.

Different languages deploy different systems of COLOR CATEGORIZATION, segmenting the color spectrum in dramatically different ways. Some languages have only two basic color terms (e.g., Dani). Other languages (e.g., English) have a rich and varied color vocabulary with eleven basic color terms (and many nonbasic color terms that denote subcategories such as *crimson* or apply to specific objects such as *a bay horse*). Prior to Berlin and Kay's (1969) now classic study, these color naming differences were accepted as evidence for the LINGUISTIC RELATIVITY HYPOTHESIS, the doctrine that different modes of linguistic representation reflect different modes of thought. Thus, speakers of languages with two-term color vocabularies were seen as conceptualizing the world in this limited fashion.

Berlin and Kay found that although the boundaries of color terms vary across languages, the focal point of each color category (e.g., that point in the array of reds that is the reddest of red) remains the same no matter how the color spectrum is segmented linguistically. There are, they argued, eleven such focal points, and therefore eleven possible basic color terms. Although there are over two thousand possible subsets of these eleven terms, only twenty-two of these subsets are ever encountered. Moreover, the sequence in which color terms enter a language is tightly constrained. Further research has led to minor revisions but ample confirmation of these findings. Here, then, we have a case where the evolved ability to discriminate colors both grounds culturally specific basic color vocabularies and constrains their variability. Further work by Kay and Kempton (1988) showed that linguistic classification could have some marginal effect on nonverbal classification of color. Nevertheless, once the paradigm example of linguistic relativity, the case of color classification, is now the paradigm illustration of the interplay between cognitive universals and cultural variations, variations that are genuine, but much less dramatic than was once thought.

Naive mathematics provides another instance of the relationship between a domain-specific competence and cultural variation. It has been shown that human infants and some other animals can distinguish collections of objects according to the (small) number of elements in the collection. They also expect changes in the number of objects to occur in accordance with elementary arithmetic principles. All cultures of the world provide some system for counting (verbal and/or gestural), and people in all cultures are capable of performing some rudimentary addition or subtraction, even without the benefit of schooling. This suggests that humans are endowed with an evolved adaptation that can be called naive mathematics. Counting systems do vary from culture to culture. Some, like that of the Oksapmin of New Guinea, are extremely rudimentary, without base structure, and allow counting only up to some small number. Others are more sophisticated and allow, through combination of a few morphemes, the expression of any positive integer. These counting systems, drawing on the morpho-syntactic resources of language, provide powerful cultural tools for the use and enhancement of the naive mathematical ability. Cultural differences in counting largely reflect the degree of linguistic enhancement of this universal ability.

There are mathematical activities that go beyond this intuitive counting ability. Their development varies considerably and in different directions across cultures. Concepts such as the zero, negative numbers, rational numbers, and variables; techniques such as written arithmetical operations; and artifacts such as multiplication tables, abacus, rulers, or calculators help develop mathematics far beyond its intuitive

basis. Some of these concepts and tools are relatively easy to learn and use, others require painstaking study in an educational setting. From a cognitive point of view, explaining these cultural developments and differences must include, among other things, an account of the cognitive resources they mobilize. For instance, given human cognitive dispositions, mathematical ideas and skills that are more intuitive, more easily grasped, and readily accepted should have a wider and more stable distribution and a stronger impact on most people's thinking and practice (see NUMERACY AND CULTURE).

NAIVE SOCIOLOGY provides a third example of the relationship between a domain-specific cognitive disposition and a varying cultural domain. According to the standard view, children learn and think about all human groupings in much the same way: they overwhelmingly attend to surface differences in forming categories and they interpret these categories virtually only in terms of these superficial features. Of course, knowledge of all social categories is not acquired at the same time. Children sort people by gender before they sort them by political party affiliation. The standard explanation is that children learn to pick out social groups that are visibly distinct and culturally salient earlier than they learn about other, less visually marked, groups.

Recent research suggests that surface differences determine neither the development of categories nor their interpretation (Hirschfeld 1996). In North America and Europe one of the earliest-emerging social concepts is "race." Surprisingly, given the adult belief that the physical correlates of "race" are extremely attention demanding, the child's initial concept of "race" contains little perceptual information. Three-year-olds, for instance, recognize that "blacks" represent an important social grouping long before they learn which physical features are associated with being "black." What little visual information they have is often inaccurate and idiosyncratic; thus, when one young child was asked to describe what made a particular person black, he responded that his teeth were longer. (Ramsey 1987.) Another set of studies suggests that even quite young children possess a deep and theory-like understanding of "race" (but not other similar groupings), expecting "race" to be a fundamental, inherited, and immutable aspect of an individual—that is, they expect it to be biological (Hirschfeld 1995).

Conceptual development of this sort—in which specific concepts are acquired in a singular fashion and contain information far beyond what experience affords—are plausibly the output of a domain-specific disposition. Since the disappearance of the Neanderthals, humans are no longer divided into subspecies or races, and the very idea of "race" appeared only relatively recently in human history. So, although there may well exist an evolved domain-specific disposition that guides learning about social groupings, it is very unlikely that it would have evolved with the function of guiding learning about "race." As noted previously, however, many cultural artifacts meet a device's input conditions despite the fact that they did not figure in the evolutionary environment that gave rise to the device. "Race" might well be a case in point.

As many have argued, "race" was initially a cultural creation linked to colonial and other overseas encounters with peoples whose physical appearance was markedly different from Europeans. The modern concept of "race" has lost some of this historic specificity and is generally (mis)interpreted as a "natural" system for partitioning humans into distinct kinds. That this modern concept has stabilized and been sustained over time owes as much to cognitive as cultural factors (Hirschfeld 1996). On the one hand, it is sustainable because a domain-specific disposition guides children to spontaneously adopt specific social representations, and "race" satisfies the input conditions of this disposition. On the other hand, it varies across cultures because each cultural environment guides children to a specific range of possible groupings. These possibilities, in turn, reflect the specific historical contexts in which colonial and other overseas encounters occurred. It is worth bearing in mind that "race" is not the only cultural domain that is "naturalized" because it resonates with an evolved disposition. It is plausible that children in South Asia, guided by the same domain-specific disposition but in another cultural context, find "caste" more biological than "race." Similarly, children in some East-African societies may find "age-grades" more biological than

either "race" or "caste." In all such cases, the fact that certain social categories are more readily learned contributes to the social and cultural stability of these categories.

The cases of color classification, mathematics, and naïve sociology illustrate a fairly direct relationship between a domain-specific ability and a cultural domain grounded in this ability, enhancing it, and possibly biasing it. Not all cultural domains correspond in this simple way to a single underlying domain-specific competence. For instance, are RELIGIOUS IDEAS AND PRACTICES grounded in a distinct competence, the domain of which would be supernatural phenomena? This is difficult to accept from the point of view of a naturalistic cognitive science. Supernatural phenomena cannot be assumed to have been part of the environment in which human psychological adaptations evolved. Of course, it is conceivable that a disposition to form false or unevidenced beliefs of a certain tenor would be adaptive and might have evolved. Thus Malinowski and many other anthropologists have argued that religious beliefs serve a social function. Nemeroff and Rozin (1994) have argued that much of MAGIC AND SUPERSTITION is based on intuitive ideas of contagion that have clear adaptive value. Another possibility is that domain-specific competencies are extended beyond their domain, in virtue of similarity relationships. Thus, Carey (1985) and Inagaki and Hatano (1987) have argued that ANIMISM results from an overextension of naïve psychology.

The cultural prevalence of religious and magical beliefs may also be accounted for in terms of a domain-specific cognitive architecture without assuming that there is a domain-specific disposition to religious or magical beliefs (see Sperber 1975, 1996; Boyer 1990, 1994). Religious beliefs typically have a strong relationship with the principles of naïve physics, biology, psychology, and sociology. This relationship, however, is one of head-on contradiction. These are beliefs about creatures capable of being simultaneously in several places, of belonging to several species or of changing from one species to another, or of reading minds and seeing scenes distant in time or space. Apart from these striking departures from intuitive knowledge, however, the appearance and behavior of these supernatural beings is what intuition would expect of natural beings. Religious representations, as argued by Boyer (1994), are sustainable to the extent that a balance between counterintuitive and intuitive qualities is reached. A supernatural being with too few unexpected qualities is not attention demanding and thus not memorable. One with too many unexpected qualities is too information rich to be memorable (see MEMORY). Thus, religious beliefs can be seen as parasitical on domain-specific competencies that they both exploit and challenge.

So far in this section, we have illustrated how evolutionary and cognitive perspectives can contribute to our understanding of specific cultural phenomena. They can also contribute to our understanding of the very phenomenon of culture. Until recently, the evolutionary and the cognitive approaches to the characterization of culture were very different and unrelated. In more recent developments, they have converged to a significant degree.

From an evolutionary point of view, there are two processes to consider and articulate: the biological evolution of the human species, and the CULTURAL EVOLUTION of human groups. There is unquestionably a certain degree of coevolution between genes and culture (see Boyd and Richerson 1985; William Durham 1991). But, given the very different rates of biological and cultural evolution—the latter being much more rapid than the former—the importance of cultural evolution to biological evolution, or equivalently its autonomy, is hard to assess.

Sociobiologists (e.g., Lumsden and Wilson 1981) tend to see cultural evolution as being very closely controlled by biological evolution and cultural traits as being selected in virtue of their biological functionality. Other biologists such as Cavalli-Sforza and Feldman (1981) and Richard Dawkins (1976, 1982) have argued that cultural evolution is a truly autonomous evolutionary process where a form of Darwinian selection operates on cultural traits, favoring the traits that are more capable of generating replicas of themselves (whether or not they contribute to the reproductive success of their carriers). Neither of these evolutionary approaches gives much place to cognitive mechanisms, the existence of which is treated as a background condition for the more or less autonomous selection of cultural traits. Both evolutionary approaches

view culture as a pool of traits (mental representations, practices, or artifacts) present in a population.

From a cognitive point of view, it is tempting to think of culture as an ensemble of representations (classifications, schemas, models, competencies), the possession of which makes an individual a member of a cultural group. In early cognitive anthropology, culture was often compared to a language, with a copy of it in the mind of every culturally competent member of the group. Since then, it has been generally recognized that cultures are much less integrated than languages and tolerate a much greater degree of interindividual variation (see CULTURAL CONSENSUS THEORY and CULTURAL VARIATION). Moreover, with the recent insistence on the role of artifacts in cognitive processes (see COGNITIVE ARTIFACTS), it has become common to acknowledge the cultural character of these artifacts: culture is not just in the mind. Still, in a standard cognitive anthropological perspective, culture is first and foremost something in the mind of every individual. The fact that culture is a population-scale phenomenon is of course acknowledged, but plays only a trivial role in explanation.

Some recent work integrates the evolutionary and cognitive perspectives. Sperber (1985, 1996) has argued for an "epidemiological" approach to culture. According to this approach, cultural facts are not mental facts but distributions of causally linked mental and public facts in a human population. More specifically, chains of interaction—of communication in particular—may distribute similar mental representations and similar public productions (such as behaviors and artifacts) throughout a population. Types of mental representations and public productions that are stabilized through such causal chains are, in fact, what we recognize as cultural.

To help explain why some items stabilize and become cultural (when the vast majority of mental representations and public productions have no recognizable descendants), it is suggested that domain-specific evolved dispositions act as receptors and tend to fix specific kinds of contents. Many cultural representations stabilize because they resonate with domain-specific principles. Because such representations tend to be rapidly and solidly acquired, they are relatively inured to disruptions in the process of their transmission. Hence the epidemiological approach to culture dovetails with evolutionary psychology (see Tooby and Cosmides 1992) and with much recent work in developmental psychology, which has highlighted the role of innate preparedness and domain-specificity in learning (Hirschfeld and Gelman 1994; Sperber, Premack, and Premack 1995).

Children are not just the passive receptors of cultural forms. Given their cognitive dispositions, they spontaneously adopt certain cultural representations and accept others only through institutional support such as that provided by schools. The greater the dependence on institutional support, the greater the cultural lability and variability. Other inputs, children reject or transform. A compelling example is provided by the case of CREOLES. When colonial, commercial, and other forces bring populations together in linguistically unfamiliar contexts a common result is the emergence of a pidgin, a cobbled language of which no individual is a native speaker. Sometimes, children are raised in a pidgin. When pidgin utterances are the input of the language acquisition process, a creole, that is a natural and fully elaborated language, is the output. Children literally transform the contingent and incomplete cultural form into a noncontingent and fully articulated form. This happens because children are equipped with an evolved device for acquiring language (Bickerton 1990).

Cultural forms stabilize because they are attention-grabbing, memorable, and sustainable with respect to relevant domain-specific devices. Of course, representations are also selected for in virtue of being present in any particular cultural environment. Domain-specific devices cannot attend to, act on, or elaborate representations that the organism does not come into contact with. For the development of culture, a cultural environment, a product of human history, is as necessary as a cognitive equipment, a product of biological evolution.

3 Cognition in an Ecological, Social, and Cultural Perspective

Ordinary cognitive activity does not take place in a fixed experimental setting where the information available is strictly limited and controlled, but in a complex, information-rich, ever-changing environment. In social species, conspecifics occupy a salient place in this environment, and much of the individual-environment interaction is, in fact, interaction with other individuals. In the human case, moreover, the environment is densely furnished with cultural objects and events most of which have, at least in part, the function of producing cognitive effects.

In most experimental psychology this ecological, social, and cultural dimension of human cognition is bracketed out. This practice has drawn strong criticisms, both from differently oriented psychologists and from social scientists. Clearly, there are good grounds for these criticisms. How damning they are remains contentious. After all, all research programs, even the most holistic ones, cannot but idealize their objects by abstracting away from many dimensions of reality. In each case, the issue is whether the idealization highlights a genuinely automous level about which interesting generalizations can be discovered, or whether it merely creates an artificial pseudodomain the study of which does not effectively contribute to the knowledge of the real world. Be that as it may, in the debate between standard and more ecologically oriented approaches to cognition, there is no doubt that the latter have raised essential questions and developed a variety of interesting answers. It is to these positive contributions that we now turn.

Issues of ecological validity arise not just when the social and cultural dimension of cognition is deployed, but at all levels of cognition. As argued by ECOLOGICAL PSYCHOLOGY, even the perceptions of an individual organism should be understood in ecological terms. Based on the work of J. J. GIBSON, ecological psychology relates perception not to "stimuli" but to the layout of the environment, to the possibilities it opens for action (the AFFORDANCES), and to the perceiver's own situation and motion in the environment. When the environment considered is social and cultural, there are further grounds to rethink even more basic tenets of cognitive science, particularly the notion that the individual mind is *the* site of cognitive processes. This is what recent work on SITUATED COGNITION AND LEARNING and on SITUATEDNESS/EMBEDDEDNESS has been doing.

Many of the issues described today in terms of situated cognition were raised in the pioneering work of the Russian psychologist LEV VYGOTSKY (1896–1934), whose work was introduced to English readers in the 1970s (see Wertsch 1985b). Vygotsky saw cognitive activity as being social as well as mental. He stressed the importance of cultural tools for cognition. His insight that historical, cultural, and institutional contexts condition learning by identifying and extending the child's capacities animates several ecological approaches in psychology. Writing in the first half of the twentieth century, Vygotsky was not aiming at an explicit modeling of the processes he discussed, nor were the first studies inspired by his work in the 1970s and 1980s (see Wertsch 1985a). Some of the more recent work about situated cognition, though inspired by Vygotsky, does involve modeling of cognitive processes, which means, of course, departing from Vygotsky's original conceptual framework.

To what extent is cognition in a social and cultural environment still an individual process? Regarding cognition in a social environment, James Wertsch raises the issue with a telling anecdote about helping his daughter remember where she left her shoes. When she was unable to remember, he began to pose questions that directed her recall

until she "remembered" where they were. Wertsch asks who remembered in this case: he didn't since he had no prior information about the shoes' location, nor did his daughter because she was unable to recall their location without his intervention. Regarding cognition in an environment containing cultural artifacts, a striking example is provided by Edwin Hutchins (1995), who has demonstrated how the cognitive processes involved in flying a plane do not take place just in the pilot's head but are distributed throughout the cockpit, in the members of the crew, the control panel, and the manuals.

This interpenetration of processes internal and external to the individual can be studied in technologically rich environment such as that provided in HUMAN-COMPUTER INTERACTION, and also in more mundane circumstances such as finding one's way with the help of a map (see HUMAN NAVIGATION), or shopping at the supermarket where the arrangement of the shelves serves as a kind of shopping list (Lave et al. 1984). This type of research is being applied in COGNITIVE ERGONOMICS, which helps design technologies, organizations, and learning environments in a way informed by cognitive science.

The study of cultural tools and the form of cognitive activity they foster is of importance for the historical and anthropological study of culture. It is an old commonplace to contrast societies with and without writing systems. As Lévi-Strauss (1971) suggested, the very structure of oral narratives reflects an optimal form for memory unaided by external inscriptions. More recent work (e.g., Goody 1977, 1987; Rubin 1995; Bloch 1998) has attempted to elaborate and in part rethink this contrast by looking at the cognitive implications of orality and writing and of other systems for displaying information in the environment (see ARTIFACTS AND CIVILIZATION). EDUCATION too has been approached in a Vygotskyan perspective, as a collaborative enterprise between teacher and learner using a specially designed environment with ad hoc props. Education is thus described at a level intermediary between individual cognitive development and cultural transmission, thus linking and perhaps locking together the psychological and the cultural level (Bruner 1996).

From the point of view of the epidemiological approach to culture evoked in the preceding section, the situated cognition approach is quite congenial. The epidemiological approach insists on the fact that the causal chains of cultural distribution are complex cognitive *and* ecological processes that extend over time and across populations. This, however, dedramatizes the contrast between a more individualistic and a more situated description of cognitive processes (see INDIVIDUALISM). Consider a situated process such as a teacher-learner interaction, or the whole cockpit of a plane doing the piloting. These processes are not wholly autonomous. The teacher is a link in a wider process of transmission using a battery of artifacts, and the learner is likely to become a link, possibly of another kind, in the same process. Their interaction cannot be fully explained by abstracting away from this wider context. Similarly, the cockpit is far from being fully autonomous. It is linked to air control on the ground, through it to other aircrafts, but also, in time, to the engineering process that designed the plane, to the educational process that trained the pilot, and so on. Of course, both the teacher-learner interaction and the cockpit have enough autonomy to deserve being considered and studied on their own. But then so do the individual cognitive processes of the teacher, the learner, the pilot, and so on at a lower level, and the complex institutional networks in which all this take place at a higher level. Cognitive cultural causal chains extend indefinitely in all directions. Various sections of these chains of different size and structure are worth studying on their own.

The study of psychological processes in their social context is traditionally the province of *social psychology* (see Ross and Nisbett 1991; Gilbert, Fiske, and Lindzey 1998). The contribution of this rich discipline to the cognitive sciences can be read in two ways. On the one hand, it can be pointed out that, at a time where mainstream psychologists were behaviorists and not interested in contentful cognitive processes, social psychologists were studying beliefs, opinions, prejudices, influence, motivation, or attitudes (e.g., Allport 1954). On the other hand, it could be argued that the interest of social psychologists for these mental phenomena is generally quite different from that of cognitive scientists. The goals of social psychologists have typically been to identify

trends and their causal factors, rather than mechanisms and their parts, so that most of social psychology has never been "cognitive" in this strong sense. In the practice of standard cognitive psychology too, it is quite often the case that a trend, a tendency, a disposition is identified well before the underlying mechanisms are considered.

Many of the phenomena identified by social psychologists could be further investigated in a more standardly cognitive way, and, more and more often, they are. For instance, according Festinger's (1957) theory of cognitive DISSONANCE, people are emotionally averse to cognitive inconsistencies and seek to reduce them. Festinger investigated various ways in which such dissonances arise (in decision making or in forced compliance, for instance), and how they can be dealt with. Recently, computational models of dissonance have been developed using artificial neural networks and relating dissonance to other psychological phenomena such as analogical reasoning. ATTRIBUTION THEORY, inspired by Heider (1958) and Kelley (1972), investigates causal judgments (see CAUSAL REASONING), and in particular interpretations of people's behavior. Specific patterns have been identified, such as Ross's (1977) "fundamental attribution error" (i.e., the tendency to overestimate personality traits and underestimate the situation in the causing of behavior). As in the case of dissonance, there has been a growing interest for modeling the inferential processes involved in these attributions (e.g. Cheng and Novick 1992). STEREOTYPING of social categories, another typical topic of social psychology, is also approached in a more cognitive way by focusing on information processing and knowledge structures.

The domain of social psychology where the influence of cognitive science is the most manifest is that of SOCIAL COGNITION (Fiske and Taylor 1991), that is the cognition of social life, sometimes extended to cognition as shaped by social life. Social cognition so understood is the very subject matter of social psychology, or at least its central part (leaving out emotion), but the reference to *cognition*, rather than to psychology generally, signals the intent to join forces with mainstream cognitive psychology. With the development of the domain-specificity approach, however, social cognition so understood may be too broad an area. For instance, it does not distinguish between naïve psychology and naïve sociology, when the trend may be rather toward distinguishing even more fine-grained mechanisms.

One issue that has always been central to social psychology and that has become important in cognitive science only later is rationality. Social judgment exhibits blatant cases of irrationality, and their study by social psychologists (see Nisbett and Ross 1980) has contributed to the development of the study of reasoning in general (see JUDGMENT HEURISTICS; CAUSAL REASONING; PROBABILITIC REASONING; DEDUCTIVE REASONING). One area of social life where rationality plays a special role is economics. It is within economics that RATIONAL CHOICE THEORY was initially developed (see also RATIONAL DECISION MAKING). The actual behavior of economic agents, however, does not fully conform to the normative theory. Drawing in particular on the work of Kahneman and TVERSKY (see Kahneman, Slovic, and Tversky 1982), experimental and behavioral economists explore and try to model the actual behavior of economic agents (see ECONOMICS AND COGNITIVE SCIENCE). In principle, economics should provide a paradigmatic case of fruitful interaction between the social and the cognitive sciences. The economic domain is quite specific, however, and it is an open question to know to what extent the cognitive approach to this area, based as it is on an abstract normative theory of rationality, can serve as a model in other areas (but see Becker 1976).

From the points of view of evolutionary psychology and situated cognition, it is tempting to adopt an alternative approach by developing a notion of evolutionarily grounded BOUNDED RATIONALITY as a criterion for evaluating the manner in which human inferential mechanisms perform their functions. Such a criterion would involve not just considerations of epistemic reliability, but also of processing speed and cost. In this perspective, evolutionary psychologists have investigated how reasoning abilities may be adjusted to specific problems and domains, and how they may privilege information available in ordinary environments (see Cosmides and Tooby 1992; Gigerenzer and Goldstein 1996; Gigerenzer and Hoffrage 1995).

We now turn to anthropological research on the role of culture in cognitive and more generally mental processes. It is hardly controversial that cultural factors enable, constrain, and channel the development of certain cognitive outcomes. Some cultural environments inhibit normal cognitive development (e.g., inequitable distributions of cultural resources underlie uneven performance on standardized tests). Other cultural environments promote the elaboration of complex knowledge structures such as modern science by providing the appropriate artifactual and institutional support. In fact, it takes little more than a trip abroad to appreciate that our abilities to make the best use of the natural and artifactual environment and to interpret the behaviors of others is culture-bound.

The social sciences, and anthropology in particular, tend to approach the relationship between culture and mind in a much more radical way. Quite commonly the claim made is not just that cultural factors affect mental activity, it is that the human mind is socially and culturally constituted. This could be understood as meaning just that human mental processes use at every moment and in every activity cultural tools, language to begin with, and also schemas, models, expertises, and values. This, surely, is correct, and makes human minds very complex and special. What is generally meant goes well beyond this triviality, however, and is part of an antinaturalistic approach common in the social sciences. On this view, there may be brains but there are no minds in nature, and, anyhow, there is no human nature. Minds are not natural systems informed and transformed by culture, they are made by culture, and differently so by different cultures. From this point of view, naturalistic psychology, at least when it deals with true mental functions, with thinking in particular, is a Western ethnocentric pseudoscience. Piaget's study of the acculturation of Swiss children is mistaken for the study of a universal human cognitive development; the study of American college students reasoning on laboratory tasks is mistaken for that of human (ir)rationality, and so on.

Such culturalism—in this extreme or in more hedged forms—goes together with a specific view of culture. We saw in the last section how cognitive anthropology puts culture essentially in the mind and how evolutionary and epidemiological approaches treat culture in terms of population-wide distributions of individual mental and artifactual phenomena. These are naturalistic views of culture, with little following in the social sciences. Much more characteristic are the influential views of the anthropologist Clifford Geertz. He writes: "The concept of culture I espouse is essentially a semiotic one. Believing, with Max Weber, that man is an animal suspended in webs of significance he himself has spun, I take culture to be those webs, and the analysis of it to be therefore not an experimental science in search of law but an interpretive one in search of meaning" (Geertz 1973: 5). Attacking cognitive anthropology for placing culture in the mind, and drawing on Wittgenstein's dismissal of the idea of a private meaning, Geertz (1973: 12) insists that "culture is public because meaning is."

This understanding of the notion of culture goes together with a strong individuation of individual cultures (comparable to the individuation of languages), each seen as a separate system of meanings. Cultures so understood are viewed as being not just different environments, but, literally, different worlds, differing from each other in arbitrary ways. This view, known as CULTURAL RELATIVISM, is, except in very watered-down versions, difficult to reconcile with any naturalistic approach to cognitive development. Given that the initial inputs to cognitive development are just myriad stimulations of nerve endings, the process of extracting from these inputs the objective regularities of a relatively stable world is already hard enough to explain. If, in fact, even the world in which cognitive development takes place is not given, if the child can draw neither from expectable environmental regularities nor from internal preparedness to deal with just these regularities, then the process is a pure mystery. It is a sign of the lack of concern for psychological issues that this mystery seems never to have worried defenders of cultural relativism.

In one area, anthropological linguistics, cultural relativism has guided positive research programs that continue to this day. The linguist and anthropologist Edward SAPIR and the linguist Whorf developed the thesis of linguistic relativity (the "Sapir-Whorf hypothesis") according to which lexical and grammatical categories of lan-

guage determine the way the world is perceived and conceptualized, and each language is at the root of a different worldview (see also LANGUAGE AND COMMUNICATION). On this view, human cognition can be understood only through analysis of the linguistic and cultural structures that support it. The classical example is Whorf's treatment of the Hopi notion of time. Noting that the Hopi language "contains no words, grammatical forms, construction or expressions that refer directly to what we call 'time,' or to the past, or future, or to enduring or lasting," he concluded that the Hopi have "no general notion or intuition of time as a smooth flowing continuum" (Whorf 1956: 57). Subsequent research (see Brown 1991 for a review) tended to show that this radical linguistic relativity is not supported by closer analysis. However, less radical versions of linguistic relativity can be sustained (Lucy 1992; Gumperz and Levinson 1996). Recent comparative work on LANGUAGE AND CULTURE has been carried out with the methods of cognitive psycholinguistics at the Max Planck Institute for Psycholinguistics in Nijmegen. It has, in particular, gathered impressive evidence of the fact that the manner in which different languages encode spatial coordinates strongly affects people's conceptualization of spatial relations and movements (see Levinson 1996).

The standard anthropological characterization of cultures as relatively bounded, homogeneous, and coherent entities has repeatedly been challenged (e.g., Leach 1954; Fried 1975). The idea of discrete tribes each with its own culture was a colonial administrator's dream—a dream they forced on people—before being an anthropologist's presupposition. In fact, different flows of cultural information—linguistic, religious, technological—have different boundaries, or, quite often, do not even have proper boundaries, just zones of greater of lesser intensities. From an epidemiological point of view, of course, these ongoing cultural flows and the fuzziness of cultural boundaries are just what one should expect. From such a point of view, the notion of *a* culture should not have more of a theoretical status than that of a region in geography. Culture is best seen not as a thing, but as a property that representations, practices, and artifacts possess to the extent that they are caused by population-wide distribution processes.

It is the standard notion of a culture as an integrated whole that has guided most anthropological research bearing, directly or indirectly, on psychological issues. Much early anthropology, notably in North America, focused on the social and cultural correlates of psychological phenomena. A major and influential program of research, pioneered by Margaret Mead and Ruth Benedict, and lasting well after World War II, examined the relationship between personality and culture. The "personality and culture" school adapted the language of psychopathology to describe and analyze cultural phenomena. Still, the thrust of this approach was an abiding skepticism about psychological claims. Relying on ethnographic data, scholars assessed and critiqued universalist claims about the mind. Both Mead and Malinowski drew considerable attention from their challenges to several of Freud's generalizations about human nature, particularly claims about the development of sexuality. Ultimately the appeal of the culture and personality school waned in part as national character studies began more to resemble national stereotypes than cultural analysis, but also in part because the approach increasingly identified the sociocultural level with the psychological level, a move that made most anthropologists uncomfortable.

Much anthropological research, although deliberately apsychological, is nevertheless of genuine cognitive interest in that it investigates knowledge structures, from specific notions to ideological systems. For example, much work has been devoted to examining different notions of person across cultures. In contrast to work in psychology that tends to take the person as a fundamental and invariant concept (see, e.g., Miller and Johnson-Laird 1976), anthropologists challenge the assumption that a person implies a bounded and unique sense of individuality and self. Rather the person is a socially situated concept that can only be understood from the perspective of social and cultural relations (Mauss 1985; Geertz 1973). For instance, Lutz (1988) argues that the Ifaluk of Melanesia do not conceive of emotions as something occurring with an individual person, but as a relation between several individuals in which the emotion exists independent of (and outside) the psyche of any one person. The notion of

persons as unique self-oriented entities, in its turn, has been analyzed as arising from the specific cultural and political-economic environments of North America and Europe (Bellah et al. 1985). Like all relativist ideas, these views are controversial. Notice, however, that, unlike the claim that the mind itself is a cultural product, the claim that the person, or the SELF, is socially and culturally constituted is compatible with a naturalistic cognitive science, and has been defended from a naturalistic point of view, for instance by Dennett (1991).

Standard anthropological evidence for the cultural character and variability of notions like "person" consists of cultural narratives and expression of conventional wisdom. More recently, however, researchers in social psychology, CULTURAL PSY-CHOLOGY and ETHNOPSYCHOLOGY have used innovative experimental methods to support ethnographic findings (see Markus and Kityama 1991; Shweder 1991). Shweder and colleagues have made important contributions (in both method and theory) toward integrating ethnographic and experimental approaches. Work on moral development, especially the way culture may fundamentally shape it, has been influential (Shweder, Mahapatra, and Miller 1990; see also Turiel 1983 for a carefully crafted and persuasive challenge to the antiuniversalist point of view).

Conclusion

The various strains of research rapidly reviewed in this last section—the Vygotskian, the social-psychological and the anthropological—are extremely fragmented, diverse, and embattled. This should not obscure the fact that they all deal with important and difficult issues, and provide extremely valuable insights. It is encouraging to observe that, in all these approaches, there is a growing concern for explicit theorizing and sound experimental testing. More generally, it seems obvious to us that the various perspectives we have considered in this chapter should be closely articulated, and we have attempted to highlight the works that particularly contribute to this articulation. We are still far from the day when the biological, the cognitive, and the social sciences will develop a common conceptual framework and a common agenda to deal with the major issues that they share.

Aboutness

Acquisition, Formal Theories of

A formal theory of language acquisition (FTLA) can be defined as a mathematical investigation of the learnability properties of the class of human languages. Every FTLA can therefore be seen as an application of COMPUTATIONAL LEARNING THEORY to the problem of LANGUAGE ACQUISITION, one of the core problems of LEARNING (see also LEARNING SYSTEMS).

The need for FTLAs stems from one of the standard assumptions of linguistics: A successful theory must prove that the grammars proposed by linguists not only account for all linguistic data (descriptive adequacy) but also are the kind of objects that can be acquired on the kind of data and with the kind of cognitive resources that are typical of human language learning (explanatory adequacy).

In order to be properly stated, every FTLA requires four distinct components:

1. A formal characterization of the class L of languages to be learned (see FORMAL GRAMMARS)
2. A formal characterization of the criterion of success C
3. A formal characterization of the class of algorithms A that one is willing to consider as possible learners
4. An explicit characterization M of how linguistic information is presented to the learner.

Given this characterization, every FTLA consists of either a proof that there is at least a learner in A that successfully acquires every language in L when success is defined as in C and data are presented as prescribed by M (a *positive* result) or a proof that there is at least a language in L that no learner in A can successfully acquire according to C and M (a *negative* result).

Although the importance of a positive result (typically the presentation of a model shown as the proof of the existence of a learning algorithm with the desired properties) is obvious, it must not be overlooked that negative results can be just as useful. In fact, as explained earlier, such results can be used to eliminate whole classes of theories that are descriptively but not explanatorily adequate.

Most recent FTLAs assume that, in human language learning, M consists of unordered and simple positive evidence. This assumption rests on twenty years of research in developmental psycholinguistics (reviewed in Marcus 1993), pointing to the conclusion that children receive a largely grammatical set of simple sentences from their target language with very little or no reliable instruction on what sentences are ungrammatical.

The criterion of success C that has been most commonly adopted is *identification in the limit* (Gold 1967): a learner is successful if and only if, for every language in L, it *eventually* stabilizes on a grammar that is equivalent to that of all the other speakers of that language (i.e., it yields the same grammaticality judgments and assigns to

sentences the same meanings). Identification in the limit, however, can be argued to be too strict and too liberal a criterion at the same time. The criterion is too strict because the evolution of languages over time (see LANGUAGE VARIATION AND CHANGE) would appear to be problematic, barring language contact, if each generation acquired *exactly* the language of the previous one, as required by the criterion of identification in the limit. The criterion is too weak because children appear to learn their target language(s) in a very short time, whereas identification in the limit considers successful any learner that *eventually* stabilizes on a correct grammar, however long this might take.

These considerations seem to recommend as a plausible alternative the PAC criterion (Probably Approximately Correct; Valian 1984): a learner is successful if and only if, for every language in L, it is very likely (but not certain) to produce a grammar that is very close (but not necessarily equivalent) to the target grammar and do so not in the limit but in a very short time, measured as a function of how close it gets and how likely it is to do so (see COMPUTATIONAL LEARNING THEORY). As an element of a FTLA, however, the PAC criterion is not without problems of its own. For example, if the error of a conjecture with respect to a target language is measured as the probability of the environment in which the language is exhibited, presenting a string that the conjecture misclassifies, then the assumption that children only receive positive evidence has as a consequence that their conjectures have error zero even if they overgeneralize. In this respect, PAC would appear to be too weak a criterion because, empirically, human learners do not appear to overgeneralize in this fashion.

The L and the A components have traditionally been the locus of the most important differences among alternative FTLAs. Common restrictions on A include memory limitations, smoothness (successive hypotheses must not be very different from one another), continuity (every hypothesis is a possible adult grammar), maturation (some possible adult grammars cannot be part of the child's early hypotheses), and so on. A principled investigation of the effects of such restrictions on identification in the limit can be found in Jain et al. (forthcoming). At the time of writing, however, developmental psycholinguists have not reached the kind of consensus on A that was reached on M.

As for the L component, it must be noted that no existing FTLA is based on a formal definition of the class of human languages quite simply because such a definition is currently unavailable. Indeed, some have even argued against the scientific relevance of formally defining a language as a set of strings (Chomsky 1986). In practice, although ultimately an FTLA would have to explain the child's ability to learn *every* aspect of a target language, most existing FTLAs have respected the division of labor that is traditional in linguistics, so that there now are formal theories of the acquisition of SYNTAX, acquisition of PHONOLOGY and acquisition of word meaning.

Within the domain of syntax, for example, several very broad results have been established with respect to classes of languages generated by formal grammars. Positive

learnability results have been established for the class of languages generated by suitably restricted Transformational Grammars (Wexler and Culicover 1980), the class generated by rigid CATEGORIAL GRAMMARS (Kanazawa 1994), and the class generated by a recently introduced formalism based on Chomsky's MINIMALISM (Stabler 1997).

It is an open question whether this division of labor can be recommended. Indeed, several *nonformal* theories have advocated one form or other of *bootstrapping,* the view that the acquisition of any one of these domains aids and must be aided by the acquisition of the other domains (see Pinker 1987; Gleitman 1990; Mazuka 1996 for *semantic, syntactic,* and *prosodic bootstrapping* respectively).

Many current FTLAs try to sidestep the problem of the unavailability of a formal characterization of L in two ways, either by explicitly modeling only the fragments of their intended domain (syntax, phonology, SEMANTICS) for which a formal grammar is available or by providing a meta-analysis of the learnability properties of *every* class of languages that can be generated, assuming various kinds of innate restrictions on the possible range of variation of human languages (as dictated, for example, by POVERTY OF THE STIMULUS ARGUMENTS; see also LINGUISTIC UNIVERSALS and INNATENESS OF LANGUAGE). Most such meta-analyses are based either on the Principles and Parameters Hypothesis (Chomsky 1981) or on OPTIMALITY THEORY (Prince and Smolensky 1993). For reviews of such analyses, see Bertolo (forthcoming) and Tesar and Smolensky (forthcoming), respectively. It is instructive to note that exactly the same kind of meta-analysis can be achieved also in connectionist models (see NEURAL NETWORKS and CONNECTIONIST APPROACHES TO LANGUAGE) when certain principled restrictions are imposed on their architecture (Kremer 1996).

Adaptation and Adaptationism

In current usage a biological adaptation is a trait whose form can be explained by natural selection. The blink reflex, for example, exists because organisms with the reflex were fitter than organisms without this adaptation to protect the eyes. Biological adaptation must be distinguished from physiological adaptation. The fact that human beings can form calluses when their skin is subjected to friction is probably a biological adaptation, but the particular callus caused by my hedge-trimmers is not. The location and form of this particular callus cannot be explained by the differential reproduction of heritable variants, that is, by natural selection. *Adaptation* is still used in its nonevolutionary sense in disciplines such as exercise physiology. An *adaptive trait* is one that currently contributes to the fitness of an organism. The ability to read is highly adaptive, but is unlikely to be an adaptation. Reading is probably a side effect of other, more ancient cognitive abilities. There are also adaptations that are no longer adaptive. The human

appendix is a vestigial trait—a trace of an earlier process of adaptation.

Some authors distinguish adaptations from exaptations (Gould and Vrba 1982). A trait is an exaptation if it is an adaptation for one purpose but is now used for a different purpose. It is unlikely that feathers evolved from scales because they helped the ancestors of birds to fly better. It is thought that they evolved as insulation and were only later exapted for flight. Other authors doubt the value of the exaptation concept (Griffiths 1992; Reeve and Sherman 1993). The importance of the concept of adaptation in biology is that it explains many traits of the organisms we see around us. It explains not only how traits first arose but also why they persisted and why they are still here. If we want to understand why there are so many feathers in the world, their later use in flight is as relevant as their earlier use in thermoregulation.

The adaptation concept underwrites the continuing use of teleology in biology, something that distinguishes life sciences from the physical sciences (Allen, Bekoff, and Lauder 1997). Adaptations have biological purposes or functions—the tasks for which they are adaptations. Hemoglobin is meant to carry oxygen to the tissues. It is not meant to stain the carpet at murder scenes, although it does this just as reliably. Some authors use the term teleonomy to distinguish adaptive purposes from earlier concepts of natural purpose. The fact that the adaptation concept can create naturalistic distinctions between function and malfunction or normal and abnormal has made it of the first interest to cognitive science. Several authors have used the adaptation concept in analyses of INTENTIONALITY.

To identify an adaptation it is necessary to determine the selective forces responsible for the origins and/or maintenance of a trait. This requires understanding the relationship between organism and environment, something more onerous than is typically recognized (Brandon 1990). Some biologists think this task so onerous that we will frequently be unable to determine whether traits are adaptations and for what (Gould and Lewontin 1978; Reeve and Sherman 1993). Others argue that we can successfully engage in both reverse engineering—inferring the adaptive origins of observed traits—and adaptive thinking—inferring what adaptations will be produced in a particular environment (Dennett 1995; Dawkins 1996). Many advocates of EVOLUTIONARY PSYCHOLOGY believe that adaptive thinking about the human mind has heuristic value for those who wish to know how the mind is structured (Cosmides, Tooby, and Barkow 1992).

Adaptationism is the name given by critics to what they see as the misuse of the adaptation concept. Steve Orzack and Elliot Sober (1994) distinguish three views about adaptation: first, that adaptation is ubiquitous, meaning that most traits are subject to natural selection; second, that adaptation is important: a "censored" model that deliberately left out the effects of natural selection would make seriously mistaken predictions about evolution; and third, that adaptation is optimal: a model censored of all evolutionary mechanisms except natural selection could predict evolution accurately. Most biologists accept that natural selection is ubiquitous and important. In Orzack and Sober's view the

distinctive feature of adaptationism is the thesis that organisms are frequently optimal. They argue that the adaptationist thesis should be empirically tested rather than assumed. Other authors, however, argue that adaptationism is not an empirical thesis, but a methodological one. Optimality concepts provide a well defined goal which it is equally illuminating to see organisms reach or to fall short of. Building models that yield the observed phenotype as an optimum is the best way to identify all sorts of factors acting in the evolutionary process (Maynard-Smith 1978).

There are several strands to antiadaptationism. One is the claim that many adaptive explanations have been accepted on insufficient evidence. Adaptationists claim that the complexity and functionality of traits is sufficient to establish both that they are adaptations and what they are adaptations for (Williams 1966). Antiadaptationists argue that adaptive scenarios do not receive confirmation merely from being qualitatively consistent with the observed trait. Some are also unsatisfied with quantitative fit between an adaptive model and the observed trait when the variables used to obtain this fit cannot be independently tested (Gray 1987). Many antiadaptationists stress the need to use quantitative comparative tests. Independently derived evolutionary trees can be used to test whether the distribution of a trait in a group of species or populations is consistent with the adaptive hypothesis (Brooks and McLennan 1991; Harvey and Pagel 1991). Other strands of antiadaptationism are concerned with broader questions about what biology should be trying to explain. Biology might focus on explaining why selection is offered a certain range of alternatives rather than explaining why a particular alternative is chosen. This would require greater attention to developmental biology (Smith 1992; Amundson 1994; Goodwin 1994). Another antiadaptationist theme is the importance of history. The outcome of an episode of selection reflects the resources the organism brings with it from the past, as well as the "problem" posed by the environment (Schank and Wimsatt 1986; Griffiths 1996). Finally, antiadaptationists have questioned whether the environment contains adaptive problems that can be characterized independently of the organisms that confront them (Lewontin 1982; Lewontin 1983).

Affordances

The term *affordance* was coined by JAMES JEROME GIBSON to describe the reciprocal relationship between an animal and its environment, and it subsequently became the central concept of his view of psychology, the *ecological* approach (Gibson 1979; Reed 1996; see ECOLOGICAL PSYCHOLOGY). An affordance is a resource or support that the environment offers an animal; the animal in turn must possess the capabilities to perceive it and to use it. "The affordances of the environment are what it offers animals, what it provides or furnishes, for good or ill" (Gibson 1977). Examples of affordances include surfaces that provide support, objects that can be manipulated, substances that can be eaten, climatic events that afford being frozen, like

a blizzard, or being warmed, like a fire, and other animals that afford interactions of all kinds. The properties of these affordances must be specified in stimulus information. Even if an animal possesses the appropriate attributes and equipment, it may need to learn to detect the information and to perfect the activities that make the affordance useful—or perilous if unheeded. An affordance, once detected, is meaningful and has value for the animal. It is nevertheless objective, inasmuch as it refers to physical properties of the animal's niche (environmental constraints) and to its bodily dimensions and capacities. An affordance thus exists, whether it is perceived or used or not. It may be detected and used without explicit awareness of doing so.

Affordances vary for diverse animals, depending on the animal's evolutionary niche and on the stage of its development. Surfaces and substances that afford use or are dangerous for humans may be irrelevant for a flying or swimming species, and substances that afford eating by an adult of the species may not be appropriate for a member in a larval stage. The reciprocal relationship between the environmental niche and a certain kind of animal has been dubbed the "animal-environment fit."

Utilization of an affordance implies a second reciprocal relationship between perception and action. Perception provides the information for action, and action generates consequences that inform perception. This information may be proprioceptive, letting the animal know how its body is performing; but information is also exteroceptive, reflecting the way the animal has changed the environmental context with respect to the affordance. Perceiving this relationship allows adaptive control of action and hence the possibility of controlling environmental change.

It is the functioning and description of the animal-environment encounter that is at the heart of research on affordances. Research has addressed three principal questions:

1. Do human adults actually perceive affordances in terms of task constraints and bodily requirements? The reality of perceptual detection of an animal-environment fit has been verified in experiments on adult humans passing through an aperture, reaching for objects with their own limbs or tools, judging appropriate stair heights for climbing, chair heights for sitting, and so forth. J. J. Gibson said that "to perceive the world is to coperceive oneself." In that case, actors should perceive their own body dimensions and powers in relation to the requirements of the relevant environmental resource or support. Warren and Whang (1987) investigated adults' judgments of aperture widths relative to their own body dimensions. Both wide- and narrow-shouldered adults rotated their shoulders when doorways were less than 1.3 times their own shoulder width. Scaling of the environment in terms of the natural yardstick of eye-height (Mark 1987; Warren 1984) has also been demonstrated.

2. Can stimulus information specifying an affordance be described and measured? Can controlled actions of an animal preparing for and acting on an affordance be observed and measured? Gibson (1950) paved the way for this research by describing the optic flow field created by one's own locomotion when flying a plane. The specification by optical stimulus information of the time for a moving animal to contact a surface or a target object was described by Lee (1980), who showed that such information for an observer approaching a surface could be expressed as a constant, τ. The information is used in controlling locomotion during braking and imminent collision by humans (Lee 1976) and by other animals (Lee and Reddish 1981; Lee, Reddish, and Rand 1991). Effective information for heading (the direction in which one is going) has been described by Warren (1995) in terms of the global radial structure of the velocity field of a layout one is moving toward.

Research on the action systems called into play and their controllability in utilizing an affordance has been the subject of study for reaching, standing upright, locomotion, steering, and so on. (Warren 1995). The control of reaching and grasping by infants presented with objects of diverse sizes shows accommodation of action to the object's size and shape by hand shaping, use of one or both arms, and so forth (see Bertenthal and Clifton 1997 for many details). Research of the specification of the affordance in stimulus information, and on control of action in realizing the affordance, converges in demonstrating that behavior is prospective (planned and intentional) and that stimulus information permits this anticipatory feature.

3. How do affordances develop cognitively and behaviorally? Developmental studies of affordances, especially during the first year, abound (Adolph, Eppler, and Gibson 1993). The behavior of crawling infants on a visual cliff (Gibson and Walk 1960) suggests that even infants perceive the affordances of a surface of support and avoid traversal of an apparent drop at an edge. Subsequent research has shown that duration of crawling experience is significantly related to dependable avoidance of the cliff, supporting other research demonstrating that LEARNING plays a role in detecting and responding effectively to many affordances, at least in humans. Development of action systems and increased postural control instigate the emergence of new affordance-related behavior. Babies begin to pay ATTENTION to objects and make exploratory reaches toward them as posture gradually enables reaching out and making contact with their surfaces (Eppler 1995).

As an infant learns about the constraints involved in the use of some affordance, learning may at first be relatively domain specific. Research by Adolph (1997) on traversal of sloping surfaces by crawling infants demonstrates that learning which slopes are traversable and strategies for successful traversal of them is not transferred automatically to traversal of the same slopes when the infant first begins upright locomotion. New learning is required to control the action system for walking and to assess the safety of the degree of slope. Learning about affordances is a kind of perceptual learning, entailing detection of both proprioceptive and exteroceptive information. The learning process involves exploratory activity, observation of consequences, and selection for an affordance fit and for economy of both specifying information and action.

The concept of affordance is central to a view of psychology that is neither mentalism nor stimulus-response BEHAVIORISM, focusing instead on how an animal interacts with its environment. Furthermore, the concept implies neither nativism nor empiricism. Rather, genetic constraints

characteristic of any particular animal instigate exploratory activity that culminates in learning what its environment affords for it.

Aging and Cognition

Any discussion of the relations between aging and cognition must acknowledge a distinction between two types of cognition that are sometimes referred to as *fluid* and *crystallized* cognitive abilities (Cattell 1972) or INTELLIGENCE. Fluid abilities include various measures of reasoning (including both CAUSAL REASONING and DEDUCTIVE REASONING), MEMORY, and spatial performance, and can be characterized as reflecting the efficiency of processing at the time of assessment. In contrast, crystallized abilities are evaluated with measures of word meanings, general information, and other forms of knowledge, and tend to reflect the accumulated products of processing carried out in the past.

The distinction between these two types of abilities is important because the relations of age are quite different for the two forms of cognition. That is, performance on crystallized measures tends to remain stable, or possibly even increase slightly, across most of the adult years, whereas increased age is associated with decreases in many measures of fluid cognition. In large cross-sectional studies age-related declines in fluid abilities are often noticeable as early as the decade of the thirties, and the magnitude of the difference across a range from twenty to seventy years of age is frequently one to two standard deviation units. Although the average trends can be quite large, it is also important to point out that individual differences are substantial because chronological age by itself seldom accounts for more than 20 to 30 percent of the total variance in the scores.

The vast majority of the research in the area of aging and cognition has focused on fluid abilities. There appear to be two primary reasons for this emphasis. First, many researchers probably believe that explanations are clearly needed to account for the differences that have been reported (as in fluid abilities), but that a lack of a difference (as in crystallized abilities) does not necessarily require an explanation. And second, because fluid abilities are assumed to reflect the individual's current status, they are often considered to be of greater clinical and practical significance than crystallized abilities that are assumed to represent the highest level the individual achieved at an earlier stage in his or her life.

Both distal and proximal interpretations of the age-related decline in fluid cognitive abilities have been proposed. Distal interpretations focus on factors from earlier periods in the individual's life that may have contributed to his or her level of performance at the current time. Examples are speculations that the age-related declines are attributable to historical changes in the quantity or quality of education, or to various unspecified cultural characteristics that affect cognitive performance. In fact, comparisons of the scores of soldiers in World War II with the norms from World War I (Tuddenham 1948), and a variety of time-lag comparisons reported by Flynn (1987), suggest that the average level of cognitive ability has been improving across successive generations. However, the factors responsible for these improvements have not yet been identified (see Neisser 1997), and questions still remain about the implications of the positive time-lag effects for the interpretation of cross-sectional age differences in cognitive functioning (see

Salthouse 1991). Hypotheses based on differential patterns of activity and the phenomenon of disuse can also be classified as distal because they postulate that an individual's current level of performance is at least partially affected by the nature and amount of activities in which he or she has engaged over a period of years. Although experientially based interpretations are very popular among the general public (as exemplified in the cliché "Use it or lose it") and among many researchers, there is still little convincing evidence for this interpretation. In particular, it has been surprisingly difficult to find evidence of interactions of age and quality or quantity of experience on measures of fluid cognitive abilities that would be consistent with the view that age-related declines are minimized or eliminated among individuals with extensive amounts of relevant experience.

Proximal interpretations of age-related differences in cognitive functioning emphasize characteristics of processing at the time of assessment that are associated with the observed levels of cognitive performance. Among the proximal factors that have been investigated in recent years are differences in the choice or effectiveness of particular strategies, differences in the efficiency of specific processing components, and alterations in the quantity of some type of processing resource (such as WORKING MEMORY, ATTENTION, or processing speed), presumed to be required for many different types of cognitive tasks. Hypotheses based on speculations about the neuroanatomical substrates of cognitive functioning (such as dopamine deficiencies or frontal lobe impairments) might also be classified as proximal because they have primarily focused on linking age-related changes in biological and cognitive characteristics, and not in speculating about the origins of either of those differences. However, not all neurobiological mechanisms are necessarily proximal because some may operate to affect the susceptibility of structures or processes to changes that occur at some time in the future.

A fundamental issue relevant to almost all proximal interpretations concerns the number of distinct influences that are contributing to age-related differences in cognitive functioning. Moderate to large age-related differences have been reported on a wide variety of cognitive variables, and recent research (e.g., Salthouse 1996) indicates that only a relatively small proportion of the age-related effects on a given variable are independent of the age-related effects on other cognitive variables. Findings such as these raise the possibility that a fairly small number of independent causal factors may be responsible for the age-related differences observed in many variables reflecting fluid aspects of cognition. However, there is still little consensus regarding the identity of those factors or the mechanisms by which they exert their influence.

Aging, Memory, and the Brain

Memory is not a unitary function but instead encompasses a variety of dissociable processes mediated by distinct brain systems. *Explicit* or *declarative* memory refers to the conscious recollection of facts and events, and is known to critically depend on a system of anatomically related structures that includes the HIPPOCAMPUS and adjacent cortical regions in the medial temporal lobe. This domain of function contrasts with a broad class of memory processes involving the tuning or biasing of behavior as a result of experience. A distinguishing feature of these *implicit* or *nondeclarative* forms of memory is that they do not rely on conscious access to information about the episodes that produced learning. Thus, implicit memory proceeds normally independent of the medial temporal lobe structures damaged in amnesia. Although many important issues remain to be resolved concerning the organization of multiple memory systems in the brain, this background of information has enabled substantial progress toward defining the neural basis of age-related cognitive decline.

Traditionally, moderate neuron death, distributed diffusely across multiple brain regions, was thought to be an inevitable consequence of aging. Seminal studies by Brody (1955) supported this view, indicating neuron loss progresses gradually throughout life, totaling more than 50 percent in many cortical areas by age ninety-five (Brody 1955, 1970). Although not all regions of the brain seemed to be affected to the same degree, significant decreases in cell number were reported for both primary sensory and associational areas of cortex. Thus, the concept emerged from early observations that diffusely distributed neuron death might account for many of the cognitive impairments observed during aging (Coleman and Flood 1987).

In recent years, the application of new and improved methods for estimating cell number has prompted substantial revision in traditional views on age-related neuron loss. A primary advantage of these modern stereological techniques, relative to more traditional approaches, is that they are specifically designed to yield estimates of total neuron number in a region of interest, providing an unambiguous

measure for examining potential neuron loss with age (West 1993a). Stereological tools have been most widely applied in recent studies to reevaluate the effects of age on neuron number in the hippocampus. In addition to the known importance of this structure for normal explicit memory, early research using older methods suggested that the hippocampus is especially susceptible to age-related cell death, and that this effect is most pronounced among aged subjects with documented deficits in hippocampal-dependent learning and memory (Issa et al. 1990; Meaney et al. 1988). The surprising conclusion from investigations using stereological techniques, however, is that the total number of principal neurons (i.e., the granule cells of the dentate gyrus, and pyramidal neurons in the CA3 and CA1 fields) is entirely preserved in the aged hippocampus. Parallel results have been observed in all species examined, including rats, monkeys and humans (Peters et al. 1996; Rapp 1995; Rapp and Gallagher 1996; Rasmussen et al. 1996; West 1993b). Moreover, hippocampal neuron number remains normal even among aged individuals with pronounced learning and memory deficits indicative of hippocampal dysfunction (Peters et al. 1996; Rapp 1995; Rapp and Gallagher 1996; Rasmussen et al. 1996). Contrary to traditional views, these findings indicate that hippocampal cell death is not an inevitable consequence of aging, and that age-related learning and memory impairment does not require the presence of frank neuronal degeneration.

Quantitative data on neuron number in aging are not yet available for all of the brain systems known to participate in LEARNING and MEMORY. However, like the hippocampus, a variety of other cortical regions also appear to maintain a normal complement of neurons during non-pathological aging. This includes dorsolateral aspects of the prefrontal cortex that participate in processing spatiotemporal attributes of memory (Peters et al. 1994), and unimodal visual areas implicated in certain forms of implicit memory function (Peters, Nigro, and McNally 1997). By contrast, aging is accompanied by substantial subcortical cell loss, particularly among neurochemically specific classes of neurons that originate ascending projections to widespread regions of the cortex. Acetylcholine containing neurons in the basal forebrain have been studied intensively in this regard, based partly on the observation that this system is the site of profound degeneration in pathological disorders of aging such as Alzheimer's disease. A milder degree of cholinergic cell loss is also seen during normal aging, affecting cell groups that project to the hippocampus, AMYGDALA, and neocortex (Armstrong et al. 1993; de Lacalle, Iraizoz, and Ma Gonzalo 1991; Fischer et al. 1991; Stroessner-Johnson, Rapp, and Amaral 1992). Information processing functions mediated by these target regions might be substantially disrupted as a consequence of cholinergic degeneration, and, indeed, significant correlations have been documented between the magnitude of cell loss and behavioral impairment in aged individuals (Fischer et al. 1991). Together with changes in other neurochemically specific projection systems, subcortical contributions to cognitive aging may be substantial. These findings also highlight the concept that neuron loss during normal aging

appears to preferentially affect subcortical brain structures, sparing many cortical regions. Defining the cell biological mechanisms that confer this regional vulnerability or protection remains a significant challenge.

Research on the neuroanatomy of cognitive aging has also examined the possibility that changes in connectivity might contribute to age-related deficits in learning and memory supported by the hippocampus. The entorhinal cortex originates a major source of cortical input to the hippocampus, projecting via the perforant path to synapse on the distal dendrites of the dentate gyrus granule cells, in outer portions of the molecular layer. Proximal dendrites of the granule cells, in contrast, receive an intrinsic hippocampal input arising from neurons in the hilar region of the dentate gyrus. This strict laminar segregation, comprised of non-overlapping inputs of known origin, provides an attractive model for exploring potential age-related changes in hippocampal connectivity. Ultrastructural studies, for example, have demonstrated that a morphologically distinct subset of synapses is depleted in the dentate gyrus molecular layer during aging in the rat (Geinisman et al. 1992). Moreover, the magnitude of this loss in the termination zone of the entorhinal cortex is greatest among aged subjects with documented deficits on tasks sensitive to hippocampal damage, and in older animals that display impaired cellular plasticity in the hippocampus (de Toledo-Morrell, Geinisman, and Morrell 1988; Geinisman, de Toledo-Morrell, and Morrell 1986).

The same circuitry has been examined in the aged monkey using confocal laser microscopy to quantify the density of *N*-methyl-D-aspartate (NMDA) and non-NMDA receptor subunits. Aged monkeys display a substantial reduction in NMDA receptor labeling that is anatomically restricted to outer portions of the molecular layer that receive entorhinal cortical input (Gazzaley et al. 1996). The density of non-NMDA receptor subunits is largely preserved. Although the impact of this change on cognitive function has not been evaluated directly, the findings are significant because NMDA receptor activity is known to play a critical role in cellular mechanisms of hippocampal plasticity (i.e., LTP). Thus, a testable prediction derived from these observations is that the status of hippocampal-dependent learning and memory may vary as a function of the magnitude of NMDA receptor alteration in the aged monkey. Studies of this sort, combining behavioral and neurobiological assessment in the same individuals, are a prominent focus of current research on normal aging.

A solid background of evidence now exists concerning the nature, severity and distribution of structural alterations in the aged brain. The mechanisms responsible for these changes, however, are only poorly understood. Molecular biological techniques are increasingly being brought to bear on this issue, revealing a broad profile of age-related effects with significant implications for cell structure and function (Sugaya et al. 1996). Although incorporating these findings within a neuropsychological framework will undoubtedly prove challenging, current progress suggests that molecular, neural-systems, and behavioral levels of analysis may soon converge on a more unified understanding of normal cognitive aging.

AI and Education

Perhaps computers could educate our children as well as the best human tutors. This dream has inspired decades of work in cognitive science. The first generation of computer tutoring systems (called Computer Aided Instruction or Computer Based Instruction) were essentially hypertext. They

mostly just presented material, asked multiple-choice questions, and branched to further presentations depending on the student's answer (Dick and Carey 1990).

The next generation of tutoring systems (called Intelligent CAI or Intelligent Tutoring Systems) were based on building knowledge of the subject matter into the computer. There were two types. One coached students as they worked complex, multiminute problems, such as troubleshooting an electronic circuit or writing a computer program. The other type attempted to carry on a Socratic dialog with students. The latter proved to be very difficult, in part due to the problem of understanding unconstrained natural language (see NATURAL LANGUAGE PROCESSING). Few Socratic tutors have been built. Coached practice systems, however, have enjoyed a long and productive history.

A coached practice system usually contains four basic components:

1. An environment in which the student works on complex tasks. For instance, it might be a simulated piece of electronic equipment that the student tries to troubleshoot.
2. An expert system that can solve the tasks that the student works on (see KNOWLEDGE-BASED SYSTEMS).
3. A student modeling module that compares the student's behavior to the expert system's behavior in order to both recognize the student's current plan for solving the problem and determine what pieces of knowledge the student is probably using.
4. A pedagogical module that suggests tasks to be solved, responds to the students' requests for help and points out mistakes. Such responses and suggestions are based on the tutoring system's model of the student's knowledge and plans.

Any of these components may utilize AI technology. For instance, the environment might contain a sophisticated simulation or an intelligent agent (see INTELLIGENT AGENT ARCHITECTURE), such as a simulated student (called co-learners) or a wily opponent. The student modeling module's job includes such classic AI problems as plan recognition and uncertain reasoning (see UNCERTAINTY). The pedagogical module's job includes monitoring an instructional plan and adapting it as new information about the student's competence is observed. Despite the immense potential complexity, many intelligent tutoring systems have been built, and some are in regular use in schools, industry, and the military.

Although intelligent tutoring systems are perhaps the most popular use of AI in education, there are other applications as well. A common practice is to build an environment without the surrounding expert system, student modeling module, or pedagogical module. The environment enables student activities that stimulate learning and may be impossible to conduct in the real world. For instance, an environment might allow students to conduct simulated physics experiments on worlds where gravity is reduced, absent, or even negative. Such environments are called interactive learning environments or microworlds. A new trend is to use networking to allow several students to work together in the same environment. Like intelligent tutoring systems, many intelligent environments have been built and used for real educational and training needs.

Other applications of AI in education include (1) using AI planning technology to design instruction; (2) using student modeling techniques to assess students' knowledge on the basis of their performance on complex tasks, a welcome alternative to the ubiquitous multiple-choice test; and (3) using AI techniques to construct interesting simulated worlds (often called "microworlds") that allow students to discover important domain principles.

Cognitive studies are particularly important in developing AI applications to education. Developing the expert module of a tutoring system requires studying experts as they solve problems in order to understand and formalize their knowledge (see KNOWLEDGE ACQUISITION). Developing an effective pedagogical module requires understanding how students learn so that the tutor's comments will prompt students to construct their own understanding of the subject matter. An overly critical or didactic tutor may do more harm than good. A good first step in developing an application is to study the behavior of expert human tutors in order to see how they increase the motivation and learning of students.

However, AI applications often repay their debt to empirical cognitive science by contributing results of their own. It is becoming common to conduct rigorous evaluations of the educational effectiveness of AI-based applications. The evaluations sometimes contrast two or more versions of the same system. Such controlled experiments often shed light on important cognitive issues.

At this writing, there are no current textbooks on AI and education. Wenger (1987) and Polson and Richardson (1988) cover the fundamental concepts and the early systems. Recent work generally appears first in the proceedings of the AI and Education conference (e.g., Greer 1995) or the Intelligent Tutoring Systems conference (e.g., Frasson, Gauthier, and Lesgold 1996). Popular journals for this work include *The International Journal of AI and Education* (http://cbl.leeds.ac.uk/ijaied/), *The Journal of the Learning Sciences* (Erlbaum) and *Interactive Learning Environments* (Ablex).

Algorithm   11

Algorithm

An *algorithm* is a recipe, method, or technique for doing something. The essential feature of an algorithm is that it is made up of a *finite* set of rules or operations that are unambiguous and simple to follow (computer scientists use technical terms for these two properties: *definite* and *effective,* respectively). It is obvious from this definition that the notion of an algorithm is somewhat imprecise, a feature it shares with all foundational mathematical ideas—for instance, the idea of a set. This imprecision arises because being unambiguous and simple are relative, context-dependent terms. However, usually algorithms are thought of as recipes, methods, or techniques for getting *computers* to do something, and when restricted to computers, the term "algorithm" becomes more precise, because then "unambiguous and simple to follow" means "a computer can do it." The connection with computers is not necessary, however. If a person equipped only with pencil and paper can complete the operations, then the operations constitute an algorithm.

A famous example of an algorithm (dating back at least to Euclid) is finding the greatest common divisor (GCD) of two numbers, m and n.

Step 1. Given two positive integers, set m to be the larger of the two; set n to be the smaller of the two.
Step 2. Divide m by n. Save the remainder as r.
Step 3. If $r = 0$, then halt; the GCD is n.
Step 4. Otherwise, set m to the old value of n, and set n to the value of r. Then go to step 2.

A tax form is also a relatively good example of an algorithm because it is finite and the instructions for completing it are mechanically and finitely completable (at least that is the intention). The recipe for cowboy chocolate cake (with two mugs of coffee) is not really an algorithm because its description is not definite enough (how much is a mug of coffee?). Of course, all computer programs are algorithms.

It should also be noted that algorithms are by no means restricted to numbers. For example, alphabetizing a list of words is also an algorithm. And, one interpretation of the computational hypothesis of the mind is that thinking itself is an algorithm—or perhaps better, the result of many algorithms working simultaneously.

Now to flesh out the definition. An algorithm is an unambiguous, precise, list of simple operations applied mechanically and systematically to a set of tokens or objects (e.g., configurations of chess pieces, numbers, cake ingredients, etc.). The initial state of the tokens is the input; the final state is the output. The operations correspond to *state transitions* where the states are the configuration of the tokens, which changes as operations are applied to them. Almost everything in sight is assumed to be finite: the list of operations itself is finite (there might be a larger but still finite set from which the operations are drawn) and each token is itself finite (or, more generally, a finitely determinable element in the set). Usually, the input, output, and intermediate sets of tokens are also finite, but this does not have to be the case, at least in theory; indeed these sets can be continuous (see Blum, Shub, and Smale 1989). An algorithm describes a process that the tokens participate in. This process (a computation) is either in a certain state or it is not, it may either go to a certain next state from its current state or it may not, and any transition taken is finite. (One way to relax this definition is to allow the state transitions to be probabilistic, but that doesn't affect their finiteness.)

And finally, in more technical parlance, an algorithm is an *intensional* definition of a special kind of function—namely a *computable* function. The intensional definition contrasts with the *extensional* definition of a computable function, which is just the set of the function's inputs and outputs. Hence, an algorithm describes *how* the function is computed, rather than merely *what* the function is. The connection with computable functions is crucial. A function F is computable if and only if it is describable as an algorithm. The relationship between the extensional definition of F and an intensional definition of it is interesting. There is one extensional definition of F, but there are an infinite number of intensional definitions of it, hence there are an infinite number of algorithms for every extensionally-described computable function F. (Proof: you can always construct a new, longer algorithm by adding instructions that essentially do nothing. Of course, usually we seek the *canonical* algorithm—the shortest and most efficient one.)

A computable function is a function whose inputs and outputs can be produced by a Turing machine. Church's thesis states that *all* the computable functions can be computed by a Turing machine (see CHURCH-TURING THESIS). The best way to understand Church's thesis is to say that Turing computability exhausts the notion of computability. Importantly, not all functions are computable, so not all functions are algorithmically describable (this was a profound discovery, first proved by TURING 1936; Church 1936a; and Kleene 1936; it and related results are among the greatest achievements of twentieth-century mathematics).

Sometimes algorithms are simply equated with Turing machines. The definition given here is logically prior to the notion of a Turing machine. This latter notion is intended to formally capture the former. Gödel (1931; 1934), among his other achievements, was the first to do this, to link a formal definition with an intuitive one: he identified a formally defined class of functions, the recursive functions, with the functions that are computable, that is, with the functions for which algorithms can be written.

This completes the definition of "algorithm." There are a few loose ends to tie up, and connections to be made. First, mathematicians and computer scientists sometimes sharply restrict the definition of "algorithm." They take the definition of "algorithm" given here, and use it to define the notion of an *effective procedure*. Then they define an algorithm as an effective procedure that always halts or terminates (not all procedures or computer programs do terminate—sometimes on purpose, sometimes accidentally).

Second, in common parlance, an algorithm is a recipe for *telling* a computer what to do. But this definition does more harm than good because it obliterates the crucial notion of a virtual machine, while it subtly reinforces the

idea that a homunculus of some sort is doing all the work, and this in turn can reinforce the idea of a "ghost in the machine" in the COMPUTATIONAL THEORY OF MIND. So this folk definition should be avoided when precision is needed. Another problem with the folk definition is that it does not do justice the profundity of the notion of an algorithm as a description of a *process.* It is fair to regard algorithms as being as crucial to mathematics as sets. A set is a collection of objects. An intentional definition of a set describes all and only the objects in the set. An algorithm describes a collection of objects that does something. It would be impossible to overstate the importance of this move from statics to dynamics.

Third, the connection between algorithms and COMPU-TATION is quite tight. Indeed, some mathematicians regard algorithms as abstract descriptions of computing devices. When implemented on a standard computer, such descriptions cease to be abstract and become real computing devices known as *virtual machines* (virtual does not mean not real, here). A virtual machine is the machine that does what the algorithm specifies. A virtual machine exists at some level higher than the machine on which the algorithm is implemented. For example: a word processor is a virtual machine that exists on top of the hardware machine on which it is implemented. The notion of a virtual machine is very important to cognitive science because it allows us to partition the study of the mind into levels, with neurochemistry at the bottom (or near the bottom) and cognitive psychology near the top. At each level, different methods and technical vocabularies are used. One of the crucial facts about virtual machines is that no one machine is more important than the rest. So it is with the brain and the rest of the nervous system that make up thinking things. Theories at all levels are going to be needed if we are to completely and truly understand the mind.

A-Life

See ARTIFICIAL LIFE; EVOLUTIONARY COMPUTATION

Altruism

In biology, *altruism* has a purely descriptive economic meaning: the active donation of resources to one or more individuals at cost to the donor. Moral values or conscious motivations are not implied, and the ideas are as applicable to plants as to animals. Four evolutionary causes of altruism will be considered here: kin selection, reciprocation, manipulation, and group selection. Each implies demonstrably different patterns for what individuals donate what resources to whom and under what circumstances and may suggest different motivational and emotional experiences by both donor and recipient.

It may seem that Darwinian EVOLUTION, directed by natural selection, could never favor altruism. Any avoidable activity that imposes a cost, always measured as reduced reproductive fitness, would be eliminated in evolution. This view is too simple. Natural selection should minimize costs whenever possible, but successful reproduction always requires donation of resources to offspring, at least by females putting nutrients into eggs. A closer look shows that offspring are important to natural selection only because they bear their parents' genes, but this is true of all relatives. From the perspective of genetics and natural selection, the survival and reproduction of any relative are partly equivalent to one's own survival and reproduction. So there must be an evolutionary force of *kin selection* that favors altruism between associated relatives.

Kin selection, first clearly formulated by Hamilton (1964), can be defined as selection among individuals for the adaptive use of cues indicative of kinship. The products of mitotic cell division are exactly similar genetically, and their special physical contact is reliable evidence of full kinship. This accounts for the subservice of somatic cells in a multicellular organism to the reproductive interests of the germ cells. Kin selection also accounts for the generally benign relations among young animals in the same nest. Such early proximity is often a cue indicative of close kinship. Nestmates are often full sibs, with a genetic relation-

ship of 0.50. They could also be half sibs if the mother mated with more than one male. They may not be related at all if one or more eggs were deposited by females other than the apparent mother. Such nest parasites are often of the same species in birds, but some species, such as the European cuckoo and the American cowbird, reproduce exclusively by parasitizing other species. Their young's competition with nest mates has not been tempered by kin selection, and this accounts for their lethal eviction of the offspring of the parasitized pair. Many sorts of cues other than early proximity can be used to assess kinship, such as the odors used by mammals and insects to recognize relatives and make genetically appropriate adjustments in altruism. The classic work on mechanisms of kin recognition is Fletcher and Michener (1987); see Slater (1994) for a critical updating.

In the insect order Hymenoptera (ants, bees, and wasps), a male has only one chromosome set, from an unfertilized egg of his mother, and his sperm are all exactly the same genetically. So his offspring by a given female have a relationship of 0.75 to one another. This factor has been used to explain the multiple independent instances, in this insect order, of the evolution of sterile worker castes that are entirely female. These workers derive greater genetic success by helping their mothers produce sisters than they would by producing their own offspring, which would have only a 0.50 genetic similarity. These special relationships are not found in termites (order Isoptera) and, as expected, both males and females form the termite worker castes.

Reciprocity is another evolutionary factor that can favor altruism. The basic theory was introduced by Trivers (1971) and refined by Axelrod and Hamilton (1980). One organism has a net gain by helping another if the other reciprocates with benefits (simultaneous or delayed) that balance the donor's cost. Cleaning symbiosis between a large fish and a small one of a different species may provide simultaneous reciprocal benefits: the large fish gets rid of parasites; the small one gets food. This reciprocation implies that the small fish is more valuable as a cleaner to the large fish than it would be as food. Reciprocity is a pervasive factor in the socioeconomic lives of many species, especially our own. It requires safeguards, often in the form of evolved adaptations for the detection of cheating (Wright 1994).

Manipulation is another source of altruism. The donation results from actual or implied threat or deception by the recipient. In any social hierarchy, individuals of lower rank will often yield to the higher by abandoning a food item or possible mate, thereby donating the coveted resource to the dominant individual. Deception often works between species: a snapper may donate its body to an anglerfish that tempts it with its lure; some orchids have flowers that resemble females of an insect species, so that deceived males donate time and energy transporting pollen with no payoff to themselves. The nest parasitism discussed above is another example. Our own donations of money or labor or blood to public appeals can be considered manipulation of donors by those who make the appeals.

Group selection is another possibility. Individuals may donate resources as a group-level adaptation, which evolu-tion can favor by operating at the level of competing groups rather than their competing members. A group of individuals that aid each other may prevail over a more individually selfish group. A difficulty here is that if selfishness is advantageous within a group, that group is expected to evolve a higher level of individual selfishness, no matter what the effect on group survival. The original concept of group selection focused on separate populations within a species (Wynne-Edwards 1962; Wade 1996). This idea has few adherents, because of the paucity of apparent population-level adaptations (Williams 1996: 51–53), because altruistic populations are readily subverted by the immigration of selfish individuals, and because the low rate of proliferation and extinction of populations, compared to the reproduction and death of individuals, would make selection among populations a relatively weak force.

More recently attention has been given to selection among temporary social groupings or *trait groups* (Wilson 1980), such as fish schools or flocks of birds. Trait groups with more benign and cooperative members may feed more efficiently and avoid predators more effectively. The more selfish individuals still thrive best within each group, and the evolutionary result reflects the relative strengths of selection within and between groups. In human history, groups with more cooperative relations among members must often have prevailed in conflicts with groups of more consistently self-seeking individuals (Wilson and Sober 1994). The resulting greater prevalence of human altruism would be more likely to result from culturally transmitted than genetic differences. It should be noted that any form of group selection can only produce modifications that benefit the sorts of groups among which selection takes place. It need not produce benefits for whole species or more inclusive groups.

A given instance of altruistic behavior may, of course, result from more than one of these four evolutionary causes. Genealogical relatives are especially likely to indulge in both reciprocation and manipulation. If reproductive processes result in stable associations of relatives, these kin-groups are inevitably subject to natural selection. The most extreme examples of altruism, those of social insects, probably resulted from the operation of all the factors discussed here, and social insect colonies may aptly be termed super-organisms (Seeley 1989). Excellent detailed discussions of altruism in the animal kingdom and in human evolution, and of the history of thought on these topics, are available (Ridley 1996; Wright 1994).

Ambiguity

A linguistic unit is said to be ambiguous when it is associated with more than one MEANING. The term is normally reserved for cases where the same linguistic form has clearly differentiated meanings that can be associated with distinct linguistic representations. Ambiguity is thus distinguished from general indeterminacy or lack of specificity.

Ambiguity has played an important role in developing theories of syntactic and semantic structure, and it has been the primary empirical testbed for developing and evaluating models of real-time language processing. Within artificial intelligence and COMPUTATIONAL LINGUISTICS, ambiguity is considered one of the central problems to be solved in developing language understanding systems (Allen 1995).

Lexical ambiguity occurs when a word has multiple independent meanings. "Bank" in the sentence "Jeremy went to the *bank*" could denote a riverbank or a financial institution. Ambiguous words may differ in syntactic category as well as meaning (e.g., "rose," "watch," and "patient"). True lexical ambiguity is typically distinguished from polysemy (e.g., "the N.Y. Times" as in this morning's edition of the newspaper versus the company that publishes the newspaper) or from vagueness (e.g., "cut" as in "cut the lawn" or "cut the cloth"), though the boundaries can be fuzzy.

Syntactic ambiguities arise when a sequence of unambiguous words reflects more than one possible syntactic relationship underlying the words in the sentence, as in:

(1) a. The company hires smart women and men.
   b. The burglar threatened the student with the knife.

In (1a), the ambiguity lies in whether the adjective *smart* modifies (provides information about) both *women* and *men* resulting in a practice not to hire unintelligent people of either sex, or whether *smart* modifies *women* only. In (1b), the phrase *with the knife* could be used to describe the manner in which the burglar threatened the student, or to indicate which student was threatened. Chomsky (1957) used

similar ambiguities to argue for the necessity of abstract syntactic structure.

The different underlying relationships in ambiguous sentences can frequently be observed directly by manipulating the form of the ambiguous sentence. When the order of the string *smart women and men* is reversed to *men and smart women,* the sentence can only be understood as involving modification of *women* but not *men.* When the adverb *wildly* is inserted before *with the knife,* only the reading in which the burglar is using the knife remains possible.

In its most technical sense, the term ambiguity is used to describe only those situations in which a surface linguistic form corresponds to more than one linguistic representation. In lexical ambiguities, one surface phonetic form has multiple independent lexical representations. For syntactic ambiguities, one surface string has different underlying syntactic structures. A subtler and more controversial example is the phenomenon of *scope ambiguity,* exemplified in:

(2) a. Some woman tolerates every man.
   b. John doesn't think the King of France is bald.

In (2a), the sentence can be understood as referring to a single woman who tolerates each and every man, or alternatively, it can mean that every man is tolerated by at least one woman (not necessarily the same one). Sentence (2b) can mean either that John believes that the King of France is not bald, or that John does not hold the particular belief that the King of France is bald. It is difficult to find clear syntactic tests for scope ambiguities that would demonstrate different underlying structures. For instance, reversing the order of *some woman* and *every man* does not eliminate the ambiguity (although it may affect the bias towards one reading):

(3) Every man is tolerated by some woman.

May (1977) argues that sentences such as (2) reflect different underlying structures at a level of linguistic representation corresponding to the LOGICAL FORM of a sentence. Subsequently, much of the linguistic literature has considered scope ambiguities as genuine ambiguities.

A broader notion of ambiguity includes a pervasive ambiguity type that involves not multiple possible structures, but rather, multiple associations between linguistic expressions and specific entities in the world. The sentence in (4) is an example of *referential ambiguity:*

(4) Mark told Christopher that he had passed the exam.

The ambiguity resides in the understanding of the pronoun *he,* which could refer to either Mark, Christopher, or some other salient entity under discussion.

Language processing necessarily involves ambiguity resolution because even unambiguous words and sentences are briefly ambiguous as linguistic input is presented to the processing system. Local ambiguities arise in spoken language because speech unfolds over time and in written language because text is processed in successive eye fixations (cf. Tanenhaus and Trueswell 1995).

The sentence in (5) illustrates how globally unambiguous sentences may contain local ambiguities.

(5) *The pupil spotted* by the proctor was expelled.

The pupil is the object of a relative clause. However, the underlined sequence is also consistent with *the pupil* being the subject of a main clause, as in "*The pupil spotted* the proctor." The ambiguity arises because the morphological form "-ed" is used for both the simple past and for the passive participle, illustrating the interdependence of ambiguity at multiple levels.

Laboratory studies have established that multiple senses of words typically become activated in memory with rapid resolution based on frequency and context. For example, when "pupil" is heard or read, both the "eye part" and the "student" senses become briefly active (Simpson 1984). Similarly, "elevator," "elegant," and "eloquent" are briefly activated as the unambiguous word "elephant" is heard because they are consistent with the initial phonemic sequence "eluh" (Marslen-Wilson 1987).

Syntactic ambiguities exhibit consistent preferences. Readers and listeners experience processing difficulty and sometimes a conscious feeling of confusion when the sentence becomes inconsistent with the preferred structure. The example in (6), from Bever (1970), is a classic example of a so-called garden-path, illustrating that the main clause is the preferred structure for the main clause/relative clause ambiguity.

(6) The raft floated down the river sank.

(7) The land mine buried in the sand exploded.

In (5), resolution in favor of the relative clause does not cause conscious confusion. Nonetheless, processing difficulty at *by the proctor* can be observed using sensitive measures, for instance the duration of eye-fixations in reading. Theoretical explanations for syntactic preferences can be roughly divided into structural and constraint-based approaches. In structural theories, principles defined over syntactic configurations determine an initial structure, which is then evaluated, and if necessary, revised. Different principles may apply for different classes of ambiguities (e.g., Frazier 1987). In constraint-based theories, preferences arise because a conspiracy of probabilistic constraints, many of them lexically based, temporarily make the ultimately incorrect interpretation the more likely one (MacDonald, Pearlmutter, and Seidenberg 1994; Tanenhaus and Trueswell 1995). The example in (7) illustrates a sentence with the same structure as (6) in which the probabilistic constraints initially favor the relative clause because "buried" is typically used as a passive participle without an agent, and land mines are more typically themes than agents of burying events. Whether or not constraint-based systems can provide a unified account of ambiguity resolution in language using general principles that hold across other perceptual domains remains a central unresolved issue.

Amygdala, Primate

For more than one century there has been evidence that the amygdala is involved in emotional behavior. Experimental lesion studies in monkeys demonstrated that large temporal lobe lesions that included the amygdala resulted in dramatic postoperative changes in behavior, including flattened affect, visual agnosia, hyperorality, and hypersexuality (Brown and Schaefer 1888; Klüver and Bucy 1938). Similar behaviors have also been observed in humans with large temporal lobe lesions that include the amygdala (Terzian and Dalle Ore 1955). The amygdala was more formally linked to emotional behavior in 1949, when Paul MacLean expanded Papez's notion of the LIMBIC SYSTEM to include this region, based on neuroanatomical criteria. Over the past several decades, converging results of neuroanatomical, behavioral, and physiological studies in macaque monkeys along with neuropsychological and neuroimaging studies in humans have firmly established a role for the amygdala in emotional processing. However, a number of important questions remain regarding the nature and specificity of this role. In addition, the amygdala has also been linked to social behavior but these data will not be reviewed here. In this article, a brief neuroanatomical review will be followed by a survey of two areas of particularly active research involving the primate amygdala: expression of emotional behavior and the recognition of facial emotion.

The unique neuroanatomical profile of the amygdala illustrates why this structure has been referred to as the "sensory gateway to the emotions" (Aggleton and Mishkin 1986). The amygdala comprises at least thirteen distinct

nuclei, each with a rich pattern of intrinsic connections. As to extrinsic connections, the amygdala is directly interconnected with unimodal and polymodal sensory cortical areas as well as with subcortical structures such as the basal forebrain, THALAMUS, hypothalamus, striatum, and brainstem areas. Thus, the amygdala is centrally positioned to receive convergent cortical and thalamic sensory information and subsequently to direct the appropriate survival-oriented response via its brainstem and hypothalamic projections. Moreover, the significant neuroanatomical connections between the amygdala and nearby medial temporal lobe regions involved in MEMORY may provide the substrate for the enhancing effect of emotional arousal on memory, as demonstrated by a significant body of animal and human studies (McGaugh et al. 1995; Cahill et al. 1995).

Experimental lesions that target the amygdala have produced many of the behaviors that were originally described after the large lesions of Klüver and Bucy and Brown and Schaefer (Weiskrantz 1956; Aggleton, Burton, and Passingham 1980; Zola-Morgan et al. 1991). However, due to methodological difficulties, these lesions typically have included inadvertent cortical and/or fiber damage; thus, interpretations of amygdala function based on these classic studies alone must be made with caution. Highly circumscribed amygdala lesions can now be produced using the neurotoxic lesion technique, and results from these studies indicate a role for the amygdala in temperament and oral exploration (Amaral et al. 1997), food preferences (Murray, Gaffan, and Flint 1996), and in the devaluation of a food reward after selective satiation (Malkova, Gaffan, and Murray 1997).

Interestingly, the behavioral changes observed after neurotoxic amygdala lesions are much less profound than those that were reported using more traditional (i.e., less discrete) lesion techniques. The perirhinal cortex, known to be important for memory (Zola-Morgan et al. 1989), lies adjacent to the amygdala, and these two regions are strongly neuroanatomically interconnected (Stefanacci, Suzuki, and Amaral 1996). It has been suggested that the amygdala and the perirhinal cortex may have some shared roles in emotional behavior (Iwai et al. 1990; Stefanacci, Suzuki, and Amaral 1996). Thus, it is possible that dramatic emotional changes may occur only after lesions that include both of these regions.

Recent studies in humans have explored the role of the amygdala in the recognition of facial emotion and of the recognition of fear in particular (see EMOTION AND THE HUMAN BRAIN). Taken together, the evidence is not entirely supportive. On the positive side, one study reported that a patient with relatively discrete, bilateral amygdala damage as determined by MAGNETIC RESONANCE IMAGING (MRI) was impaired at recognizing fear in facial expressions (Adolphs et al. 1994). A second patient who has partial bilateral amygdala damage, determined by MRI, was similarly impaired (Calder et al. 1996) and was also impaired in recognizing fear and anger in the auditory domain (Scott et al. 1997). However, this patient also has more general facial and auditory processing impairments (Young et al. 1996; Scott et al. 1997).

Functional neuroimaging data provide additional support for the notion that the amygdala is preferentially involved in the recognition of fearful versus happy faces (Morris et al. 1996). However, the results from other studies are not consistent with this notion. First, recognition of facial emotion, including fear, may occur even in the absence of the amygdala (Hamann et al. 1996). Second, single neurons in the human amygdala respond to particular facial expressions but do not respond exclusively to fearful expressions (Fried, MacDonald, and Wilson 1997). In monkeys, there is a population of amygdala neurons that respond selectively to faces (Leonard et al. 1985), but there is little or no evidence to support the idea that these neurons respond selectively to fearful expressions. Finally, functional magnetic resonance imaging (fMRI) has revealed increased activation in the amygdala in response to both happy and fearful faces (Breiter et al. 1996).

To conclude, studies in monkeys and humans over the past several decades have reinforced the long-held view, supported by findings in other species (see EMOTION AND THE ANIMAL BRAIN), that the amygdala has an important role in emotional function. New experimental approaches, such as functional neuroimaging and the use of highly selective lesion techniques, hold promise for an exciting new era of progress that builds on this work.

Analogy

Analogy is (1) similarity in which the same relations hold between different domains or systems; (2) inference that if two things agree in certain respects then they probably agree in others. These two senses are related, as discussed below.

Analogy is important in cognitive science for several reasons. It is central in the study of LEARNING and discovery. Analogies permit transfer across different CONCEPTS, situations, or domains and are used to explain new topics. Once learned, they can serve as MENTAL MODELS for understanding a new domain (Halford 1993). For example, people often use analogies with water flow when reasoning about electricity (Gentner and Gentner 1983). Analogies are often used in PROBLEM SOLVING and inductive reasoning because they can capture significant parallels across different situations. Beyond these mundane uses, analogy is a key mechanism in CREATIVITY and scientific discovery. For example, Johannes Kepler used an analogy with light to hypothesize that the planets are moved by an invisible force from the sun. In studies of microbiology laboratories, Dunbar (1995) found that analogies are both frequent and important in the discovery process.

Analogy is also used in communication and persuasion. For example, President Bush analogized the Persian Gulf crisis to the events preceding World War II, comparing Saddam Hussein to Hitler, Spellman and Holyoak 1992). The invited inference was that the United States should defend Kuwait and Saudi Arabia against Iraq, just as the Allies defended Europe against Nazi Germany. On a larger scale, conceptual metaphors such as "weighing the evidence" and "balancing the pros and cons" can be viewed as large-scale conventionalized analogies (see COGNITIVE LINGUISTICS). Finally, analogy and its relative, SIMILARITY, are important because they participate in many other cognitive processes. For example, exemplar-based theories of conceptual structure and CASE-BASED REASONING models in artificial intelligence assume that much of human categorization and reasoning is based on analogies between the current situation and prior situations (cf. JUDGMENT HEURISTICS).

The central focus of analogy research is on the mapping process by which people understand one situation in terms of another. Current accounts distinguish the following subprocesses: *mapping,* that is, *aligning* the representational structures of the two cases and projecting inferences; and *evaluation* of the analogy and its inferences. These first two are signature phenomena of analogy. Two further processes that can occur are *adaptation* or *rerepresentation* of one or both analogs to improve the match and abstraction of the structure common to both analogs. We first discuss these core processes, roughly in the order in which they occur during normal processing. Then we will take up the

issue of analogical *retrieval,* the processes by which people are spontaneously reminded of past similar or analogous examples from long-term memory.

In analogical *mapping,* a familiar situation—the base or source analog—is used as a model for making inferences about an unfamiliar situation—the target analog. According to Gentner's *structure-mapping* theory (1983), the mapping process includes a *structural alignment* between two represented situations and the *projection of inferences* from one to the other. The alignment must be *structurally consistent,* that is, there must be a one-to-one correspondence between the mapped elements in the base and target, and the arguments of corresponding predicates must also correspond (*parallel connectivity*). Given this alignment, candidate inferences are drawn from the base to the target via a kind of structural completion. A further assumption is the *systematicity principle:* a system of relations connected by higher-order constraining relations such as causal relations is more salient in analogy than an equal number of independent matches. Systematicity links the two classic senses of analogy, for if analogical similarity is modeled as common relational structure, then a base domain that possesses a richly linked system of connected relations will yield candidate inferences by completing the connected structure in the target (Bowdle and Gentner 1997).

Another important psychological approach to analogical mapping is offered by Holyoak (1985), who emphasized the role of pragmatics in problem solving by analogy—how current goals and context guide the interpretation of an analogy. Holyoak defined analogy as similarity with respect to a goal, and suggested that mapping processes are oriented toward attainment of goal states. Holyoak and Thagard (1989) combined this pragmatic focus with the assumption of structural consistency and developed a multiconstraint approach to analogy in which similarity, structural parallelism, and pragmatic factors interact to produce an interpretation.

Through *rerepresentation* or *adaptation,* the representation of one or both analogs is altered to improve the match. Although central to conceptual change, this aspect of analogy remains relatively unexplored. And through *schema abstraction,* which retains the common system representing the interpretation of an analogy for later use, analogy can promote the formation of new relational categories and abstract rules.

Evaluation is the process by which we judge the acceptability of an analogy. At least three criteria seem to be involved: structural soundness—whether the alignment and the projected inferences are structurally consistent; factual validity of the candidate inferences—because analogy is not a deductive mechanism, this is not guaranteed and must be checked separately; and finally, in problem-solving situations, goal-relevance—the reasoner must ask whether the analogical inferences are also relevant to current goals. A lively arena of current research centers on exactly how and when these criteria are invoked in the analogical mapping process.

As discussed above, processing an analogy typically results in a common schema. Accounts of how *cognitive*

simulation occurs fall into two classes: projection-first models, in which the schema is derived from the base and mapped to the target; and alignment-first models, in which the abstract schema is assumed to arise out of the analogical mapping process. Most current cognitive simulations take the latter approach. For example, the structure-mapping engine (SME) of Falkenhainer, Forbus, and Gentner (1989), when given two potential analogs, proceeds at first rather blindly, finding all possible local matches between elements of the base and target. Next it combines these into structurally consistent kernels, and finally it combines the kernels into the two or three largest and deepest matches of connected systems, which represent possible interpretations of the analogy. Based on this alignment, it projects candidate inferences—by hypothesizing that other propositions connected to the common system in the base may also hold in the target. The analogical constraint-mapping engine (ACME) of Holyoak and Thagard (1989) uses a similar local-to-global algorithm, but differs in that it is a multiconstraint, winner-take-all connectionist system, with soft constraints of structural consistency, semantic similarity, and pragmatic bindings. Although the multiconstraint system permits a highly flexible mapping process, it often arrives at structurally inconsistent mappings, whose candidate inferences are indeterminate. Markman (1997) found that this kind of indeterminacy was rarely experienced by people solving analogies. Other variants of the local-to-global algorithm are Hofstadter and Mitchell's Copycat system (1994) for perceptual analogies and Keane's incremental analogy machine (IAM; 1990), which adds matches incrementally in order to model effects of processing order. In contrast to alignment-first models, in which inferences are made after the two representations are aligned, projection-first models find or derive an abstraction in the base and then project it to the target (e.g., Greiner 1988). Although alignment-first models are more suitable for modeling the generation of new abstractions, projection-first models may be apt for modeling conventional analogy and metaphor.

Finally, analogy has proved challenging to subsymbolic connectionist approaches. A strong case can be made that analogical processing requires structured representations and structure-sensitive processing algorithms. An interesting recent "symbolic connectionist" model, Hummel and Holyoak's LISA (1997), combines such structured symbolic techniques with distributed concept representations.

Thus far, our focus has been on how analogy is processed once it is present. But to model the use of analogy and similarity in real-life learning and reasoning we must also understand how people think of analogies; that is, how they *retrieve* potential analogs from long-term memory. There is considerable evidence that similarity-based *retrieval* is driven more by surface similarity and less by structural similarity than is the mapping process. For example, Gick and Holyoak (1980; 1983) showed that people often fail to access potentially useful analogs. People who saw an analogous story prior to being given a very difficult thought problem were three times as likely to solve the problem as those who did not (30 percent vs. 10 percent). Impressive as this is, the majority of subjects nonetheless failed to benefit from the analogy. However,

when the nonsolvers were given the hint to think back to the prior story, the solution rate again tripled, to about 80–90 percent. Because no new information was given about the story, we can infer that subjects had retained its meaning, but failed to think of it when reading the problem. The similarity match between the story and the problem, though sufficient to carry out the mapping once both analogs were present in working memory, did not lead to spontaneous retrieval. This is an example of the inert knowledge problem in transfer, a central concern in EDUCATION.

Not only do people fail to retrieve analogies, but they are often reminded of prior surface-similar cases, even when they know that these matches are of little use in reasoning (Gentner, Rattermann, and Forbus 1993). This relative lack of spontaneous analogical transfer and predominance of surface remindings is seen in problem solving (Ross 1987) and may result in part from overly concrete representations (Bassok, Wu, and Olseth 1995).

Computational models of similarity-based retrieval have taken two main approaches. One class of models aims to capture the phenomena of human memory retrieval, including both strengths and weaknesses. For example, analog retrieval by constraint satisfaction (ARCS; Thagard et al. 1990) and Many are called/but few are chosen (MAC/FAC; Forbus, Gentner, and Law 1995) both assume that retrieval is strongly influenced by surface similarity and by structural similarity, goal relevance, or both. In contrast, most case-based reasoning (CBR) models aim for optimality, focusing on how to organize memory such that relevant cases are retrieved when needed.

Theories of analogy have been extended to other kinds of similarity, such as METAPHOR and mundane literal similarity. There is evidence that computing a literal similarity match involves the same process of structural alignment as does analogy (Gentner and Markman 1997). Current computational models like ACME and SME use the same processing algorithms for similarity as for analogy.

The investigation of analogy has been characterized by unusually fruitful interdisciplinary convergence. Important contributions have come from philosophy, notably Hesse's analysis (1966) of analogical models in science, and from artificial intelligence (AI), beginning with Winston's research (1982), which laid out computational strategies applicable to human processing. Recent research that combines psychological investigations and computational modeling has advanced our knowledge of how people align representational structures and compute further inferences over them. Theories of analogy and structural similarity have been successfully applied to areas such as CATEGORIZATION, DECISION MAKING, and children's learning. At the same time, cross-species comparisons have suggested that analogy may be especially well developed in human beings. These results have broadened our view of the role of structural similarity in human thought.

Anaphora

The term *anaphora* is used most commonly in theoretical linguistics to denote any case where two nominal expressions are assigned the same referential value or range. Discussion here focuses on noun phrase (NP) anaphora with pronouns (see BINDING THEORY for an explanation of the types of expressions commonly designated "anaphors," e.g., reflexive pronouns).

Pronouns are commonly viewed as variables. Thus, (1b) corresponds to (2), where the predicate contains a free variable. This means that until the pronoun is assigned a value, the predicate is an open property (does not form a set). There are two distinct procedures for pronoun resolution: *binding* and *covaluation.* In binding, the variable gets bound by the λ-operator, as in (3a), where the predicate is closed, denoting the set of individuals who think they have the flu, and where the sentence asserts that Lili is in this set.

(1) a. Lucie didn't show up today.
    b. Lili thinks she's got the flu.

(2) Lili (λx (x thinks z has got the flu))

(3) a. *Binding:* Lili (λx (x thinks x has got the flu))
    b. *Covaluation:* Lili (λx (x thinks z has got the flu) & z = Lucie)

In covaluation, the free variable is assigned a value from the DISCOURSE storage, as in (3b). An assumption standard since the 1980s is that, while processing sentences in context, we build an inventory of discourse entities, which can

further serve as antecedents of anaphoric expressions (Heim 1982; McCawley 1979; Prince 1981). Suppose (1b) is uttered in the context of (1a). We have stored an entry for *Lucie,* and when the pronoun *she* is encountered, it can be assigned this value. In theory-neutral terms, this assignment is represented in (3b), where *Lucie* is a discourse entry, and the pronoun is covalued with this entry.

The actual resolution of anaphora is governed by discourse strategies. Ariel (1990) argues that pronouns look for the most accessible antecedent, and discourse topics are always the most accessible. For example, (3b) is the most likely anaphora resolution for (1b) in the context of (1a), since *Lucie* is the discourse topic that will make this minimal context coherent.

Given the two procedures, it turns out that if *Lili* is identified as the antecedent of the pronoun in (1b), the sentence has, in fact, two anaphora construals. Since *Lili* is also in the discourse storage, (1b) can have, along with (3a), the covaluation construal (4).

(4) Lili (λx (x thinks z has got the flu) & z = Lili)

(5) Lili thinks she has got the flu, and Max does too.

Though (3a) and (4) are equivalent, it was discovered in the 1970s that there are contexts in which these sentences display a real representational ambiguity (Keenan 1971). For example, assuming that *she* is *Lili,* the elliptic second conjunct of (5) can mean either that Max thinks that Lili has the flu, or that Max himself has it. The first is obtained if the elided predicate is construed as in (4), and the second if it is the predicate of (3a).

Let us adopt here the technical definitions in (6). ((6a) differs from the definition used in the syntactic binding theory). In (3a), then, *Lucie* binds the pronoun; in (4), they are covalued.

(6) a. Binding: α binds β iff α is an argument of a λ-predicate whose operator binds β.
    b. Coevaluation: α and β are covalued iff neither binds the other and they are assigned the same value.

Covaluation is not restricted to referential discourse-entities—a pronoun can be covalued also with a bound variable. Indeed, Heim (1998) showed that covaluation-binding ambiguity can show up also in quantified contexts. In (7a), the variable *x* (*she*) binds the pronoun *her.* But in (7b) *her* is covalued with *x.*

(7) Every wife thinks that only she respects her husband.
    a. Binding: Every wife (λx (x thinks that [only x (λy(y respects y's husband))]))
    b. Coevaluation: Every wife (λx (x thinks that [only x (λy(y respects x's husband))]))

In many contexts the two construals will be equivalent, but the presence of *only* enables their disambiguation here: (7a) entails that every wife thinks that other wives do not respect their husbands, while (7b) entails that every wife thinks other wives do not respect her husband. This is so, because the property attributed only to *x* in (7a) is respecting one's own husband, while in (7b) it is respecting *x*'s husband.

The binding interpretation of pronouns is restricted by syntactic properties of the derivation (see BINDING THEORY).

A question that has been debated is whether there are also syntactic restrictions on their covaluation interpretation. On the factual side, under certain syntactic configurations, covaluation is not allowed. For example, in (9), binding is independently excluded. The NP Lucie is not in a configuration to bind the pronoun (since it is not the argument of a λ-predicate containing the pronoun). Suppose, however, that (9) is uttered in the context of (8), so that Lucie is in the discourse storage. The question is what prevents the covaluation construal in (10) for (9) (# marks an excluded interpretation). It cannot be just the fact that the pronoun precedes the antecedent. For example, in (11), the preceding pronoun can be covalued with Max.

(8) Can we go to the bar without Lucie?

(9) She said we should invite Lucie.

(10) #She (λx x said we should invite Lucie) & she = Lucie)

(11) a. The woman next to him kissed Max.
      b. The woman next to him (λx (x kissed Max) & him = Max)

In the 1970s, it was assumed that there is a syntactic restriction blocking such an interpretation (Langacker 1966; Lasnik 1976). Reinhart (1976) formulated it as the requirement that a pronoun cannot be covalued with a full NP it c-commands, which became known as Chomsky's "condition C" (1981). (In (11), the pronoun does not c-command *Max.*) Another formulation in logical syntax terms was proposed by Keenan (1974): The reference of an argument must be determinable independently of its predicate.

The empirical problem with these restrictions is that, as shown in Evans (1980), there are systematic contexts in which they can be violated. Reinhart (1983) argued that this is possible whenever covaluation is not equivalent to binding.

(12) [Who is the man with the gray hat?] He is Ralph Smith.
      a. He (λx (x is Ralph Smith) & he = Ralph Smith)
      b. He (λx (x is x) & he = Ralph Smith)

(13) Only he (himself) still thinks that Max is a genius.
      a. Only he (λx (x thinks Max is a genius) & he = Max)
      b. Only Max (λx (x thinks x is a genius)

In (12), it is not easy to imagine a construal of the truth conditions that would not include covaluation of the pronoun with *Ralph Smith.* But this covaluation violates condition C, as does (13). In both cases, however, the covaluation reading (a) is clearly distinct from the bound reading (b). (12b) is a tautology, whereas (12a) is not. (13a) attributes a different property only to Max from what (13b) does. Believing oneself to be a genius may be true of many people, but what (13) attributes only to Max is believing Max to be a genius (13a).

The alternative (proposed by Reinhart 1983) is that covaluation is not governed by syntax, but by a discourse strategy that takes into account the options open for the syntax in generating the given derivation. The underlying assumption is that variable binding is a more efficient way to obtain anaphora than covaluation. So whenever the syntactic configuration allows, in principle, variable binding, obtaining an equivalent anaphora-interpretation through covaluation is excluded. Given a structure like (9), variable binding could be derived, with a different placement of Lucie and her, as in Lucie said we should invite her. The result would be equivalent to the covaluation construal (10) (for (9)). Hence, (10) is excluded. In (11a), no placement of *he* and *Max* could enable variable binding, so the covaluation in (11b) is the only option for anaphora. When a variable binding alternative exists, but it is not equivalent to covaluation, covaluation is permitted, as in (12)–(13).

A relevant question is why variable binding is more efficient than covaluation. One answer, developed in Levinson (1987), is purely pragmatic and derives this from the Gricean maxims of quantity and manner. The other, developed in Fox (1998), is based on the notion of semantic processing: variable binding is less costly since it enables immediate closure of open properties, while covaluation requires that the property is stored open until we find an antecedent for the variable.

The optimality account for the covaluation restriction entails a much greater computational complexity than the syntactic approach (condition C), since it requires constructing and comparing two interpretations for one derivation. This is among the reasons why covaluation is still a matter of theoretical debate. Nevertheless, evidence that such complexity is indeed involved in computing sentences like (10) comes from the acquisition of anaphora. Many studies (e.g., Wexler and Chien 1991) report that children have much greater difficulties in ruling out illicit covaluation than in violations of the syntactic restrictions on variable binding. Grodzinsky and Reinhart (1993) argue that this is because their working memory is not yet sufficiently developed to carry such complex computation.

Animal Cognition

See ANIMAL NAVIGATION; COMPARATIVE PSYCHOLOGY; PRIMATE COGNITION; SOCIAL PLAY BEHAVIOR

Animal Communication

Fireflies flash, moths spray pheromones, bees dance, fish emit electric pulses, lizards drop dewlaps, frogs croak, birds sing, bats chirp, lions roar, monkeys grunt, apes grimace, and humans speak. These systems of communication, irrespective of sensory modality, are designed to mediate a flow of information between sender and receiver (Hauser 1996).

Early ethologists argued that signals are designed to proffer information to receptive companions, usually of their own species (Tinbergen 1951; Hinde 1981; Smith 1969). When a bird or a monkey gives a "hawk call," for example, this conveys information about a kind of danger. And when a redwing blackbird reveals its red epaulette during territorial disputes, it is conveying information about aggressive intent. Analyses of aggressive interactions, however, revealed only weak correlations between performance of certain displays and the probability of attack as opposed to retreat, leaving the outcome relatively unpredictable (Caryl 1979). Thus, while information transfer is basic to all communication, it is unclear how best to characterize the information exchange, particularly because animals do not always tell the truth.

In contradistinction to the ethologists, a new breed of animal behaviorist—the behavioral ecologists—proposed an alternative approach based on an economic cost-benefit analysis. The general argument was made in two moves: (1) selection favors behavioral adaptations that maximize gene propagation; and (2) information exchange cannot be the entire function of communication because it would be easy for a mutant strategy to invade by providing dishonest information about the probability of subsequent actions. This

places a premium on recognizing honest signals. Zahavi (1975) suggested a mechanism for this, using the following recipe: signals are honest, if and only if they are costly to produce relative to the signaler's current condition and if the capacity to produce honest signals is heritable. Consider the anti predator stotting displays of ungulates—an energetically expensive rigid-legged leap. In Thompson's gazelle, only males in good physical condition stot, and stotting males are more likely to escape cheetah attacks than those who do not.

Departing slightly from Zahavi, behavioral ecologists Krebs and Dawkins (1984) proposed that signals are designed not to inform but to manipulate. In response to such manipulation, selection favors skeptical receivers determined to discriminate truths from falsehoods. Such manipulative signaling evolves in situations of resource competition, including access to mates, parental care, and limited food supplies. In cases where sender and receiver must cooperate to achieve a common goal, however, selection favors signals that facilitate the flow of information among cooperators. Thus signals designed to manipulate tend to be loud and costly to produce (yelling, crying with tears), whereas signals designed for cooperation tend to be quiet, subtle, and cheap (whispers).

Turning to ecological constraints, early workers suggested that signal structure was conventional and arbitrary. More in-depth analyses, however, revealed that the physical structure of many signals is closely related to the functions served (Green and Marler 1979; Marler 1955). Thus, several avian and mammalian species use calls for mobbing predators that are loud, short, repetitive, and broad band. Such sounds attract attention and facilitate sound localization. In contrast, alarm calls used to warn companions of an approaching hawk are soft, high-pitched whistles, covering a narrow frequency range, only audible at close range and hard to locate (Marler 1955; Klump and Shalter 1984). The species-typical environment places additional constraints on the detectability of signals and the efficiency of transmission in long-distance communication, selecting for the optimal time of day and sound frequency window (Marten, Quine, and Marler 1977; Morton 1975; Wiley and Richards 1978). To coordinate the movements of groups who are out of sight, elephants and whales use very low frequency sounds that circumvent obstacles and carry over long distances. In contrast, sounds with high frequency and short wavelengths, such as some alarm calls and the biosonar signals used by bats and dolphins for obstacle avoidance and prey capture, attenuate rapidly.

The design of some signals reflects a conflict between natural and sexual selection pressures (Endler 1993). An elegant example is the advertisement call of the male *Tungara* frog (Ryan and Rand 1993). In its most complete form, one or more introductory whines are followed by chucks. Because females are attracted to the chucks, males who produce these sounds have higher mating success. But because frog-eating bats can localize chucks more readily than whines, frogs producing chucks are more likely to be eaten. They compromise by giving more whines than chucks until a female comes by. There are many such cases in which signal design is closely related to function, reflecting a tightly stitched tapestry of factors that include the sender's production capabilities, habitat

structure, climate, time of day, competitors for signal space, the spatiotemporal distribution of intended recipients, and the pressures of predation and mate choice.

When signals are produced or perceived, complex processing by the sense organs and the central nervous system is engaged. Songbirds have a set of interconnected forebrain nuclei specialized for song learning and production. Nuclei vary widely in size between the sexes, between species and even between individuals of the same sex, though there are significant exceptions to these generalizations. Variations appear to correlate, not only with the commitment to singing behavior, but also with the size of the song repertoire (Arnold 1992; Nottebohm 1989). Some aspects of song learning are analogous to those documented for human speech, including involvement of particular brain areas, local dialects, categorical perception, innate learning preferences, and a motor theory-like system for coordinating articulatory production and feature perception (Nelson and Marler 1989).

For most animals, the acoustic morphology of the vocal repertoire appears to be innately specified, with experience playing little to no role in altering call structure during development. In contrast, the ontogeny of call usage and comprehension is stongly influenced by experience in several nonhuman primates, and possibly in some birds (Cheney and Seyfarth 1990; Hauser 1996; Marler 1991), with benefits accruing to individuals that can learn to use call types and subtypes in new ways. Generally speaking, however, the number of discrete signals in animal repertoires seems to be limited (Green and Marler 1979; Moynihan 1970), although reliable repertoire estimates are hard to come by, especially when signals intergrade extensively. Explosive expansion of the repertoire becomes possible if elements of the repertoire can be recombined into new, meaningful utterances, as they are in human speech.

Empirical studies documenting the decomposability of speech into smaller units, themselves meaningless, prepared the groundwork for the Chomskyan revolution in linguistics. The human brain takes our repertoire of phonemes and recombines them into an infinite variety of utterances with distinct meanings. There is no known case of animals using this combinatorial mechanism. Some birds create large learned song repertoires by recombination, but like human music, birdsongs are primarily affective signals, lacking the kind of referential meaning that has been attributed to primate vocalizations and chicken calls. Thus it appears that the songbirds' repertoire expansion serves more to alleviate habituation than to enrich meaning. The same is almost certainly true of animals with innate repertoires that engage in a more limited degree of recombination, although some researchers have reported evidence of syntactical organization (Hailman et al. 1987). More detailed analyses of the production and perception of vocal signals are required before we can reach any comprehensive conclusions on the developmental plasticity of animal communication systems.

At least one bird (the domestic chicken) and a few primates (ring-tailed lemurs, rhesus and diana monkeys, vervets) produce vocalizations that are functionally referential, telling others about specific objects and events (food, predators). Use of such calls is often contingent on the presence and nature of a social audience (e.g., allies or enemies). Vocalizing animals will, for example, withhold alarm calling in response to a predator if no audience is present, and in other cases, will use vocalizations to actively falsify information (Cheney and Seyfarth 1990; Evans and Marler 1991; Marler, Karakashian, and Gyger 1991; reviewed in Hauser 1996). While there is no evidence that animal signals are guided by awareness of beliefs, desires, and intentions, essential to human linguistic behavior (see PRIMATE COGNITION), there is a clear need for researchers in call semantics and cognition to work closely together to elucidate the mental states of animals while communicating.

Animal Navigation

Animal navigation is similar to conventional (formalized) navigation in at least three basic ways. First, it relies heavily on *dead reckoning,* the continual updating of position by summing successive small *displacements* (changes in position). In the limit (as the differences between successive positions are made arbitrarily small), this process is equivalent to obtaining the position vector by integrating the velocity vector with respect to time, which is why the process is

also called *path integration* (see Gallistel 1990, chap. 4, for review of literature).

Second, it only occasionally *takes a fix,* that is, establishes position and *heading* (orientation) on a map using perceived distances and directions from mapped features of the terrain. While it is necessary from time to time to correct the inevitable cumulative error in dead reckoning, animals, like human navigators, often invert the process in the intervals between fixes, using their reckoned position and heading on their map to estimate their relation to surrounding features. In doing so, they appear to ignore the current testimony of their senses. Thus, when the dimensions of a familiar maze are altered, a rat moving rapidly through it collides with walls that come too soon, and turns into a wall where it expects an opening (Carr and Watson 1908). Indeed, it runs right over the pile of food that is its goal when it encounters that pile much sooner than expected (Stoltz and Lott 1964). Bats threading their way through obstacle courses bring their wings together over their head to squeeze through a gap that is no longer so narrow as to require this maneuver (Neuweiler and Möhres 1967).

And third, it places relatively minor reliance on *beacon navigation,* the following of sensory cues from a goal or its immediate surroundings. Animals of widely diverse species locate a goal by the goal's position relative to the general framework provided by the mapped terrain (see Gallistel 1990, chap. 5, for review), not by the sensory characteristics of the goal or its immediate surroundings. Indeed, when the two are placed in conflict, the animal goes to the place having the correct position in the larger framework, not to the place having the correct sensory characteristics. For example, if a chimpanzee sees food hidden in one of two differently colored containers whose positions are then surreptitiously interchanged, the chimpanzee searches for the food in the container at the correct location rather than in the one with the correct color (Tinkelpaugh 1932). In human toddlers, position also takes precedence over the characteristics of the container. When a toddler is misoriented within a rectangular room, it ignores the container in which it saw a toy hidden, but which it now mistakenly takes to be in the wrong location. It looks instead in an altogether different container, which it takes to be in the correct location, even though the child demonstrably remembers the appearance of the container in which it saw the toy hidden (Hermer and Spelke 1996).

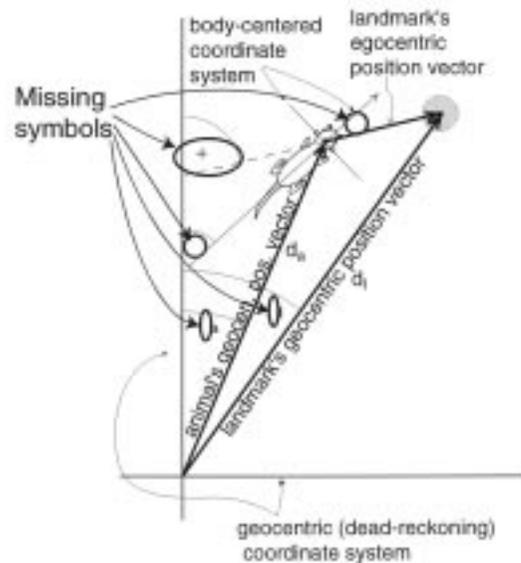
The sensory cues from the goal itself appear to control approach behavior only in the final approach to the goal, and even then, only when the goal is in approximately the correct location. The same is true for the nearby landmarks with respect to which an animal more precisely locates its goal. It uses them as aids to locating its goal only if they occupy approximately the correct place in the larger framework. Bees readily learn to search for food on one side of a landmark in one location but on the opposite side of the identical landmark placed in a different location (Collett and Kelber 1988). In effect, location confers identity, rather than vice versa. A container or landmark with the wrong properties in the right place is taken to be the correct container or landmark, while a container or landmark with the correct properties in the wrong place is taken to be a different container or different landmark.


Figure 1. Conversion of egocentric position coordinates to a common geocentric framework. The egocentric position vector of the landmark, with angle β (bearing of landmark) and magnitude d_1 is first rotated so that it has angle $\eta + \beta$ (heading plus bearing), then added to the geocentric position vector of the animal (with compass angle γ_a and magnitude d_a), producing the geocentric position vector for the landmark (with compass angle γ_l and magnitude d_l). (Slightly modified from figure 1 in Gallistel and Cramer 1996. Used by permission of the authors and publisher.)

From the above, it is clear that COGNITIVE MAPS are a critical component in animal navigation, just as conventional maps are in conventional navigation. A cognitive map is a representation of the layout of the environment. Its properties and the process by which it is constructed are questions of basic importance. These cognitive maps are known to be *Euclidean, sense-preserving* representations of the environment, that is, they encode the metric relations (distances and angles) and the sense relation (right versus left). This is most readily demonstrated by showing an animal the location of a hidden goal within a featureless rectangular room, then inertially disorienting the animal (by slow rotation in the dark) before allowing it to search for the goal. Animals of diverse species search principally at the correct location and its rotational equivalent, for example, in the correct corner and the corner diagonally opposite to it (Cheng 1986; Hermer and Spelke 1996; Margules and Gallistel 1988). They rarely look elsewhere, for example, in the other two corners. To distinguish between the diagonals of a rectangle, however, they must record both metric relations and sense relations on their map of the rectangular room. The short wall is on the left for one diagonal, regardless of which way one faces along that diagonal, but on the right for the other diagonal. If an animal could not distinguish walls based on their length (a metric relationship), or on which was to the left and which to the right (a sense relationship), then it could not distinguish between the diagonals of a rectangle.

Until recently, there were no suggestions about how animals might construct a Euclidean map of their environment. They only perceive small portions of it at any one time, so how can they perceive the relations between these portions? Recently, it has been suggested that the dead reckoning process is the key to the construction of the map (Gallistel 1990; Gallistel and Cramer 1996; McNaughton et al. 1996) because it specifies the Euclidean relationship between different points of view within a *geocentric framework,* a system of coordinates anchored to the earth, as opposed to an *egocentric framework,* a system of coordinates anchored to the animal's body (egocentric position vector in figure). Rotating the egocentric position vector by the animal's heading (its orientation in the geocentric framework) and adding the rotated vector to the geocentric position vector provided by the dead reckoning process carries the representation of the perceived portion of the environment into a common geocentric positional framework (landmark's geocentric position vector in figure). This method of map construction, in which the animal's dead reckoning automatically represents its position on its cognitive map, tells us much about how the animal perceives the shape of its environment.

Animal Navigation, Neural Networks

Animals show a remarkable ability to navigate through their environment. For example, many animals must cover large regions of the local terrain in search of a goal (food, mates, etc.), and then must be able to return immediately and safely to their nesting spot. From one occasion to the next, animals seem to use varied, novel trajectories to make these searches, and may enter entirely new territory during part of the search. Nonetheless, on obtaining the goal, they are typically able to calculate a direct route to return to their home base.

For many species, this ANIMAL NAVIGATION is thought to be based on two general abilities. The first, called "dead reckoning" (or "path integration"), uses information about the animal's own movements through space to keep track of current position and directional heading, in relation to an abstract representation of the overall environment. The second, landmark-based orientation, uses familiar environmental landmarks to establish current position, relative to familiar terrain.

Over the last few decades, some insight has been gained about how NEURAL NETWORKS in the mammalian brain might work to provide the basis for these abilities. In particular, two specialized types of cells have been observed to possess relevant spatial signals in the brains of navigating rats.

"Place cells," originally discovered in the rat HIPPOCAMPUS (O'Keefe and Dostrovsky 1971), fire whenever the animal is in one specific part of the environment. Each place cell has its own, unique region of firing. As the animal travels through the environment, these cells seem to form a maplike representation, with each location represented by neural activity in a specific set of place cells.

Remarkably, these cells also seem to use the two general abilities mentioned above: dead reckoning and landmark-based orientation. Evidence that place cells use landmarks to establish the place-specific firing patterns came from early studies in which familiar landmarks were moved (e.g., O'Keefe and Conway 1978; Muller and Kubie 1987). For example, in one experiment (Muller and Kubie 1987), rats foraged in a large, cylindrical apparatus, equipped with a single, white cue card on its otherwise uniformly gray wall. When this single orienting landmark was moved to a different location on the wall, this caused an equal rotation of the place cell firing fields. Evidence that the cells can also use dead reckoning, however, was obtained from studies in which the landmarks were removed entirely (e.g., Muller and Kubie 1987; O'Keefe and Speakman 1987). In this case, the place cells were often able to maintain their firing patterns, so that they continued to fire in the same location, as the animal made repeated, winding trajectories through the environment. It was reasoned that this ability must be based on a dead reckoning process because in the absence of orienting landmarks, the only ongoing information about current position would have to be based on the animal's own movements through space. Further support for the dead reckoning (path integration) process came from a study in which artificial movement-related information was given directly to the animal while it navigated (Sharp et al. 1995). Animals foraged in a cylinder with black and white stripes, of uniform width.

Both activation of the vestibular system (indicating that the animal had moved through space), or rotation of the vertical stripes (as would happen due to the animal's own movement in relation to the stripes) could sometimes "update" the place cell firing fields, so that they shifted the location of their fields, as though the animal had actually moved in the way suggested by the vestibular or optic flow input. Thus movement-related inputs directly influence the positional setting of the hippocampal place cells.

The second type of navigation-related cells, known as "head direction cells" (Taube, Muller, and Ranck 1990a), complement the place cells by signaling the animal's current directional heading, regardless of its location. Each head direction cell fires whenever the animal is facing one particular direction (over an approximately 90 degree range). Each has its own, unique, directional preference, so that each direction the animal faces is represented by activity in a particular subset of head direction cells. These cells were initially discovered in the postsubiculum (a brain region closely related to the hippocampus), and have since been discovered in several other anatomically related brain regions.

Although it might be thought that these directional cells derive a constant, earth-based orientation from geomagnetic cues, this seems not to be the case. Rather, like place cells (and the animal's own navigational behavior), head direction cells seem to use both landmark orientation and dead reckoning (Taube, Muller, and Ranck 1990b). For example, in a familiar environment, these cells will rotate the preferred direction when familiar landmarks are rotated, using the landmarks to get a "fix" on the animal's current directional heading. When, however, all familiar landmarks are removed, the cells retain the animal's previously established directional preference. And, again like place cells, head direction cells use both vestibular and optic flow information to update their locational setting (Blair and Sharp 1996).

Theoretical models have been developed to simulate the spatial firing properties of these cells (e.g., Blair 1996; McNaughton et al. 1995; Skaggs et al. 1995; Redish, Elga, and Touretzky 1997; Samsonovich and McNaughton 1997). Most of these models begin with the idea that the place and head direction cells are respectively linked together to form stable attractor networks that can stabilize into a unitary representation any one of the possible places or directions. For example, in the head direction cell system, cells representing similar directional headings are linked together through predominantly excitatory connections, while cells representing different directional headings are linked through inhibitory connections. This reflects the basic phenomenon that, at any one time, cells within one particular portion of the directional range (e.g., 0 to 90 degrees) will be active, while all other head direction cells will be silent. Thus the stable attractor network, left on its own, will always settle into a representation of one particular direction (place). To reflect the finding that place and head direction cells can be "set" by environmental landmarks, most models equip the cells with sensory inputs that can influence which particular place or direction is represented. To reflect the finding that the navigation system can also be updated by movement related information, most models also incorporate an additional layer of cells (in some other, as yet unidentified brain

region) that combines place or head direction information, along with movement-related cues, to feed back onto the place or head direction cells, permitting them to choose a new locational or directional setting in response to movement.

While these complementary place and directional representations are thought to guide the animal's overall navigational behavior (see O'Keefe and Nadel 1978), the mechanism is not yet clear.

Animism

Animism means labeling inanimate objects as living, attributing characteristics of animate objects (typically humans) to inanimate objects, and making predictions or explanations about inanimate objects based on knowledge about animate objects (again usually represented by human beings). *Anthropomorphism* or *personification* means the extension of human attributes and behaviors to any nonhumans. Thus animistic reasoning can be regarded as personification of an inanimate object. In both cases, assigning mental states (desires, beliefs, and consciousness) to inanimate objects, including extraterrestrial entities (e.g., the sun) and geographical parts (e.g., a mountain), provides the most impressive example ("The sun is hot because it wants to keep people warm").

The term *animism* was introduced by English anthropologists to describe mentalities of indigenous people living in small, self-sufficient communities. Although such usage was severely criticized by Lévy-Bruhl (1910), the term became popular among behavioral scientists, as PIAGET (1926) used it to characterize young children's thinking. Piaget and his followers (e.g., Laurendeau and Pinard 1962) took animistic and personifying tendencies as signs of immaturity, as reflecting the fact that young children have not yet learned to differentiate between animate and inanimate objects or between humans and nonhumans. Chiefly because of methodological differences, a large number of studies on child animism inspired by Piaget, conducted in the 1950s and early 1960s, obtained conflicting results as to the frequency of animistic responses (Richards and Siegler 1984), but the results were discussed only within the Piagetian framework.

Since the 1980s, studies of young children's biological understanding or naive biology have shed new light on child animism. A number of investigators have shown that even young children possess the knowledge needed to differentiate between humans, typical nonhuman animate objects, and inanimate ones (see COGNITIVE DEVELOPMENT). For example, Gelman, Spelke, and Meck (1983) found that even three-year-olds can almost always correctly attribute the presence or absence of animal properties to familiar animals and nonliving things. Simons and Keil (1995) demonstrated that young children can distinguish between natural and artificial constituent parts of their bodies even when they do not know specifics about them. Young children may even assume that each animal and plant has its underlying essential nature (Gelman, Coley, and Gottfried 1994; see also ESSENTIALISM).

Then why do young children, even when they are intellectually serious, make animistic or personifying remarks fairly often, although not so often as Piaget claimed? What functions does the mode of reasoning behind animistic or personifying errors have? Both Carey (1985) and Inagaki and Hatano (1987) propose that, though young children are able to classify entities into ontological categories, when they have to infer an object's unknown attributes or reactions, the children apply their knowledge about human beings to other animate objects or even to inanimate objects. This is probably because they do not have rich categorical knowledge, and thus have to rely on ANALOGY in inferences. Because they are intimately familiar with humans, although necessarily novices in most other domains, they can most profitably use their knowledge about humans as a source analogue for making analogies.

Inagaki and Hatano (1987) propose that animistic or personifying tendencies of young children are products of their active minds and basically adaptive natures. Young children's personification or person analogies may lead them to accurate predictions for animate objects phylogenetically similar to humans. It can also provide justification for a variety of experiences, sometimes even with phylogenetically less similar objects, such as trees or flowers. Young children may have learned these heuristic values through their prior contacts with a variety of animate objects. The analogies young children make may involve structurally inaccurate mapping (e.g., mapping the relation between humans and food to that between plants and water), and induce biased reasoning (neglect of the roles of nutrients in the soil and photosynthesis). Although young children may carry analogy beyond its proper limits, and produce false inferences, they can generate "educated guesses" by analogies, relying on their only familiar source analogue of a person (Holyoak and Thagard 1995). Animistic errors and overattribution of human characteristics to nonhuman animate objects should therefore be regarded as accidental by-products of this reasoning process. Because their personification is subject to a variety of constraints, such as checking the plausibility of the inference against what is known about the target, it does not produce many personifying errors, except for assigning mental states to nonhumans.

How can we explain animistic thinking among indigenous adults? According to Atran (forthcoming), in cultures throughout the world it is common to classify all entities into four ontological categories (humans, nonhuman animals, plants, and nonliving things, including artifacts), and to arrange animals and plants hierarchically and more or less accurately because such taxonomies are products of the human mind's natural classification scheme (see also FOLK BIOLOGY). Because indigenous people generally possess rich knowledge about major animals and plants in their ecological niche, their animistic and personifying remarks cannot result from having to rely on the person analogy, except for poorly understood nonnatural entities like God (Barrett and Keil 1996). Such remarks seem to be products of cultural beliefs, acquired through discourse about a specific class of entities. Mead's early observation (1932) that children in the Manus tribes were less animistic than adults lends support to this conjecture. Animistic or personifying explanations are widespread, but they are more about the metaphysical or imaginative universe than about the real world (Atran 1990). Even contemporary Japanese culture, outside the science classroom does not consider it a silly idea that large, old inanimate entities (e.g., giant rocks, mountains) have CONSCIOUSNESS.

Anomalous Monism

Anomalous monism is the thesis that mental entities (objects and events) are identical with physical entities, but under their mental descriptions mental entities are neither definitionally nor nomologically reducible to the vocabulary of physics. If we think of views of the relation between the mental and the physical as distinguished, first, by whether or not mental entities are identical with physical entities, and, second, divided by whether or not there are strict psychophysical laws, we get a fourfold classification: (1) *nomological monism,* which says there are strict correlating laws, and that the correlated entities are identical (this is often called materialism); (2) *nomological dualism* (interactionism, parallelism, epiphenomenalism); (3) *anomalous dualism,* which holds there are no laws correlating the mental and the physical, and the substances are discrete (Cartesianism); and (4) *anomalous monism,* which allows only one class of entities, but denies the possibility of definitional and nomological reduction. It is claimed that anomalous monism is the answer to the MIND-BODY PROBLEM, and that it follows from certain premises, the main ones being:

1. All mental events are causally related to physical events. For example, changes in PROPOSITIONAL ATTITUDES such as beliefs and desires cause agents to act, and actions cause changes in the physical world. Events in the physical world often cause us to alter our beliefs, intentions and desires.

2. If two events are related as cause and effect, there is a strict law under which they may be subsumed. This means that cause and effect have descriptions that instantiate a strict law. A strict law is one that makes no use of open-ended escape clauses such as "other things being equal." Such laws must belong to a closed system: whatever can affect the system must be included in it.

3. There are no strict psychophysical laws (laws connecting or identifying mental events under their mental descriptions with physical events under their physical descriptions). From this premise and the fact that events described in psychological terms do not belong to a closed system, it follows that there are no strict PSYCHOLOGICAL LAWS; psychological laws, if carefully stated, must always contain ceteris paribus clauses.

Take an arbitrary mental event *M*. By (1), it is causally connected with some physical event *P*. By (2), there must be a strict law connecting *M* and *P*; but by (3), that law cannot be a psychophysical law. Because only physics aims to provide a closed system governed by strict laws, the law connecting *M* and *P* must be a physical law. But then *M* must have a physical description—it must be a physical event.

(The term "anomalous monism" and the argument were introduced in Davidson 1970.)

The three premises are not equally plausible. (1) is obvious. (2) has seemed true to many philosophers; HUME and KANT are examples, though their reasons for holding it were very different (Davidson 1995). It has been questioned by others (Anscombe 1971; Cartwright 1983). A defense of (2) would begin by observing that physics is defined by the aim of discovering or devising a vocabulary (which among other things determines what counts as an event) which allows the formulation of a closed system of laws. The chief argument for the nomological and definitional irreducibility of mental concepts to physical is that mental concepts, insofar as they involve the propositional attitudes, are normative, while the concepts of a developed physics are not. This is because propositions are logically related to one another, which places a normative constraint on the correct attribution of attitudes: since an attitude is in part identified by its logical relations, the pattern of attitudes in an individual must exhibit a large degree of coherence. This does not mean that people may not be irrational, but the possibility of irrationality depends on a background of rationality (Davidson 1991).

(3) rules out two forms of REDUCTIONISM: reduction of the mental to the physical by explicit definition of mental predicates in physical terms (some forms of behaviorism suggest such a program), and reduction by way of strict bridging laws—laws that connect mental with physical properties. (1)–(3) do, however, entail ontological reduction, because they imply that mental entities do not add to the physical furniture of the world. The result is ontological monism coupled with conceptual dualism. (Compare Spinoza's metaphysics.) Anomalous monism is consistent with the thesis that psychological properties or predicates are supervenient on physical properties or predicates, in this sense of SUPERVENIENCE: a property *M* is supervenient on a set of properties *P* if and only if *M* distinguishes no entities not distinguishable by the properties in *P* (there are other definitions of supervenience).

A widely accepted criticism of anomalous monism is that it makes MENTAL CAUSATION irrelevant because it is the physical properties of events that do the causing (Kim 1993). The short reply is that it is events, not properties, that are causes and effects (Davidson 1993). If events described in physical terms are effective, and they are identical with those same events described in psychological terms, then the latter must also be causally effective. The vocabularies of physics and of psychology are irreducibly different ways of describing and explaining events, but one does not rule out, or supercede, the other.

Aphasia

Aphasia (acquired aphasia) is a disorder of communication caused by brain damage. The acquired aphasias constitute a family of disruptions to comprehension and production of language in both oral and written form. Much of the history of aphasia has been (and continues to be) concerned with attempts to characterize the natural organization of language as revealed by the selective manner in which language breaks down under focal brain damage.

The history of the field has precursors in the very earliest recordings of medicine, but largely achieved modern form with the work of Paul BROCA (1861) and Carl Wernicke (1874). From this clinical work, two generalizations concerning the brain-language relationship were derived that have become canonical in the field. First, it was documented that lesions to areas in the left, but not right, cerebral hemisphere standardly result in language disruption (leading to the concept of unilateral cerebral dominance for language; e.g., Broca 1865). Second, within the left hemisphere, lesions to different areas result in reliably different patterns of language loss (e.g., Wernicke 1874).

Thus, damage to what has become known as Broca's area, in the lower portion of the left frontal lobe (more particularly, the opercular and triangular parts of the inferior frontal gyrus, including the foot of the third frontal convolution, and extending into subcortical white matter), produces clinical observations of difficulty in articulation and production of speech with relative (but not complete) sparing of comprehension, resulting in what has come to be called Broca's aphasia. Patients with damage to this area produce little (or at least labored) speech, which is poorly articulated and telegraphic, involving omission of so-called function or closed-class words (articles, auxiliaries, etc.). Their speech relies heavily on nouns, and (to a far smaller degree) verbs. Their written communication follows this same production-comprehension dissociation, with impaired writing but often less severe disturbance to reading. Because Broca's area lies next to motor areas for muscular control of speech (lips, palate, vocal chords, jaw), early assumptions were that Broca's area was a center for the encoding of articulated speech.

Wernicke's aphasia, by contrast, results from damage to the posterior region of the left hemisphere, specifically in the areas adjacent to the primary auditory cortex on the posterior portion of the superior left temporal gyrus. Patients with Wernicke's aphasia produce speech that is fluent, effortless, and rapid (hence the term *fluent aphasia*). The content of their productions, however, is remarkably "empty" and filled with inappropriate word use (verbal paraphasias). Importantly, patients with Wernicke's aphasia demonstrate a profound comprehension deficit—often even at the single word level. Both writing and (particularly) READING are standardly highly impaired.

The discovery of a link between these two distinct types of language disruption and two distinct brain areas led to neuroanatomical-connectionist models of brain organization for language (Wernicke 1874; Lichtheim 1884), which, in one form or another, have been pervasive through to the later twentieth century (e.g., GESCHWIND 1979). These models attempted to capture and predict the wide variety of language deficits that had been reported throughout the literature in terms of "disconnection" syndromes. Thus, for example, the early Wernicke-Lichtheim connectionist model easily represented the fact that damage to the arcuate fasciculus (which roughly connects Wernicke's to Broca's area) leads to the inability to repeat language, a syndrome that was termed *conduction aphasia*. (For a complete review of aphasic syndromes, see Goodglass 1993.)

Early versions of such models were modality-based, viewing Broca's and Wernicke's areas as essentially motor and sensory language areas, respectively. Broca's area was considered primarily responsible for the encoding of articulatory form for production (speaking), and Wernicke's area was considered primarily responsible for the organization of language perception (listening/understanding).

However, these connectionist/associationist approaches were criticized nearly from their inception as oversimplifications that did not capture the cognitive and conceptual complexity of the behavioral disruptions found in even the "classic" (Broca's and Wernicke's) aphasias (e.g., Jackson 1878; Head 1926; Pick 1931; Goldstein 1948; Luria 1966). Such criticisms led to changes in the postulated nature of the "nodes" underlying anatomical-connectionist models (or to nonconnectionist characterizations entirely), with movement toward more linguistically and cognitively relevant characterizations.

Zurif, Caramazza, and Myerson (1972) were major modern proponents of this movement, with empirical demonstrations of an "overarching agrammatism" underlying the deficit in many instances of Broca's aphasia. They demonstrated that not only was production in these patients "agrammatic," but that comprehension also suffered from a disruption to the comprehension of structural relationships, particularly when closed-class function words were critical to interpretation or when disambiguating semantic information was unavailable.

Similarly, a modality-overarching difficulty in semantical interpretation was claimed for patients with damage to Wernicke's area. In the early versions of this "linguistic-relevance" approach to aphasia, the loci of damage were described in terms of "loss of knowledge" (e.g., loss of syntactic rules). However the claim of knowledge-loss proved empirically difficult to sustain, whereas descriptions in terms of disruptions to the processing (access, integration) of linguistically relevant representations (words, SYNTAX, SEMANTICS) was empirically demonstrable. In support of such modality-independent descriptions of aphasia, this same distribution of deficits has been shown in languages that do not rely on the auditory/oral modality. Studies of SIGN LANGUAGES (a visuospatial, nonauditory language) in deaf signers have demonstrated that left-hemisphere damage results in marked impairment to sign language abilities, but right hemisphere damage does not (despite the fact that such damage disrupts non-language spatial and cognitive abilities). Further, syntactic versus semantic sign-language disruptions have been shown to pattern neuroanatomically with the language problems accompanying damage to Broca's and Wernicke's areas, respectively (Bellugi, Poizner, and Klima 1989).

In all, much work has demonstrated that characterizations of the functional commitment of brain architecture to language as revealed via the aphasias requires explicit consideration of the abstract, modality-neutral functional architecture (syntax, etc.) of language.

The use of behavioral techniques that examine language processing as it takes place in real time (online techniques; e.g., Swinney et al. 1996) have recently served to further detail the brain-language relationships seen in aphasia. This work has demonstrated disruptions to functional systems underlying language at finely detailed levels of linguistic processing/analysis, even providing a basis for the argument that some disruptions underlying "classic" syndromes may represent, at least partially, disruptions to elemental processing resources that are recruited by the language system (MEMORY, ATTENTION, access, etc.). With the details provided by these temporally fine-grained examinations of aphasias and by modern brain imaging, the apparent lack of homogeneity of the language disruptions found in aphasic syndromes (including the many putative aphasic syndromes not associated with Broca's or Wernicke's areas) appears on course to being better understood. It has led, on one hand, to increasing examination of individual cases of aphasia for determination of "new" aspects of the brain-language relationship (and, to more cautious claims about group/syndrome patterns), and on the other hand, to new models of language, based increasingly on verifiable language behaviors as revealed by "anomalous" aphasic cases.

Articulation

Articulation means movement. In speech, articulation is the process by which speech sounds are formed. The articulators are the movable speech organs, including the tongue, lips, jaw, velum, and pharynx. These organs, together with related tissues, comprise the *vocal tract,* or the resonating cavities of speech production that extend from the larynx (voice box) to the lips or nostrils. Human speech production is accomplished by the coordination of muscular actions in the respiratory, laryngeal, and vocal tract systems. Typically, the word *articulation* refers to the functions of the vocal tract, but speech production requires the action of all three systems. A full account of speech production would go beyond articulation to include such topics as intonation and emotional expression. Essentially, articulation is the means by which speech is formed to express language (see LANGUAGE PRODUCTION and LANGUAGE AND COMMUNICATION).

Articulation is a suitable topic for cognitive science for several reasons, but especially because it is (1) arguably the most precisely performed of human movements, (2) a serial behavior of exceptional complexity, (3) the most natural means of language expression in all communities except people with impairments of hearing, and (4) a uniquely human behavior linked to a variety of other accomplishments.

Ordinary conversational speech is produced at rates of five to ten syllables per second, or about twenty to thirty phonemes (sound units that distinguish words) per second. Individual speech sounds therefore have an average duration of approximately fifty milliseconds. This rapid rate has been emphasized in studies of speech perception because no other sound sequence can be perceived at comparable rates of presentation (Liberman et al. 1967). The rapid rate is impressive also from the perspective of production and the motor control processes it entails. Each sound must be uttered in the correct sequence, and each, in turn, requires the precise timing of the movements that distinguish it from other sounds. Although a given sound can be prototypically defined by its associated movements (e.g., closure of the lips and laryngeal vibrations for the *b* in *boy*), the actual pattern of movements varies with other sounds in the sequence to be produced (the phonetic context). Generally, articulatory movements overlap one another and can be mutually adjusted. At any one instant, the articulators may appear to be simultaneously adjusted to the requirements of two or more sounds. For example, the *s* sound in the word *stew* is typically produced with lip rounding, but the *s* sound in the word *stay* is not. The reason for this difference is that the *s* sound in the word *stew* anticipates the lip rounding required for the forthcoming rounded vowel. This phenomenon is called *coarticulation* and has been one of the most challenging issues in speech production theory. Coarticulation is not restricted to immediately adjacent sounds and may, in fact, extend over several segments and even cross syllable and word boundaries. The complex overlapping of articulatory movements has been the subject of considerable research, as summarized by Fowler and Saltzman (1993) and by Kent and Minifie (1977). Coarticulation is an obstacle to segmentation, or the demarcation of speech behavior into discrete units such as phonemes and words.

With the exception of SIGN LANGUAGES used by people who are deaf, speech is the primary means of communication in all human communities. Speech is therefore closely related to language (and to the auditory perception of language) and is often the only means by which a particular language can be studied, because the majority of the world's languages do not have a written form. Speech appears to be unique to humans (see ANIMAL COMMUNICATION). Because speech is harnessed to language, it is difficult or impossible to gain a deep understanding of speech apart from its linguistic service. As Fujimura (1990) observed, "While speech signals convey information other than linguistic codes, and the boundary between linguistic and extra- or paralinguistic issues may not be clearcut, there is no question that the primary goal of speech research is to understand the relation of the units and organization of linguistic forms to the properties of speech signals uttered and perceived under varying circumstances" (p. 244). The output of the phonological component of the grammar has often been assumed as the input to the system that regulates speech production (see PHONETICS and PHONOLOGY).

Because the speech signal is perishable, expression and perception of its serial order are essential to communication by speech. In his classic paper, LASHLEY (1951) considered speech as exemplary of the problem of serial order in human behavior. He proposed three mechanisms for the control of seriation: determining tendency (the idea to be expressed), activation of the selected units (meaning that they are primed for use but not yet serially ordered), and the schema of order (or the syntax of the act that finally yields a serial ordering of the intended utterance). Lashley's insights illuminate some of the major cognitive dimensions of articulation, and Lashley's ideas resonate in contemporary studies of speech. One area in particular is the study of sequencing errors (e.g., substitutions, deletions, and exchanges of segments) in both normal and pathological speech. These errors have attracted careful study because of the belief that the mistakes in the motor output of speech can reveal the underlying organization of speech behavior. Large corpora of speech errors have been collected and analyzed in attempts to discover the structures of speech organization (Fromkin 1980). But this is only part of the problem of serial order in speech. It is also necessary to understand how individual movements are coordinated to meet the needs of intelligibility while being energetically efficient (Kelso, Saltzman, and Tuller 1986; MacNeilage 1970).

A number of laboratory techniques have been developed to study speech production. The two major methodologies are physiologic and acoustic. Physiological methods are

diverse because no single method is suited to study the different structures and motor systems involved in speech. Among the methods used are electromyography, aerodynamics, various kinds of movement transduction, X-ray, and photoelectrical techniques (Stone 1997). Of these, X-ray techniques have provided the most direct information, but, to avoid the hazards of X-ray exposure, investigators are using alternative methods such as the use of miniature magnetometers. Acoustic studies offer the advantages of economy, convenience, and a focus on the physical signal that mediates between speaker and listener. Acoustic methods are limited to some degree because of uncertainties in inferring articulatory actions from the acoustic patterns of speech (Fant 1970), but acoustic analysis has been a primary source of information on articulation and its relation to speech perception (Fujimura and Erickson 1997, Stevens 1997).

Among the most influential theories or models of articulation have been stage models, dynamic systems, and connectionist networks. In stage models, information is successively processed in serially or hierarchically structured components (Meyer and Gordon 1985). Dynamic systems theories seek solutions in terms of task-dependent biomechanical properties (Kelso, Saltzman, and Tuller 1986). Connectionist networks employ massively parallel architectures that are trained with various kinds of input information (Jordan 1991). Significant progress has been made in the computer simulation of articulation, beginning in the 1960s (Henke 1966) and extending to contemporary efforts that combine various knowledge structures and control strategies (Saltzman and Munhall 1989, Guenther 1995, Wilhelms-Tricarico 1996). This work is relevant both to the understanding of how humans produce speech and to the development of articulatory speech synthesizers (*see* SPEECH SYNTHESIS).

A major construct of recent theorizing about speech articulation is the *gesture,* defined as an abstract characterization of an individual movement (e.g., closure of the lips). It has been proposed that gestures for individual articulators are combined in a motor score that specifies the movements for a particular phonetic sequence. A particularly appealing property of the gesture is its potential as a construct in phonology (Browman and Goldstein 1986), speech production (Saltzman and Munhall 1989), SPEECH PERCEPTION (Fowler 1986), and speech development in children (Goodell and Studdert-Kennedy 1993).

Artifacts

See ARTIFACTS AND CIVILIZATION; COGNITIVE ARTIFACTS; HUMAN NAVIGATION; TECHNOLOGY AND HUMAN EVOLUTION

Artifacts and Civilization

The development of civilization meant more than social and technological innovations. It required the acquisition of complex cognitive processes. In particular, the ability to manipulate data abstractly was key to the development of urban society. This is illustrated by the evolution of artifacts for counting and accounting associated with the rise of the very first civilization in Sumer, Mesopotamia, about 3300–3100 B.C. Here, the development of a system of clay tokens and its final transmutation into writing on clay tablets document the importance for an administration to process large amounts of information in ever greater abstraction (Schmandt-Besserat 1992). Tokens and economic clay tablets made it possible to levy taxes and impose forced labor; in other words, they gave the temple institutional control over manpower and the production of real goods. The accumulation of wealth in the hands of a ruling priesthood bolstered the development of monumental architecture and the arts. More importantly, the temple economy fostered long distance trade and critical industries such as metallurgy (Moorey 1985). In turn, metal tools revolutionized crafts. For example, metal saws could cut wooden planks into circular shapes, allowing such inventions as the wheel (Littauer and Crauwel 1979). Metal weapons transformed warfare, leading to conquests far and near that could be administered with tokens and economic tablets (Algaze 1993). Finally, tokens and writing fostered new cognitive skills and thereby transformed the way people thought (Schmandt-Besserat 1996).

Starting with the beginning of agriculture ca. 8000 B.C., clay tokens of multiple shapes were used for counting and accounting goods. They were the first code or system for storing/communicating information: each token shape represented one unit of merchandise, for example, a cone and a sphere stood, respectively, for a small and a large measure of grain, and an ovoid for a jar of oil (figure 1). The tokens represent a first stage of abstraction. They translated daily-life commodities into miniature, mostly geometric counters, removing the data from its context and the knowledge from the knower. However, the clay counters represented plurality concretely, in one-to-one correspondence. Three jars of oil were shown by three ovoids, as in reality.

About 3500–3300 B.C., envelopes in the form of hollow clay balls were invented to keep in temple archives the tokens representing unfinished transactions (tax debts?). For convenience, the accountants indicated the tokens hidden inside the envelopes by impressing them on the outside. The two-dimensional markings standing for three-dimensional tokens represented a second step of abstraction. A third level of abstraction was reached ca. 3200–3100 B.C., when solid clay balls—tablets—did away with the actual tokens, only displaying the impressions. The impressed markings

Figure 1. Tokens held in an envelope from Susa, present-day Iran, ca. 3300 B.C. The large and small cones stood for large and small measures of grain and each of the lenticular disks represented a flock of animals (10?). The markings impressed on the outside of the envelope correspond to the tokens inside. Both tokens and impressed markings represented units of goods concretely, in one-to-one correspondence. Published in Schmandt-Besserat, D. (1992), *Before Writing,* vol. 1. Austin: University of Texas Press, p. 126, fig. 73. Courtesy Musée du Louvre, Département des Antiquités Orientales.

still represented numbers of units of goods concretely, in one-to-one correspondence. Three jars of oil were shown by three impressions of the ovoid token. Each impressed marking therefore continued to fuse together the concept of the item counted (jar of oil) with that of number (one), without the possibility of dissociating them.

The fourth step, the abstraction of numbers, ca. 3100 B.C., coincided with pictography—signs in the shape of tokens but traced with a stylus, rather than impressed. These incised signs were never repeated in one-to-one correspondence. Numbers of jars of oil were shown by the sign for jar of oil preceded by numerals (figure 2). The symbols to express abstract numbers were not new. They were the former units of grain: the impression of a cone token that formerly was a small measure of grain stood for 1 and that of a sphere representing a large measure of grain was 10. When, finally, the concept of number was abstracted from that of the item counted, numerals and writing could evolve in separate ways. Abstract numerals grew to unprecedented large numbers, paving the way for mathematics and thereby providing a new grasp on reality (Justus 1996). Pictographs assumed a phonetic value in order to satisfy new administrative demands, namely, the personal names of recipients or donors of the stipulated goods. The syllables or words composing an individual's name were rendered in a rebus fashion. That is to say, a new type of pictographs no longer stood for the objects they pictured, but rather for the sound of the word they evoked. This fifth step in abstraction marked the final departure from the previous token system. The phonetic signs featured any possible items, such as the head of a man standing for the sound "*lu*" or that of a man's mouth that was read "*ka*." This further abstraction also marked the true takeoff of writing. The resulting syllabary was no longer restricted to economic record keeping but opened ca. 2900 B.C. to other fields of human endeavor. In sum, in Mesopotamia, the earliest civilization corresponded with the transmutation of an archaic token system of accounting into a script written on clay tablets. The metamorphosis meant far more than the reduction from a three- to a two-dimensional recording device. It signified step-by-step acquisition of new cognitive skills for processing data in greater abstraction.

Artifacts for counting and writing were also part and parcel of the rise of all subsequent Near Eastern civilizations. However, the cultures following in the wake of Sumer were spared some of the hurdles to abstract data manipulation. Elam, in present-day western Iran, the nearest neighbor to Mesopotamia, is the only exception where the stages from tokens to impressed markings on envelopes and tablets took place synchronically with Mesopotamia—no doubt because of the Sumerian domination of Elam ca. 3300–3200 B.C. But, when the Proto-Elamites created their own script ca. 3000 B.C., they borrowed simultaneously abstract numerals and phonetic signs (Hoyrup 1994). About 2500 B.C., the Indus Valley civilizations emulated their Sumerian trade partners by devising a script that had no links with the Mesopotamian-like tokens recovered in pre-Harappan sites (Possehl 1996). Crete probably adopted first the idea of tokens and then that of writing. This is suggested by the fact that Minoan clay counters in the shape of miniature vessels

Figure 2. Economic clay tablet showing an account of thirty-three jars of oil, from Godin Tepe, present-day Iran, ca. 3100 BC. The units of oil are no longer repeated in one-to-one correspondence, but the sign for a measure of oil is preceded by numerals. The circular sign stood for 10 and the wedge for 1. Published in Schmandt-Besserat, D. (1992), *Before Writing,* vol. 1. Austin: University of Texas Press, p. 192, fig. 115. Courtesy T. Cuyler Young, Jr.

seem unrelated to the following hieroglyphic, Linear A or B scripts used in the Aegean between 2200–1300 B.C. (Poursat 1994). Farther afield, Egypt, where the use of tokens is not clearly attested, produced ca. 3000 B.C. a full-blown system of writing based on the rebus principle, visibly imitating Sumer (Ray 1986). These examples imply that the multiple cognitive steps from concrete to abstract data manipulation occurred only once in the Near East. The Mesopotamian concrete tokens and abstract tablets loomed large over the process of civilization in the Old World. In fact, abstract accounting is probably a universal prerequisite for civilization. But this has to remain an hypothesis as long as the precursors of writing in China and the New World remain elusive.

Artificial Intelligence

See INTRODUCTION: AI AND EDUCATION; COGNITIVE MODELING, SYMBOLIC; COMPUTATIONAL INTELLIGENCE

Artificial Life

Artificial life (A-Life) uses informational concepts and computer modeling to study life in general, and terrestrial life in particular. It aims to explain particular vital phenomena, ranging from the origin of biochemical metabolisms to the coevolution of behavioral strategies, and also the abstract properties of life as such ("life as it could be").

It is thus a form of mathematical biology—albeit of a highly interdisciplinary type. Besides their presence in biology, especially ETHOLOGY and evolutionary theory, A-Life's research topics are studied also (for instance) in artificial intelligence, computational psychology, mathematics, physics, biochemistry, immunology, economics, philosophy, and anthropology.

A-Life was named by Christopher Langton in 1986 (Langton 1986 and 1989). Langton's term suggests (deliberately) that the aim of A-Life is to build new living things. However, not all A-Life scientists share this goal. Even fewer believe this could be done without providing some physical body and metabolism. Accordingly, some A-Life workers favor less philosophically provocative terms, such as "adaptive systems" or "animats" (real or simulated robots based on animals) (Meyer and Wilson 1991).

The claim that even virtual creatures in cyberspace could be genuinely alive is called strong A-Life, in analogy to strong AI. Most A-Lifers reject it (but see Langton 1989 and Ray 1994). Or rather, most reject the view that such creatures can be alive in just the same sense that biological organisms are, but allow that they are, or could be, alive to a lesser degree. Whether life does require material embodiment, and whether it is a matter of degree, are philosophically controversial questions. Proponents of *autopoiesis* (the continual self-production of an autonomous entity), for example, answer "Yes" to the first and "No" to the second (Maturana and Varela 1980). Others also answer the first question with a "Yes," but for different reasons (Harnad 1994). However, these philosophical questions do not need to be definitively answered for A-Life to progress, or be scientifically illuminating. Using artifacts to study life, even "life as it could be," is not the same as aiming to instantiate life artificially.

The theoretical focus of A-Life is the central feature of living things: self-organization. This involves the spontaneous EMERGENCE, and maintenance, of order out of an origin that is ordered to a lesser degree. (The lower level may, though need not, include random "noise.") Self-organization is not mere superficial change, but fundamental structural development. This development is spontaneous, or autonomous. That is, it results from the intrinsic character of the system (often in interaction with the environment), rather than being imposed on it by some external force or designer.

In SELF-ORGANIZING SYSTEMS, higher-level properties result from interactions between simpler ones. In living organisms, the relevant interactions include chemical diffusion, perception and communication, and processes of variation and natural selection. One core problem is the way in which self-organization and natural selection interact to produce biological order over time. Some work in A-Life suggests that whereas self-organization generates the fundamental order, natural selection (following on variation) weeds out the forms that are least well adapted to (least fit for) the environment in question (Kauffman 1993).

The higher-level properties in living organisms are very varied. They include universal characteristics of life (e.g., autonomy and evolution); distinct lifestyles (e.g., parasitism and symbiosis); particular behaviors (e.g., flocking,

hunting, or evasion); widespread developmental processes (e.g., cell differentiation); and bodily morphology (e.g., branching patterns in plants, and the anatomy of sense organs or control mechanisms in animals).

A-Life studies all these biological phenomena on all these levels. A-Life simulations vary in their degree of abstractness or idealization. Some model specific behaviors or morphologies of particular living things, whereas others study very general questions, such as how different rates of mutation affect coevolution (Ray 1992). They vary also in their mode of modeling: some A-Life work concentrates on programs, displaying its creatures (if any) only as images on the VDU, while some builds (and/or evolves) physical robots. The wide range of A-Life research is exemplified in the journals *Artificial Life* and *Adaptive Behavior,* and in international (including European) conference proceedings of the same names. Brief overviews include Langton (1989) and Boden (1996, intro.). For popular introductions, see Emmeche (1994) and Levy (1992).

A-Life is closely related to—indeed, it forms part of—cognitive science in respect of its history, its methodology, and its philosophy.

Historically, it was pioneered (around the mid-twentieth century) by the founders of AI: Alan TURING and John VON NEUMANN. They both developed theoretical accounts of self-organization, showing how simple underlying processes could generate complex systems involving emergent order. Turing (1952) showed that interacting chemical diffusion gradients could produce higher-level (including periodic) structures from initially homogeneous tissue. Von Neumann, before the discovery of DNA or the genetic code, identified the abstract requirements for self-replication (Burks 1966). He even defined a universal replicator: a cellular automaton (CA) capable of copying any system, including itself. A CA is a computational "space" made up of many discrete cells; each cell can be in one of several states, and changes (or retains) its state according to specific—typically localistic—rules. Von Neumann also pointed out that copy errors could enable evolution, an idea that later led to the development of EVOLUTIONARY COMPUTATION (evolutionary programming, evolution strategies, genetic algorithms, etc.).

Even in relatively simple CAs, (some) high-level order may emerge only after many iterations of the relevant lower-level rules. Such cases require high-performance computing. Consequently, Turing's and von Neumann's A-Life ideas could be explored in depth only long after their deaths. Admittedly, CAs were studied by von Neumann's colleague Arthur Burks (1970) and his student John Holland, who pioneered genetic algorithms soon after CAs were defined (Holland 1975); and more people—John Conway (Gardner 1970), Steve Wolfram (1983 and 1986), Stuart Kauffman (1969 and 1971), and Langton (1984), among others—became interested in them soon afterward. But these early studies focused on theory rather than implementation. Moreover, they were unknown to most researchers in cognitive science. The field of A-Life achieved visibility in the early 1990s, largely thanks to Langton's initiative in organizing the first workshop on A-Life (in Los Alamos) in 1987.

Methodologically, A-Life shares its reliance on computer modeling with computational psychology and AI—especially connectionism, situated robotics, and genetic algorithms (evolutionary programming). These three AI approaches may be integrated in virtual or physical systems. For instance, some A-Life robots are controlled by evolved NEURAL NETWORKS, whose (initially random) connections specify "reflex" responses to specific environmental cues (e.g., Cliff, Harvey, and Husbands 1993).

A-Life's methodology differs from classical (symbolic) AI in many ways. It relies on bottom-up (not top-down) processing, local (not global) control, simple (not complex) rules, and emergent (not preprogrammed) behavior. Often, it models evolving or coevolving populations involving many thousands of individuals. It commonly attempts to model an entire creature, rather than some isolated module such as vision or problem-solving (e.g., Beer 1990). And it claims to avoid methods involving KNOWLEDGE REPRESENTATION and PLANNING, which play a crucial role in classical AI (Brooks 1991). The behavior of A-Life robots is the result of automatic responses to the contingencies of the environment, not preprogrammed sequences or internal plans. Each response typically involves only one body part (e.g., the third leg on the right), but their interaction generates "wholistic" behavior: the robot climbs the step, or follows the wall.

Philosophically, A-Life and AI are closely related. Indeed, if intelligence can emerge only in living things, then AI is in principle a subarea of A-Life. Nevertheless, some philosophical assumptions typical of classical AI are queried, even rejected, by most workers in A-Life. All the philosophical issues listed below are discussed in Boden 1996, especially the chapters by Bedau, Boden, Clark, Godfrey-Smith, Hendriks-Jansen, Langton, Pattee, Sober, and Wheeler; see also Clark (1997).

Much as AI highlights the problematic concept of intelligence, A-Life highlights the concept of life—for which no universally agreed definition exists. It also raises questions of "simulation versus realization" similar to those concerning strong AI. Problems in A-Life that are relevant also to the adequacy of FUNCTIONALISM as a philosophy for AI and cognitive science include the role of embodiment and/or environmental embeddedness in grounding cognition and INTENTIONALITY.

A-Life in general favors explanations in terms of emergence, whereas AI tends to favor explanation by functional decomposition. Moreover, many A-Life researchers seek explanations in terms of closely coupled dynamical systems, described by phase-space trajectories and differential equations rather than computation over representations. Although A-Life does avoid the detailed, "objective," world-modeling typical of classical AI, whether it manages to avoid internal representations entirely is disputed. Also in dispute is whether the "autonomy" of environmentally embedded A-Life systems can capture the hierarchical order and self-reflexiveness found in some human action (and partly modeled by classical AI). Many philosophers of A-Life justify their rejection of representations by criticizing the broadly Cartesian assumptions typical of classical, and most connectionist, AI. They draw instead on philosophical insights drawn from Continental philosophy, or phenomenology, sometimes using the concept of autopoiesis.

Besides its theoretical interest, A-Life has many technological applications. These include evolutionary computation for commercial problem solving, environmentally embedded robots for practical use, and computer animation for movies and computer games. The "Creatures" computer environment, for example, employs A-Life techniques to evolve individual creatures capable of interacting, and of learning from their "world" and the human user's "teaching."

Attention

William JAMES once wrote, "Every one knows what attention is. It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration, of consciousness are of its essence. It implies withdrawal from some things in order to deal effectively with others" (James 1890: 403–404). The study of selectivity in information processing operations, of "withdrawal from some things in order to deal effectively with others," has its modern origins in the 1950s with BROADBENT's *Perception and Communication* (1958). Loosely speaking, much of this work may be taken as research into "attention," though problems of selective information processing of course need not be identical to James's first-person view of selective consciousness or awareness.

In fact many aspects of selectivity must contribute to the organization of any focused line of activity. At any given time, the person is actively pursuing some goals rather than others. Some actions rather than others bring those goals closer. Some parts rather than others of the sensory input are relevant and must be examined or monitored. The general state of alertness or drowsiness is also often considered an aspect of "attention." In *Perception and Communication*, a single selective device was used to handle many different phenomena: selective listening, loss of performance with long work periods, impairments by loud noise, and so forth. When the theory was updated in *Decision and Stress* (1971), data from many experimental tasks already required a substantially more complex approach, with a variety of distinct selective mechanisms. Modern work seeks to understand both separate aspects of processing selectivity and their relations.

Selective perception in a variety of modalities has been particularly well investigated. Experiments on selective listening in the 1950s dealt with people listening to two simultaneous speech messages. First, these experiments showed *limited capacity*: People were often unable to identify both messages at once. Second, they showed conditions for effective selectivity: People could identify one message and

ignore the other providing the messages differed in simple physical characteristics such as location, loudness, or voice, but not when they differed only in content. Third, these experiments showed the striking consequences of efficient selection: A person listening to one message and ignoring another would subsequently be able to report only the crudest characteristics of the ignored message, for example, that it had changed from speech to a tone, but not whether it had been in a familiar or an unfamiliar language.

All three points have received much subsequent study. As an example of the many things learned regarding limited capacity, experiments with mixed visual and auditory stimuli show that the major limit on simultaneous perception is modality-specific: One visual and one auditory stimulus can be identified together much better than two stimuli in the same modality (Treisman and Davies 1973). Regarding the control of stimulus selection, experiments show the joint influence of top-down (task-driven) and bottom-up (stimulus-driven) considerations. Top-down influences are important when a person is specifically instructed to pay attention just to objects in a certain region of a visual display (selection by location), objects having a certain color or other property (selection by object feature), or objects of a certain category (e.g., letters rather than digits) (von Wright 1968). Selection by location (*spatial attention*) has been particularly well studied (Posner 1978). Irrespective of the task or instruction, however, stimulus factors such as intensity (Broadbent 1958) or sudden onset (Jonides and Yantis 1988) also contribute to the choice of which stimulus is processed. Long practice in considering a certain stimulus relevant or important will also favor its selection, as when one's own name attracts attention in a crowded room (Moray 1959). Regarding the results of efficient selection, finally, experiments have detailed what differs in the processing of attended and ignored stimuli. Often, very little can be explicitly remembered of stimuli a person was asked to ignore, even though those stimuli were perfectly audible or visible (Wolford and Morrison 1980). In contrast, indirect measures may suggest a good deal of hidden or unconscious processing; for example, an ignored word previously associated with shock may produce a galvanic skin response even while subjects fail to notice its occurrence (Corteen and Dunn 1974). The nature and duration of such implicit processing of unattended material remains a topic of active debate, for example, in the discussion of IMPLICIT VS. EXPLICIT MEMORY.

These studies reflect general questions that may be asked of any selective process. One is the question of *divided attention*, or how much can be done at once. Another is the question of *selective attention*, or how efficiently desired stimuli can be processed and unwanted stimuli ignored. Experiments measuring establishment of a new selective priority concern *attention setting and switching*. The complement to switching is *sustained attention*, or ability to maintain one fixed processing set over an extended time period.

The neurobiology of visual attention is a particularly active topic of current research. In the primate brain, visual information is distributed to a network of specialized cortical areas responsible for separate visual functions and dealing partially with separate visual dimensions such as shape, motion and color (Desimone and Ungerleider 1989). Taken together, these "visual areas" cover roughly the posterior third of the cerebral hemispheres. Recordings from single cells in several visual areas of the monkey show weak or suppressed responses to stimuli that the animal is set to ignore (Moran and Desimone 1985). Measurements of gross electrical activity in the human brain, and associated changes in local cerebral bloodflow, similarly suggest greater responses to attended than to unattended stimuli (Heinze et al. 1994). Damage to one side of the brain weakens the representation of stimuli on the opposite side of visual space. Such stimuli may be seen when they are presented alone, but pass undetected when there is concurrent input on the unimpaired side (Bender 1952). All these results suggest that concurrent visual inputs compete for representation in the network of visual areas (Desimone and Duncan 1995). Attended stimuli are strongly represented, while responses to unwanted stimuli are suppressed.

Complementary to selective perception is the selective activation of goals or components of an action plan. Here, too, errors reflect limited capacity, or difficulty organizing two lines of thought or action simultaneously. Everyday slips of action, such as driving to work instead of the store, or stirring coffee into the teapot, are especially likely when a person is preoccupied with other thoughts (Reason and Mycielska 1982). Practice is again a key consideration. Although it may be impossible to organize two unfamiliar activities at once, familiar behavior seems to occur automatically, leaving attention (in this sense) free for other concerns. Indeed, familiar actions may tend to occur "involuntarily," or when they are currently inappropriate. Again everyday action slips provide clear examples: taking a familiar route when intending to drive elsewhere, or taking out one's key on arrival at a friend's door (James 1890). A laboratory version is the Stroop effect: Naming the color of a written word suffers substantial interference from a tendency instead to read the word itself (Stroop 1935). Such results suggest a model in which conflicting action tendencies compete for activation. Practice increases an action's competitive strength.

Disorganized behavior and action slips occur commonly after damage to the frontal lobes of the brain (Luria 1966). Disorganization can take many forms: intrusive actions irrelevant to a current task, perseverative repetition of incorrect behavior, choices that seem ill-judged or bizarre. A major question is how action selection develops from the joint activity of multiple frontal lobe systems. A more detailed treatment is given in ATTENTION AND THE HUMAN BRAIN.

To some extent, certainly, it is appropriate to consider different aspects of "attention" as separate. To take one concrete example, it has been amply documented that there are many distinct forms of competition or interference between one line of activity and another. These include modality-specific perceptual competition, effector-specific response competition, and competition between similar internal representations (e.g., two spatial or two verbal representations; see Baddeley 1986); though there are also very general sources of interference even between very dissimilar tasks (Bourke, Duncan, and Nimmo-Smith 1996). Each aspect of competition reflects a distinct way in which the nervous system must select one set of mental operations over another.

At the same time, selectivities in multiple mental domains must surely be integrated to give coherent, purposive behaviour (Duncan 1996). It has often been proposed that some mental "executive" takes overall responsibility for coordinating mental activity (e.g., Baddeley 1986); for example, for ensuring that appropriate goals, actions, and perceptual inputs are all selected together. At least as attractive, perhaps, is an approach through self-organization. By analogy with "relaxation" models of many mental processes (McClelland and Rumelhart 1981), selected material in any one mental domain (e.g., active goals, perceptual inputs, material from memory) may support selection of related material in other domains. The description of top-down control given earlier, for example, implies that goals control perceptual selection; equally, however, active goals can always be overturned by novel perceptual input, as when a telephone rings or a friend passes by in the street. Whichever approach is taken, a central aspect of "attention" is this question of overall mental coordination.

Attention in the Animal Brain

In most contexts ATTENTION refers to our ability to concentrate our perceptual experience on a selected portion of the available sensory information, and, in doing so, to achieve a clear and vivid impression of the environment. To evaluate something that seems as fundamentally introspective as attention, cognitive science research usually uses a measure of behavioral performance that is correlated with attention. To examine brain mechanisms of attention, the correlations are extended another level by measuring the activity of neurons during different 'attentive' behaviors. Although this article focuses exclusively on attentive processes in the visual system, attentive processing occurs within each sensory system (see AUDITORY ATTENTION) and more generally in most aspects of cognitive brain function. Our understanding of the neuronal correlates of attention comes principally from the study of the influence of attentive acts on visual processing as observed in animals. The selective aspects of attention are apparent in both of vision's principal functions, identifying objects and navigating with respect to objects and surfaces.

Attention is a dynamic process added on top of the passive elements of selection provided by the architecture of

the visual system. For foveate animals, looking or navigating encompasses the set of actions necessary to find a desired goal and place it in foveal view. The selective aspects of attention within this context deal primarily with decisions about information in the peripheral field of view. Seeing or identifying objects encompasses a more detailed analysis of centrally available information. In this context the selective aspects of attention deal primarily with the delineation of objects and the integration of their parts that lead to their recognition (see OBJECT RECOGNITION, ANIMAL STUDIES).

Although the retinae encode a wide expanse of the visual environment, object analysis is not uniform across the visual field but instead is concentrated in a small zone called the field of focal attention (Neisser 1967). Under most circumstances this restricted zone has little to due with acuity limits set by the receptor density gradient in the retina but is due to an interference between objects generated by the density of the visual information. Focal attention encompasses the dynamic phenomena that enable us to isolate and examine objects under the conditions of interference. The selective aspect of attention raises an important question, namely, how many things can be attended to at one time? Interestingly, the answer varies, and depends at least in part on the level of analysis that is necessary to distinguish between the things that are present. What is clear is that the moment-to-moment analytic capacity of the visual system is surprisingly limited.

An examination of the physiology and anatomy of visual processes in animals, especially primates, provides us with key pieces of the attention puzzle. Visual information is dispersed from primary visual cortex through extrastriate cortex along two main routes. One leads ventrally toward anterior temporal cortex, the other dorsally into parietal association cortex. The ventral stream progression portrays a system devoted to object analysis, and in anterior temporal areas, represents a stage where sensory processes merge with systems associated with object recognition and memory (Gross 1992). The dorsal stream emphasizes the positions of surfaces and objects and in parietal areas represents a stage where the sensory and motor processes involved in the exploration of the surrounding space become intertwined (Mountcastle 1995). The different emphasis in information processing within parietal and temporal areas is also apparent with respect to the influences of attentional states. Both the sensitivity to visual stimuli and the effective receptive field size are more than doubled for parietal visual neurons during an attentive fixation task, whereas under similar conditions the receptive fields of inferior temporal cortical neurons are observed to collapse around a fixation target.

As visual processing progresses in both the dorsal and ventral streams, there is an accompanying expansion in the receptive field size of individual neurons and a corresponding convergence of information as an increasing number of objects fit within each receptive field. Despite the convergence, an inseparable mixture of information from different objects does not occur in part because of the competitive, winner-take-all nature of the convergence and in part because of attentive selection. Directing attention to a particular object alters the convergent balance in favor of the attended object and suppresses the neural response to other objects in the neuron's receptive field (Moran and Desimone 1985; Treue and Maunsell 1996).

Within the ventral stream and at progressively higher levels of object analysis, the competitive convergence of the system forces a narrowing of processing by selecting what information or which objects gain control of the neural activity. The connectivity of the visual system is not simply a feedforward system but a highly interconnected concurrent network. Whatever information wins the contention at one level is passed forward and backward and often laterally (Van Essen and DeYoe 1995). These factors heavily constrain the neural activity, limiting the activation of neurons at each subsequent level to a progressively restricted set of stimulus configurations. As increasingly higher levels of analytic abstraction are attained in the ventral stream, the receptive field convergence narrows the independence of parallel representations until in the anterior temporal lobe the neuronal receptive fields encompass essentially all of the central visual field. Because directing attention emphasizes the processing of the object(s) at the attended location, the act of attending both engages the ventral stream on the object(s) at that location and dampens out information from the remaining visual field (Chelazzi et al. 1993). These circumstances parallel the capacity limitation found in many forms in vision and may constitute the performance limiting factor. Capacity limits may vary depending upon the level of convergence in the cortical stream that must be reached before a discriminative decision about the set of observed objects can be achieved (Merigan, Nealey, and Maunsell 1993).

When attention is to be shifted to a new object, as we read the next word or reach for a cup or walk along a path, information must be obtained from the periphery as to the spatial layout of objects. The dorsal stream appears to provide this information. The convergence of information within the neuronal receptive fields generates sensitivity to large surfaces, their motion and boundaries and the positions of objects within them, without particular sensitivity to the nature of the objects themselves. The parietal visual system is especially sensitive to the relative motion of surfaces such as that generated during movement through the environment. An object to which attention is shifted is usually peripherally located with respect to the object currently undergoing perceptual analysis. For parietal cortical neurons, maintained attention on a particular object results in a heightened visual sensitivity across the visual field and, in contrast to the temporal stream, a suppressed sensitivity to objects currently at the locus of directed attention (Motter 1991).

The transition between sensory information and MOTOR CONTROL is subject to a clear capacity limitation—competition between potential target goals must be resolved to produce a coherent motor plan. When target goals are in different locations, spatially selective processing can be used to identify locations or objects that have been selected as target goals. In the period before a movement is made, the neural activity associated with the visual presence of the object at the target site evolves to differentiate the target object from other objects. This spatially selective change, consistent with an attentive selection process, has been observed in parietal cortex as well as the motor eye fields of

frontal cortex and subcortical visuomotor areas such as the superior colliculus (Schall 1995).

How early in the visual system are attentive influences active? If attention effectively manipulates processing in the earliest stages of vision, then the visual experiences we have are in part built up from internal hypotheses about what we are seeing or what we want to see. Two sets of physiological observations suggest these important consequences of selective attention do occur. First, directed attention studies and studies requiring attentive selection of stimulus features have shown that the neural coding of objects can be completely dominated by top-down attentive demands as early as extrastriate cortex and can bias neuronal processing even in primary visual cortex. Second, after arriving in primary visual cortex, visual information spreads through the cortical systems within 60–80 msec. The effects of selective attention develop in parallel during the next 100 msec in extrastriate occipital, temporal, and parietal cortex and the frontal eye fields, making it not only difficult to pinpoint a single decision stage but also making it likely that a coherent solution across areas is reached by a settling of the network (Motter 1997).

The detailed physiological insights gained from animal studies complement the imaging studies of ATTENTION IN THE HUMAN BRAIN that have probed higher-order cognitive functions and attempted to identify the neural substrates of volitional aspects of attention. Together these sets of studies have provided new views of several classic phenomena in attention including capacity limitations and the temporal progression of selection.

Attention in the Human Brain

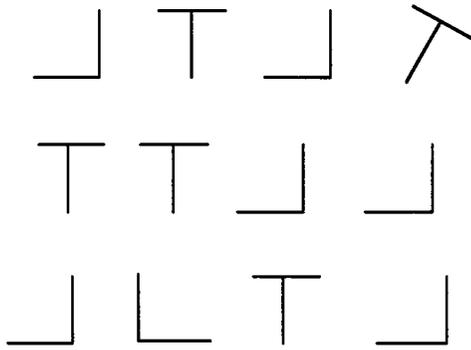
To illustrate what is meant by attention, consider the display in figure 1. Your ATTENTION may be drawn to the tilted T because it differs in such a striking way from the background. When one figure differs from the background by a


Figure 1.

single feature, it pops out and your attention is drawn to it. This is an example of attention driven by input. However, if you know that the target is an L you can guide your search among the stimuli with horizontal and vertical strokes. This is an example of the form of higher level voluntary control that is the subject of this section. Voluntary control is accompanied by the subjective feeling of selection between potential actions and is one of the most distinctive features of human experience. The interaction of top-down voluntary actions with bottom-up automatic processes, which is illustrated by figure 1, has interested researchers since the beginnings of psychology (James 1890; see WILLIAM JAMES).

One approach to the question of voluntary control is to argue that it is an illusion that arises out of the competitive activation of a large number of brain systems. What appears to be volition is the result of a complex network relaxing to a particular state. Although without denying the top-down component, this view stresses the bottom-up processes. A different view elaborated in this section is that there is a high-level executive attention network with its own anatomy that works to resolve competition and in the process gives rise to subjective feelings of cognitive control (Norman and Shallice 1986). This view emphasizes the top-down control.

The executive system participates in tasks that involve conflict between systems. This is a property one expects to find in a system that has as a major function inhibition of reflexive or bottom-up responses to external stimuli in order to allow autonomous action. A classical paradigm to study the inhibition of habitual responses is the Stroop task (Stroop 1935). In this task, subjects name the color of the ink of a word. Sometimes, the word is a color name (e.g., red) in a different ink color (e.g., blue). In those incongruent trials subjects automatically read "red" and have to inhibit this answer to respond "blue." Inhibition produces interference revealed by slow reaction times in the incongruent condition.

Is it possible to uncover the neural substrates of cognitive control? Imaging techniques developed in the last several years have yielded promising results (Toga and Mazziota 1996). An area in the medial surface of the frontal lobe, named the anterior cingulate gyrus, appears to be important for the inhibition of automatic response that is central to voluntary action. Five studies involving measurement of blood flow by POSITRON EMISSION TOMOGRAPHY (PET) in a Stroop task have shown activation of the anterior cingulate

in the incongruent condition when compared with the congruent condition (e.g., the noun blue displayed in blue color) or neutral (noncolor word; see Posner and DiGirolamo 1996 for a review).

Other tasks requiring inhibition of habitual responses also activate the anterior cingulate. For example, responding to a noun by generating an associated use produces more activation of the anterior cingulate than simply repeating the noun (Petersen et al. 1989). In the generate condition, the most familiar response (i.e., repeating the noun) needs to be repressed, to allow the expression of the verb. Classifying a noun into a category also produces cingulate activation related to the number of targets. This finding suggests that the anterior cingulate activation is due to special processing of the target rather than being necessary to make the classification, a result consistent with the idea of cognitive control. The cingulate has close connection to underlying subcortical areas in the BASAL GANGLIA (Houk 1995). These areas have also shown activity in some of the same tasks described above and play a role in the inhibition of reflexive motor responses. It seems likely they form part of the network subserving this form of voluntary control.

Goldberg and Bloom (1990) proposed a "dual premotor system hypothesis" of volitional movement. This theory, which attributes an executive function to the anterior cingulate and the supplementary motor area, was developed to explain the alien hand sign. The alien hand sign is the performance of apparently purposive movements that the patient fails to recognize as self-generated. The theory posits a lateral premotor system (LPS; Area 6), that organizes motor behavior in reaction to external stimulus, and a medial premotor system (MPS; anterior cingulate, supplementary motor area, and basal ganglia loops), which underlies intentional behavior. MPS underlies volitional movement by inhibiting the LPS. If a lesion occurs in MPS, LPS is released and obligatory dependence on external information emerges. The patient develops compulsive automatisms, which are not perceived as self-generated. The inhibitory effect of MPS over LPS during volitional movement resembles the inhibitory effect of MPS (i.e., anterior cingulate) over semantic networks during the Stroop task. The idea of alien rather than self control is also found in some forms of schizophrenia, a disorder that has also been shown to involve abnormalities in the anterior cingulate and basal ganglia (Benes 1993; Early 1994).

Cognitive studies have shown several forms of short term or WORKING MEMORY and considerable independence between them (Baddeley 1986). Recent imaging data show that verbal, spatial, and object memories involve separate anatomical areas (Smith and Jonides 1995). There is evidence that all forms of memory are interfaced to a common executive system that involves the same midline frontal anatomy described previously (Baddeley 1986; Posner and Raichle 1994).

PET studies have also shown that executive attention plays an important role in high level skills (Kosslyn 1994; Posner and Raichle 1994). Studies involving recording from scalp electrodes have provided some information on the time course of the activations found in PET studies during reading. Skills such as READING have a very strong dependence

on rapid processing. A skilled reader fixates on a given word for only about 275 msec (Rayner and Sereno 1994). In generating the use of visual words, activation of the cingulate begins as early as 150 msec after input when blocks of trials in which subjects derive a word meaning alternate with blocks in which they read the word aloud (Snyder et al. 1995). The cingulate activation occurs whenever higher level supervisory control is needed to organize the mental response to the input. In the case of generating the use of a word, attention leads and probably is required for the activation of a network of areas that lead eventually to articulation of novel ideas associated with the input string. We see an early semantic analysis of the input word after 200 msec and development of associations to the input in frontal and parietal sites over the next second. Although it is possible to lay out a sequence of processing steps, they can be misleading. Because attention may occur rather early it is possible for subjects to reprogram the organization of these steps and thus to carry out a number of different instructions with the same brain network. Studies of the role of attention suggest that reorganization involves amplification of the operations that are attended in comparison to unattended operations. Increases in overall neuronal activity appear to produce faster speed and higher priority for the attended computations. As attention is released from high order activity during practice in the skill it becomes possible to improve the speed of performance by amplification of early processing steps.

Studies of mental arithmetic, visual IMAGERY, and other forms of skilled performance using neuroimaging methods seem to support many of the same principles that have been outlined above for word reading.

Attribution Theory

Because humans are social animals, an individual's prospects for survival and success depend on the ability to understand, predict, and influence the behavior of other persons. Hence "people watching" is an essential human impulse. Yet it does not suffice to merely watch other people's overt actions; we strive to infer *why* people behave as they do. The psychological processes underlying these interpretations of the causes of behavior are studied in a subfield of social psychology known as attribution theory.

Although all proposed models of attribution assume that *accurate understanding* of the actual causes of behavior is a primary goal, models differ in assumptions about processing limitations that impede accuracy and about other human goals that interfere with accuracy. As in many areas of cognitive science, such as perception and DECISION MAKING, researchers often attempt to learn how the system works from where it fails, testing predictions about the errors that would arise from a process. One pattern of error is the tendency of observers to overestimate how much another's behavior is determined by the person's stable traits, a tendency first described by Ichheiser (1949) and formalized by Ross (1977) as "the fundamental attribution error" (FAE). Errors in attributing to stable dispositions (e.g., aptitudes, attitudes, and traits) have important consequences for the observer's subsequent expectancies, evaluations, and behavioral responses. For example, when a teacher attributes a student's failure to lack of intelligence (as opposed to a situational factor) this leads to reduced expectations of the student's future success, reduced liking of the student, and reduced teaching investment in the student. We will review theory and research on the FAE to illustrate how attribution theory has progressed.

The blueprint for attribution theory was Heider's (1958) GESTALT PERCEPTION analysis of interpersonal interaction. He argued that a person's response to a social situation is largely a function of how the person subjectively organizes the stimulus of a social situation, such as through attributions. Perhaps the most influential idea is that attributions are guided by *lay theories* such as the schema that achievement reflects both situational forces (environmental factors that facilitate or constrain the actor) and internal forces (the combination of effort and aptitude). Heider contended that the attributor, like a scientist, uses such theories in combination with his or her observations. However, the attributor errs because his or her observations are distorted by perceptual processes and, sometimes, emotional processes. For Heider, the FAE results from Gestalt perceptual processes that draw an observer's attention to the other person rather than to the situation surrounding the other person; that is, the person is "figural" against the "ground" of the situation.

A key development in research on the *perceptual* interpretation of the FAE was Jones and Nisbett's (1972) argument that although to an observer of action the person is figural, to the actor the situation is figural and hence self-attributions for behavior are less dispositional. The perceptual account of this *actor-observer difference* was supported by experiments that presented actors with the visual perspective on their behavior of an observer (by use of videotape) and found that their self-attributions became more dispositional (Storms 1973). Nevertheless, evidence also emerged for nonperceptual interpretations of why first-person explanations differ. An actor draws on different information—information about one's mental state while acting and about one's behavior in the past (see Eisen 1979).

A shift toward emphasis on *cognitive* mechanisms came in the research programs constructed on the foundation of Kelley's (1967 and 1972) models. Kelley's (1967) *covariation* model focused on cases where an uncertain or curious observer generates an attribution "bottom up" from the data provided by multiple instances of a behavior. Attributors induce the general locus of causation for a behavior by assessing how the behavior covaries with the actor, the situation, and the temporal occasion. For example, to interpret why Sue's date John is dancing by himself, one would consider whether a consensus of people at the party are dancing alone, whether dancing alone is something that Sue's dates have often done, and whether it is something that John has often done. In tests of the model, participants generally respond to summaries of covariation data roughly as predicted, with the exception that consensus information is under-weighted (McArthur 1972). Biases in INDUCTION have been interpreted in terms of "extra" information implicitly communicated to participants (see GRICE; Hilton and Slugoski 1985; McGill 1989) or in terms of "missing" information that participants lack (Cheng and Novick 1992). Of late, research on causal induction has merged with the field of CAUSAL REASONING.

To model more typical cases of attribution where people lack time and energy to work "bottom up," Kelley (1972) proposed that people interpret a single instance of behavior "top down" from a theory. For example, an attributor who applies the Multiple Sufficient Causes (MSC) schema follows the *discounting principle* that if one of two alternative causes is present then the other is less likely. Tests of this model, however, found that a dispositional attribution is not fully discounted by information about the presence of a sufficient situational cause for the behavior (Snyder and Jones 1974). This manifestation of the FAE was interpreted primarily in terms of human cognitive limitations that require the use of JUDGMENT HEURISTICS, such as anchoring, when making discounting inferences about a dispositional cause (Jones 1979).

To integrate insights about different mechanisms contributing to the FAE, researchers have proposed sequential *stage models*: An initial perception-like process traces an actor's behavior to a corresponding disposition, then a second inference-like process adjusts the initial attribution to account for any situational factors. Whereas the first stage is posited to be automatic, much like a perceptual module, the

second stage requires effort and attention and hence takes place only if these are available—that is, if the attributor is not "cognitively busy." In support of a dual process model, experiments find that increasing participants' "busyness" results in more dispositional attributions (Gilbert, Pelham, and Krull 1988). However, it remains unclear whether the initial dispositional process is a perceptual module or merely a well-learned schematic inference.

Reacting against analyses of attribution as a decontextualized cognitive task, another recent theme is that attributions are markedly influenced by *goals* related to particular *social contexts*. The goal of assigning blame seems to accentuate the FAE (Shaver 1985). The goal of maintaining self-esteem leads people to dispositional attributions for successes but not failures (Snyder, Stephan, and Rosenfield 1976). The goal of making a good impression on an audience mitigates the FAE (Tetlock 1985). Studies of attributions in context have brought renewed attention to the important consequences of attribution, for example, the relation of dispositional attributions to sanctioning decisions (Carroll and Payne 1977). Applied research has found that self-serving styles of attribution not only protect an individual against clinical depression (Abrahamson, Seligman, and Teasdale 1978) but also contribute to achievement motivation and performance (Weiner 1985).

A current direction of attribution research involves closer attention to the *knowledge structures* that shape causal explanations. Explanations are constructed in order to cohere with the content knowledge triggered by observation of behavior, such as stereotypes and scripts (Read and Miller 1993). They are also constrained by frames for what constitutes an EXPLANATION in a given setting (Pennington and Hastie 1991). The guiding role of knowledge structures elucidates why the pattern of attribution errors differs across individuals, institutions, and cultures. Recent evidence points to individual differences (Dweck, Hong, and Chiu 1993) and cultural differences (Morris and Peng 1994) in the underlying causal schemas or lay theories that guide attribution. For example, findings that the FAE is stronger in Western, individualistic societies than in collectivist societies such as China seems to reflect different lay theories about the autonomy of individuals relative to social groups. Closer measurement of causal schemas and theories reveals that attribution errors previously interpreted in terms of processing limitations, such as the incomplete discounting of dispositions, reflect participants' knowledge structures rather than their inferential processes (Morris and Larrick 1995).

In sum, attribution theory has moved beyond the identification of errors like the FAE to an understanding of how they are produced by perceptual and cognitive limitations, by contextual goals, and by knowledge structures. As the story of research on the FAE phenomenon illustrates, attribution theory uncovers reciprocal relations between individual cognition, on one hand, and social and cultural contexts, on the other hand, and hence bridges the cognitive and social sciences.

Audition

Audition refers to the perceptual experience associated with stimulation of the sense of hearing. For humans, the sense of hearing is stimulated by acoustical energy—sound waves—that enter the outer ear (pinna and external auditory meatus) and set into vibration the eardrum and the attached bones (ossicles) of the middle ear, which transfer the mechanical energy to the inner ear, the cochlea. The auditory system can also be stimulated by bone conduction (Tonndorf 1972) when the sound source causes the bones of the skull to vibrate (e.g., one's own voice may be heard by bone conduction). Mechanical energy is transduced into neural impulses within the cochlea through the stimulation of the sensory hair cells which synapse on the eighth cranial, or auditory, nerve. In addition to the ascending, or afferent, auditory pathway from the cochlea to the cortex, there is a descending, efferent, pathway from the brain to the cochlea, although the functional significance of the efferent pathway is not well understood at present (Brugge 1992). Immediately following stimulation, the auditory system may become less sensitive due to adapta-

tion or fatigue (Ward 1973), and prolonged high-intensity stimulation can damage the sensory process (noise-induced hearing loss; for a series of review articles, see *J. Acoust. Soc. Am.* 1991, vol. 90: 124–227).

The auditory system is organized tonotopically such that the frequency of a stimulating sound is mapped onto a location along the basilar membrane within the cochlea, providing a *place* code (cf. AUDITORY PHYSIOLOGY). For example, low-frequency tones lead to maximal displacement of the apical portion of the basilar membrane and high-frequency tones lead to maximal displacement of the basal portion of the basilar membrane. In addition, cells exhibit frequency selectivity throughout the auditory pathway (e.g., Pickles 1988). This tonotopic organization provides a basis for spectral analysis of sounds. Temporal aspects of the stimulus (waveform fine structure or envelope) are preserved in the pattern of activity of auditory nerve fibers (Kiang et al., 1965), providing a basis for the coding of synchronized activity both across frequency and across the two ears. The dual presence of place and timing cues is pervasive in models of auditory perception.

The percept associated with a particular sound might be described in a variety of ways, but descriptions in terms of pitch, loudness, timbre, and perceived spatial location are probably the most common (Blauert 1983; Yost 1994; Moore 1997). Pitch is most closely associated with sound frequency, or the fundamental frequency for complex periodic sounds; loudness is most closely associated with sound intensity; and timbre is most closely associated with the distribution of acoustic energy across frequency (i.e., the shape of the power spectrum). The perceived location of a sound in space (direction and distance) is based primarily on the comparison of the sound arriving at the two ears (binaural hearing) and the acoustical filtering associated with the presence of the head and pinnae. Each of these perceptual classifications also depends on other factors, particularly when complex, time-varying sounds are being considered.

The frequency range of human hearing extends from a few cycles per second (Hertz, abbreviated Hz) to about 20,000 Hz, although the upper limit of hearing decreases markedly with age (e.g., Weiss 1963; Stelmachowitcz et al. 1989). The intensity range of human hearing extends over many orders of magnitude depending on frequency; at 2–4 kHz, the range may be greater than twelve orders of magnitude (120 decibels, abbreviated dB).

Despite the wide dynamic range of human hearing, the auditory system is remarkably acute: the just-discriminable difference (JND) in frequency is as small as 0.2 percent (e.g., Wier, Jesteadt, and Green 1977) and in intensity is approximately one dB (e.g., Jesteadt, Wier, and Green 1977). Sensitivity to differences in sounds arriving at the two ears is perhaps even more remarkable: time delays as small as a few microseconds may be discerned (Klumpp and Eady 1956). Although behavioral estimates of the JND for intensity, frequency, etc., provide invaluable information regarding the basic properties of the human auditory system, it is important to keep in mind that estimates of JNDs depend on both sensory and nonsensory factors such as memory and attention (e.g., Harris 1952; Durlach and Braida 1969; Berliner and Durlach 1972; Howard et al. 1984).

The interference one sound causes in the reception of another sound is called masking. Masking has a peripheral component resulting from interfering/overlapping patterns of excitation in the auditory nerve (e.g., Greenwood 1961), and a central component due to uncertainty, sometimes called "informational masking" (Watson 1987; see also AUDITORY ATTENTION). In a classic experiment, Fletcher (1940) studied the masking of a tone by noise in order to evaluate the frequency selectivity of the human auditory system. To account for the obtained data, Fletcher proposed a "critical band" that likened the ear to a bandpass filter (or, to encompass the entire frequency range, a set of contiguous, overlapping bandpass filters). This proposed "auditory filter" is a theoretical construct that reflects frequency selectivity present in the auditory system, and, in one form or another, auditory filters comprise a first stage in models of the spectrotemporal (across frequency and time) analysis performed by the auditory system (e.g., Patterson and Moore 1986).

The separation of sound into multiple frequency channels is not sufficient to provide a solution to the problem of sound segregation. Sound waves from different sources simply add, meaning that the frequencies shared by two or more sounds are processed *en masse* at the periphery. In order to form distinct images, the energy at a single frequency must be appropriately parsed. The computations used to achieve sound segregation depend on the coherence/incoherence of sound onsets, the shared/unshared spatial location of the sound sources, differences in the harmonic structure of the sounds and other cues in the physical stimulus. Yost has proposed that the spectrotemporal and spatial-location analysis performed by the auditory system serves the purpose of sound source determination (Yost 1991) and allows the subsequent organization of sound images into an internal map of the acoustic environment (Bregman 1990).

Approximately 28 million people in the United States suffer from hearing loss, and a recent census indicated that deafness and other hearing impairments ranked 6th among chronic conditions reported (National Center for Health Statistics 1993). Among those aged sixty-five and older, deafness and other hearing impairments ranked third among chronic conditions. The assessment of function and non-medical remediation of hearing loss is typically performed by an audiologist, whereas the diagnosis and treatment of ear disease is performed by an otologist.

Auditory Attention

Selective ATTENTION may be defined as a process by which the perception of certain stimuli in the environment is enhanced relative to other concurrent stimuli of lesser immediate priority. A classic auditory example of this phenomenon is the so-called cocktail party effect, wherein a person can selectively listen to one particular speaker while tuning out several other simultaneous conversations.

For many years, psychological theories of selective attention were traditionally divided between those advocating early levels of stimulus selection and those advocating late selection. Early selection theories held that there was an early filtering mechanism by which "channels" of irrelevant input could be attenuated or even rejected from further processing based on some simple physical attribute (BROADBENT 1970; Treisman 1969). In contrast, late selection theories held that all stimuli are processed to the same considerable detail, which generally meant through completion of perceptual analysis, before any selection due to attention took place (Deutsch and Deutsch 1963).

Various neurophysiological studies have attempted to shed light on both the validity of these theories and the neural mechanisms that underlie auditory attention. One possible neural mechanism for early stimulus selection would be the attenuation or gating of irrelevant input at the early levels of the sensory pathways by means of descending modulatory pathways (Hernandez-Peón, Scherrer, and Jouvet, 1956). For example, there is a descending pathway in the auditory system that parallels the ascending one all the way out to the cochlea (Brodal 1981), and direct electrical stimulation of this descending pathway at various levels, including auditory cortex, can inhibit the responses of the afferent auditory nerves to acoustic input. Other animal studies have indicated that stimulation of pathways from the frontal cortex and the mesencephalic reticular formation can modulate sensory transmission through the THALAMUS, thus providing another mechanism by which higher brain centers might modulate lower level processing during selective attention (Skinner and Yingling 1977). In addition, sensory processing activity in primary auditory CEREBRAL CORTEX or early auditory association cortices could conceivably be directly modulated by "descending" pathways from still higher cortical levels.

It has proven difficult, however, to demonstrate that any of these possible mechanisms for sensory modulation are actually used during auditory attention. Early animal studies purporting to show attenuation of irrelevant auditory input at the sensory periphery (Hernandez-Peón, Scherrer, and Jouvet 1956) were roundly criticized on methodological grounds (Worden 1966). Nevertheless, there have been animal studies providing evidence of some very early (i.e., brainstem-level) modulation of auditory processing as a function of attentional state or arousal (e.g., Oatman and Anderson 1977). In addition, Benson and Heinz (1978), studying single cells in monkey primary auditory cortex during a selective attention task (dichotic listening), reported relative enhancement of the responses to attended stimuli. Attending to sounds to perform sound localization vs. simple detection also has been shown to result in enhanced firing of units in auditory cortex (Benson, Heinz, and Goldstein 1981).

Auditory attention has been investigated extensively in humans using event-related potentials (ERPs) and event-related magnetic fields (ERFs). These recordings can noninvasively track with high temporal resolution the brain activity associated with different types of stimulus events. By analyzing changes in the ERPs or ERFs as a function of the direction of attention, one can make inferences about the timing, level of processing, and anatomical location of stimulus selection processes in the brain.

In an early seminal ERP study, Hillyard et al. (1973) implemented an experimental analog of the cocktail party effect and demonstrated differential processing of attended and unattended auditory stimuli at the level of the "N1" wave at ~100 msec poststimulus. More recent ERP studies furthering this approach have reported that focused auditory selective attention can affect stimulus processing as early as 20 msec poststimulus (the "P20-50" effect; Woldorff et al. 1987). Additional studies using ERPs (Woldorff and Hillyard 1991) and using ERFs and source-analysis modeling (Woldorff et al. 1993) indicated these electrophysiological attentional effects occurred in and around primary auditory cortex, had waveshapes that precisely took the form of an amplitude modulation of the early sensory-evoked components, and were colocalized with the sources of these sensory-evoked components. These results were interpreted as providing strong evidence for the existence of an attentionally modulated, sensory gain control of the auditory input channels at or before the initial stages of cortical processing, thereby providing strong support for early selection attentional theories that posit that stimulus input can be selected at levels considerably prior to the completion of perceptual analysis. Moreover, the very early onset latency of these attentional effects (20 ms) strongly suggests that this selection is probably accomplished by means of a top-down, preset biasing of the stimulus input channels.

On the other hand, reliable effects of attention on the earliest portion of the human auditory ERP reflecting auditory nerve and brainstem-level processing have generally not been found (Picton and Hillyard 1974), thus providing no evidence for peripheral filtering via the descending auditory pathway that terminates at the cochlea. Nevertheless, recent research measuring a different type of physiological response—otoacoustic cochlear emissions—has provided some evidence for such early filtering (Giard et al. 1991).

Additional evidence that attention can affect early auditory processing derives from studies of another ERP/ERF wave known as the mismatch negativity/mismatch field (MMN/MMF), which is elicited by deviant auditory stimuli in a series of identical stimuli. Because the MMN/MMF can be elicited in the absence of attention and by deviations in any of a number of auditory features, this wave was proposed to reflect a strong automaticity of the processing of

auditory stimulus features (reviewed in Naatanen 1990 and 1992). Both the MMN (Woldorff et al. 1991) and the MMF (Woldorff et al. 1998), however, can also be modulated by attention, being greatly reduced when attention is strongly focused elsewhere, thus providing converging evidence that attention can influence early auditory sensory analysis. On the other hand, the elicitation of at least some MMN/MMF for many different feature deviations in a strongly ignored auditory channel has been interpreted as evidence that considerable feature analysis is still performed even for unattended auditory stimuli (Alho 1992). An intermediate view that may accommodate these findings is that various aspects of early auditory sensory processing and feature analysis may be "partially" or "weakly" automatic, occurring even in the absence of attention but still subject to top-down attentional modulation (Woldorff et al. 1991; Hackley 1993). Under this view, the very earliest stimulus processing (i.e., peripheral and brainstem levels) tends to be strongly automatic, but at the initial cortical levels there is a transition from strong to weak automaticity, wherein some amount of analysis is generally obligatory but is nevertheless modifiable by attention (reviewed in Hackley 1993).

There are also various slower-frequency, longer-latency ERP auditory attention effects that are not modulations of early sensory activity, but rather appear to reflect "endogenous," additional activations from both auditory and nonauditory association cortex (e.g., "processing negativity," target-related "N2b," "P300"). This type of activity occurs only or mainly for attended-channel stimuli or only for target stimuli within an attended channel and might reflect later selection, classification, or decision processes that also occur during auditory attention (reviewed in Alho 1992; Näätänen 1992). Attention to less discriminable features of auditory stimuli (Hansen and Hillyard 1983) or to a conjunction of auditory features (Woods et al. 1991) also produces longer-latency differential activation that may reflect later selection processes. In addition, there is a build-up of endogenous brain electrical activity (a "DC shift") as subjects begin to attend to a short stream of auditory stimuli (Hansen and Hillyard 1988), which could reflect some sort of initiation of the controlling executive function.

In contrast to electrophysiological studies, relatively few hemodynamically-based functional neuroimaging studies have been directed at studying auditory attention in humans. In a recent study using POSITRON EMISSION TOMOGRAPHY (PET), O'Leary et al. (1996) reported enhanced activity in the auditory cortex contralateral to the direction of attention during a dichotic listening task. PET studies have also shown that attention to different aspects of speech sounds (e.g., phonetics vs. pitch) can affect the relative activation of the two hemispheres (Zatorre, Evans, and Meyer 1992). In addition, functional MAGNETIC RESONANCE IMAGING has indicated that intermodal attention can modulate auditory cortical processing (Woodruff et al. 1996).

Most neurophysiological studies of auditory attention in humans have focused on the *effects* of attention on the processing of sounds in auditory cortical areas. Less work has been directed toward elucidating the neural structures and mechanisms that *control* auditory attention. Based on various hemodynamic imaging studies, the anterior cingulate is likely to be involved, as it is activated during a number of cognitive and/or executive functions (Posner et al. 1988). In addition, human lesion studies suggest the prefrontal cortex is important for modulating the activity in the ipsilateral auditory cortex during auditory attention (Knight et al. 1981). It may be that some of the slower-frequency, endogenous ERP auditory attention effects reflect the activation of these areas as they serve to modulate or otherwise control auditory processing. Whether these mechanisms actually employ thalamic gating, some other modulatory mechanism, or a combination, is not yet known.

Auditory Physiology

The two main functions of hearing lie in auditory communication and in the localization of sounds. Auditory physiology tries to understand the perception, storage, and recognition of various types of sounds for both purposes in terms of neural activity patterns in the auditory pathways. The following article will try to analyze what auditory representations may have in common with other sensory systems, such as the visual system (see VISUAL ANATOMY AND PHYSIOLOGY), and what may be special about them.

Since the days of HELMHOLTZ (1885) the auditory system has been considered to function primarily as a frequency analyzer. According to von Békésy's work (1960), which was awarded the Nobel Prize in 1961, sound reaching the tympanic membrane generates a traveling wave along the basilar membrane in the cochlea of the inner ear. Depending on the frequency of the sound, the traveling wave achieves maximum amplitude in different locations. Thus frequency gets translated into a place code, with high frequencies represented near the base and low frequencies near the apex of the cochlea. Although the traveling wave has a rather broad peak, various synergistic resonance mechanisms assure

effective stimulation of the cochlear hair cells at very precise locations.

Electrophysiological studies using tones of a single frequency (pure tones) led to a multitude of valuable data on the responses of neurons to such stimuli and to the recognition of tonotopic organization in the auditory pathways. Tonotopy, the neural representation of tones of best frequency in a topographic map, is analogous to retinotopy in the visual and somatotopy in the somatosensory system. The map is preserved by maintaining neighborhood relationships between best frequencies from the cochlea and auditory nerve through the initial stages of the central auditory system, such as cochlear nuclei, inferior colliculus and medial geniculate nucleus, to primary auditory cortex (A1; fig. 1). The standard assumption in pure-tone studies is that in order to understand stimulus coding at each subsequent level, one has to completely analyze the lower levels and then establish the transformations taking place from one level to the next (Kiang 1965). While this approach sounds logical, it assumes that the system is linear, which cannot always be taken for granted. Another problem that this theory has not solved is how information from different frequency channels gets integrated, that is, how complex sounds are analyzed by the auditory system.

The use of complex sound stimuli, therefore, is of the essence in the analysis of higher auditory pathways. This has been done successfully in a number of specialized systems, such as frogs, songbirds, owls, and bats. For all these species, a neuroethological approach has been adopted based on functional-behavioral data (Capranica 1972; see also ANIMAL COMMUNICATION, ECHOLOCATION, and ETHOLOGY). The same approach has been used only sparingly in higher mammals, including primates (Winter and Funkenstein 1973).

The neurophysiological basis in humans for processing complex sounds, such as speech (see SPEECH PERCEPTION), cannot be studied directly with invasive methods. Therefore, animal models (e.g., nonhuman primates) have to be used. The question then arises to what extent human speech sounds can be applied validly as stimuli for the study of neurons in a different species. From a biological-evolutionary vantage point, it is more meaningful to employ the types of complex sounds that are used for communication in those same species (see ANIMAL COMMUNICATION). In using conspecific vocalizations we can be confident that the central auditory system of the studied species must be capable of processing these calls. By contrast, human speech sounds may not be processed in the same way by that species.

When comparing human speech sounds with communication sound systems in other species it is plain to see that most systems have certain components in common, which are used as carriers of (semantic) information. Among these DISTINCTIVE FEATURES are segments of frequency changing over time (FM sweeps or "glides") and bandpass noise bursts with specific center frequencies and bandwidths (fig. 2). Such universal elements of auditory communication signals can be used as stimuli with a degree of complexity that is intermediate between the pure tones used in traditional auditory physiology and the whole signal whose representation one really wants to understand.

Psychophysical studies have indeed provided evidence for the existence of neural mechanisms tuned to the rate and direction of FM glides (Liberman et al. 1967, Kay 1982) as well as to specific bands of noise (Zwicker 1970). Neurophysiologically, neurons selective to the same parameters have been identified in the auditory cortex of various species. Most notably, a large proportion of FM selective neurons as well as neurons tuned to certain bandwidths have recently been found in the lateral belt areas of the superior temporal gyrus (STG) in rhesus monkeys (Rauschecker, Tian, and Hauser 1995). The posterior STG region has also been found to contain mechanisms selective for phoneme identification in humans, using functional neuroimaging techniques (see PHONOLOGY, NEURAL BASIS OF).

Many neurons in the lateral belt or STG region of rhesus monkeys (fig. 1B) also respond well and quite selectively to the monkey calls themselves. The question arises by what neural mechanisms such selectivity is generated. Studies in which monkey calls are dissected into their constituent elements (both in the spectral and temporal domains), and the elements are played to the neurons separately or in combination can provide an answer to this question (Rauschecker 1998). A sizable proportion of neurons in the STG (but not in A1) responds much better to the whole call than to any of the elements. These results are indicative of nonlinear summation in the frequency and time domain playing a crucial role in the generation of selectivity for specific types of calls. Coincidence detection in the time domain is perhaps the most important mechanism in shaping this selectivity. Temporal integration acts over several tens (or hundreds) of milliseconds, as most "syllables" in monkey calls (as well as in human speech) are of that duration.

There is some limited evidence for a columnar or patchy representation of specific types of monkey calls in the lateral belt areas. Rhesus calls can be subdivided into three coarse classes: tonal, harmonic, and noisy calls. Neurons responsive to one or another category are often found grouped together. It would be interesting to look for an orderly "phonetic map" of the constituent elements themselves, whereby interactions in two-dimensional arrays of time and frequency might be expected.

It is very likely that the lateral belt areas are not yet the ultimate stage in the processing of communication sounds. They may just present an intermediate stage, similar to V4 in the visual system, which also contains neurons selective for the size of visual stimuli. Such size selectivity is obviously of great importance for the encoding of visual patterns or objects, but the differentiation into neurons selective for even more specific patterns, such as faces, is not accomplished until an even higher processing stage, namely, the inferotemporal cortex (Desimone 1991; see also FACE RECOGNITION). In the auditory cortex, areas in the anterior or lateral parts of the STG or in the dorsal STS may be target areas for the exploration of call-specific neurons.

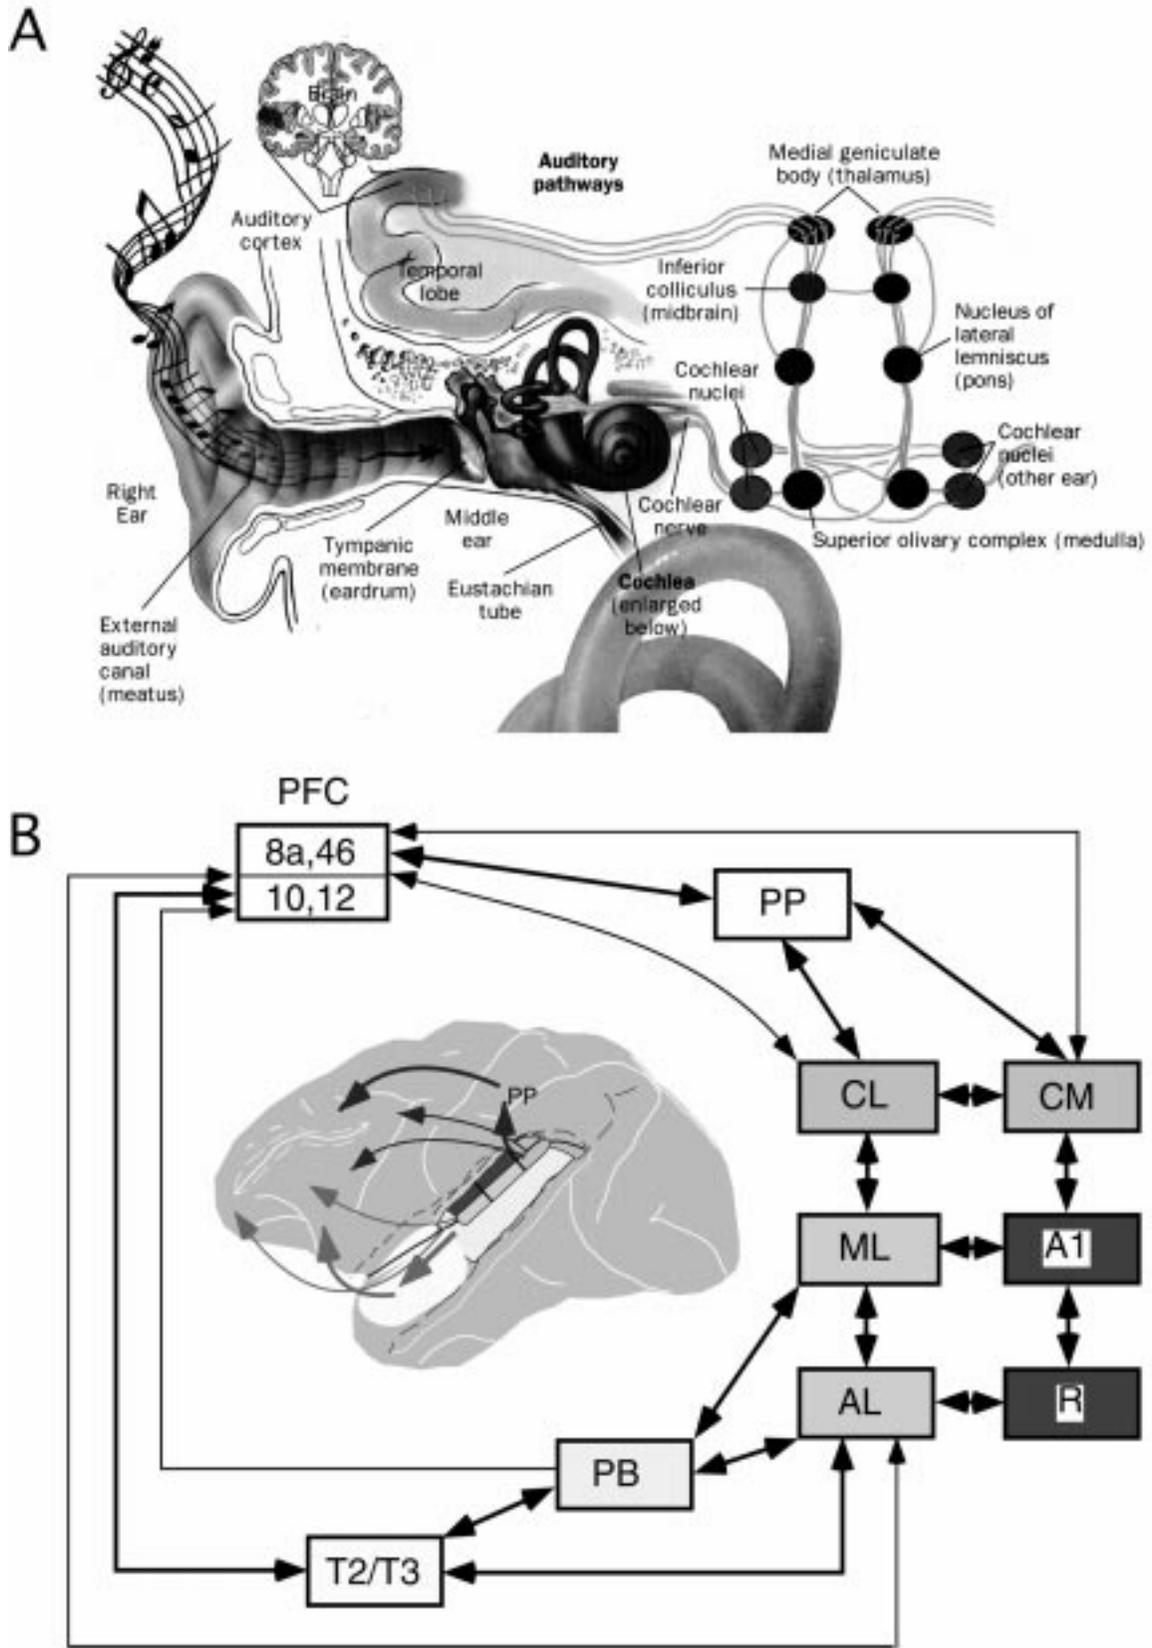
The second main task of hearing is to localize sound sources in space. Because the auditory periphery does not a priori possess a two-dimensional quality, as do the visual and somatosensory peripheries, auditory space has to be computed from attributes of sound that vary systematically with spatial location and are thus processed differentially by the


Figure 1. Schematic illustration of the major structures and pathways in the auditory system of higher mammals. Figure 2. Sound spectrograms human speech samples (A) and monkey calls (B) illustrating the common occurrence of FM glides and band-pass noise bursts in vocalizations from both species.

central auditory system. This problem is logistically similar to the computation of 3-D information from two-dimensional sensory information in the visual system. Sound attributes most commonly assigned to spatial quality are differences between sound arriving at the two ears. Both the intensity and the time of arrival of sound originating from the same source differ when the sound source is located outside the median plane. Interaural time and intensity differences (ITD and IID, respectively) are registered and mapped already in areas of

the brainstem, such as the superior olivary complex (Irvine 1992). In addition, the spectral composition of sound arriving at the two ears varies with position due to the spectral filter characteristics of the external ears (pinnae) and the head. Even monaurally, specific spectral "fingerprints" can be assigned to spatial location, with attenuation of particular frequency bands ("spectral notches") varying systematically with azimuth or elevation (Blauert 1996). Neurons in the dorsal cochlear nuclei are tuned to such spectral notches and may

thus be involved in extracting spatial information from complex sounds (Young et al. 1992).

The information computed by these lower brainstem structures is used by higher centers of the midbrain, such as the inferior and superior colliculi, to guide orienting movements toward sounds. For more "conscious" spatial perception in higher mammals, including humans, auditory cortex seems to be indispensable, as cortical lesions almost completely abolish the ability to judge the direction of sound in space. Neurons in the primary auditory cortex of cats show tuning to the spatial location of a sound presented in free field (Imig, Irons, and Samson 1990). Most recently, an area in the anterior ectosylvian sulcus (AES), which is part of the cat's parietal cortex, has been postulated to be crucially involved in sound localization (Korte and Rauschecker 1993, Middlebrooks et al. 1994). Functional neuroimaging studies in humans also demonstrate specific activation in the posterior parietal cortex of the right hemisphere by virtual auditory space stimuli (Rauschecker 1998a,b).

Both animal and human studies suggest, therefore, that information about auditory patterns or objects gets processed, among others, in the superior temporal gyrus (STG). By contrast, auditory spatial information seems to get processed in parietal regions of cortex (fig. 1B). This dual processing scheme is reminiscent of the visual pathways, where a ventral stream has been postulated for the processing of visual object information and a dorsal stream for the processing of visual space and motion (Mishkin, Ungerleider, and Macko 1983; see also VISUAL PROCESSING STREAMS).

Auditory Plasticity

The perception of acoustic stimuli can be altered as a consequence of age, experience, and injury. A lasting change in

either the perception of acoustic stimuli or in the responses of neurons to acoustic stimuli is known as auditory plasticity, a form of NEURAL PLASTICITY. This plasticity can be demonstrated at both the perceptual and neuronal levels through behavioral methods such as operant and classical CONDITIONING or by lesions of the auditory periphery both in the adult and during development. The plasticity of neuronal responses in the auditory system presumably reflects the ability of humans and animals to adjust their auditory perceptions to match the perceptual world around them as defined by the other sensory modalities, and to perceive the different acoustic-phonetic patterns of the native languages(s) learned during development (see Kuhl 1993).

There are several examples within the psychophysical literature where human subjects can improve their performance at making specific judgments of acoustic stimulus features over the course of several days to weeks, presumably due to changes in the cortical representation of the relevant stimulus parameters. For example, it has recently been shown that normal human subjects will improve their performance at a temporal processing task over the course of several days of training (Wright et al. 1997).

Training-induced changes in perceptual ability have recently been tested as a treatment strategy for children with language-based learning disabilities (cf. LANGUAGE IMPAIRMENT, DEVELOPMENTAL). It had been suggested that children with this type of learning disability are unable to determine the order of two rapidly presented sounds (Tallal and Piercy 1973). Recent studies have demonstrated that some children with this type of learning disability can make such discriminations following several weeks of practice (Merzenich et al. 1996), and these children also showed significant improvements in language comprehension (Tallal et al. 1996).

Several approaches in experimental animals have been employed to address the neuronal mechanisms that underlie auditory plasticity. Single auditory neurons have been shown to change their response properties following classical conditioning paradigms. As an example, SINGLE-NEURON RECORDING techniques define the response of a single neuron to a range of frequencies, and then a tone that was not optimal in exciting the neuron (the conditioned stimulus, CS) is paired with an unconditioned stimulus (US, e.g., a mild electrical shock). When the frequency response profile of the neuron is defined after conditioning, the response of the neuron to the conditioned tone can be much larger, in some cases to the point that the paired tone is now the best stimulus at exciting the neuron. These changes require a pairing of the CS and the US (Bakin and Weinberger 1990). This response plasticity has been demonstrated in both the auditory THALAMUS and auditory divisions of the CEREBRAL CORTEX (Ryugo and Weinberger 1978; Diamond and Weinberger 1986; Bakin and Weinberger 1990).

It has also been demonstrated that the modulatory neurotransmitter acetylcholine is an important contributor to this effect. If the acetylcholine receptor is blocked, there is no change in the response properties of the neurons (McKenna et al. 1989). Similarly, activation of the acetylcholine receptor produces a similar enhancement of the neuronal response to the conditioned stimulus (Metherate and Weinberger 1990).

A different experimental strategy is to observe the effects of the representation of frequencies across a wide region of the cerebral cortex. For example, if a limited region of the hair cells in the cochlea are destroyed, there is an expansion of the representation of the neighboring spared frequencies in the auditory cortex (Robertson and Irvine 1989; Rajan et al. 1993). These results indicate that the cerebral cortex is able to adjust the representation of different frequencies depending on the nature of the input. This same type of cortical reorganization probably occurs in normal humans during the progressive loss of high frequency hair cells in the cochlea with aging.

Cortical reorganization can also occur following a period of operant conditioning, where the perception of acoustic stimuli is improved over time, similar to the studies on human subjects described above. Monkeys trained at a frequency discrimination task show a continual improvement in performance during several weeks of daily training. After training, the area within the primary auditory cortex that is most sensitive to the trained frequencies is determined. This area of representation is the greatest in the monkeys trained to discriminate that frequency when compared to the representation of untrained monkeys. This occurs regardless of what particular frequency the monkey was trained to discriminate, but it occurs only at those trained frequencies, and no others. The cortical area of the representation of these trained and untrained frequencies is correlated with the behavioral ability (Recanzone, Schreiner, and Merzenich 1993). A further finding was that only animals that attended to and discriminated the acoustic stimuli showed any change in the cortical representations; monkeys stimulated in the same manner while engaged at an unrelated task had normal representations of the presented frequencies. Thus, stimulus relevance is important in both operant and classical conditioning paradigms.

Auditory plasticity also occurs during development, which has been investigated by taking advantage of the natural orienting behavior of barn owls. These birds can locate the source of a sound extremely accurately. Rearing young owls with optically displacing prisms results in a shift in the owl's perception of the source of an acoustic stimulus (Knudsen and Knudsen 1989). This shift can also be demonstrated electrophysiologically as an alignment of the visual and displaced auditory receptive fields of neurons in the optic tectum (Knudsen and Brainard 1991).

The converging neuronal data from experimental animals suggest that similar changes in response properties of cortical and subcortical neurons also occur in humans. The improvements in performance of human subjects in auditory discrimination tasks, the normal high frequency hearing loss during aging, the change from "language-general" to "language-specific" processing of phonetic information during language acquisition, and injuries to the cochlea or central auditory structures, are presumably resulting in changes in single neuron responses and in cortical and subcortical representations. It is quite likely that neuronal plasticity across other sensory modalities and other cognitive functions, particularly in the cerebral cortex, underlies the ability of humans and other mammals to adapt to a changing environment and acquire new skills and behaviors throughout life.

Autism

A developmental disorder of the brain, autism exists from birth and persists throughout life. The etiology of the disorder is still unknown, but is believed to be largely genetic, while different organic factors have been implicated in a substantial proportion of cases (for reviews see Ciaranello and Ciaranello 1995; Bailey, Phillips, and Rutter 1996). Autism was identified and labeled by Kanner (1943) and Asperger (1944).

The diagnosis of autism is based on behavioral criteria. The chief criteria as set out in ICD-10 (WHO 1992) and in DSM-IV (APA 1994) include: abnormalities of social interaction, abnormalities of verbal and nonverbal communication, and a restricted repertoire of interests and activities. Behavior suggestive of these impairments can already be discerned in infancy. A recent screening instrument, based on a cognitive account of autism, appears to be remarkably successful at eighteen months, involving failure of gaze monitoring, protodeclarative pointing, and pretend play (Baron-Cohen et al. 1996). These appear to be the first clear behavioral manifestations of the disorder. Contrary to popular belief, failure of bonding or attachment is not a distinguishing characteristic of autism.

The autistic spectrum refers to the wide individual variation of symptoms from mild to severe. Behavior not only varies with age and ability, but is also modified by a multitude of environmental factors. For this reason, one of the major problems with behaviorally defined developmental disorders is how to identify primary, associated, and secondary features. Three highly correlated features, namely characteristic impairments in socialization, communication, and imagination, were identified in a geographically defined population study (Wing and Gould 1979). These impairments appear to persist in development even though their

outward manifestation is subject to change. For example, a socially aloof child may at a later age become socially interested and show "pestering" behavior; a child with initially little speech may become verbose with stilted, pedantic language. The triad of impairments appears to be a common denominator throughout a spectrum of autistic disorders (Wing 1996).

The prevalence of autistic disorder has been studied in a number of different countries, and is between 0.16 and 0.22 percent, taking into account the most recent estimates. Males predominate at approximately 3 to 1, and this ratio becomes more extreme with higher levels of ability. The prevalence of a milder variant of autism, Asperger syndrome, is estimated as between 0.3 and 0.7 percent of the general population on the basis of preliminary findings. These individuals are sometimes thought to be merely eccentric and may not be diagnosed until late childhood or even adulthood. Because they have fluent language and normal, if not superior verbal IQ, they can compensate to some extent for their problems in social communication.

MENTAL RETARDATION, a sign of congenital brain abnormality, is one of the most strongly associated features of autism; IQ is below 70 in about half the cases, and below 80 in three quarters. Epilepsy is present in about a third of individuals, while other neurological and neuropsychological signs are almost always detectable (for reviews see Gillberg and Coleman 1992). Postmortem brain studies have shown a number of abnormalities in cell structure in different parts of the brain, including temporal and parietal lobes, and in particular, limbic structures, as well as the CEREBELLUM. Findings indicate a curtailment of neuronal development at or before thirty weeks of gestation (Bauman and Kemper 1994). No consistent and specific structural or metabolic abnormalities have as yet been revealed, but overall brain volume and weight tend to be increased.

A genetic basis for autism is strongly indicated from twin and family studies favoring a multiplicative multilocus model of inheritance, perhaps involving only a small number of genes (reviewed by Bailey et al. 1995). There is evidence for a broader cognitive phenotype with normal intelligence and varying degrees of social and communication impairments which may be shared by family members. Other disorders of known biological origin, such as fragile X-syndrome, phenylketonuria, tuberous sclerosis, can lead to the clinical picture of autism in conjunction with severe mental retardation (Smalley, Asarnow, and Spence 1988). There is no known medical treatment. However, special education and treatment based on behavior management and modification often have beneficial effects (see chapters in Schopler and Mesibov 1995). Whatever the treatment, the developmental progress of children with autism is quite variable.

Cognitive explanations of the core features of autism provide a vital interface between brain and behavior. The proposal of a specific neurologically based problem in understanding minds was a significant step in this endeavor. The hypothesis that autistic children lack the intuitive understanding that people have mental states was originally tested with the Sally-Ann false belief paradigm (Baron-Cohen, Leslie, and Frith 1985). This impairment has been confirmed in a number of studies (see chapters in Baron-Cohen, Tager-Flusberg, and Cohen 1993) and has become known as the THEORY OF MIND deficit. Most individuals with autism fail to appreciate the role of mental states in the explanation and prediction of everyday behavior, including deception, joint attention, and those emotional states which depend on monitoring other people's attitudes, for example pride (Kasari et al. 1993). The brain basis for the critical cognitive ability that enables a theory of mind to develop has begun to be investigated by means of functional brain imaging (Fletcher et al. 1995; Happé et al. 1996). Other explanations of social communication impairments in autism have emphasized a primary emotional deficit in INTERSUBJECTIVITY (Hobson 1993).

The nonsocial features of autism, in particular those encompassed by the diagnostic sign *restricted repertoire of interests,* are currently tackled by two cognitive theories. The first proposes a deficit in executive functions. These include planning and initiation of action and impulse control, and are thought to depend on intact prefrontal cortex. Evidence for poor performance on many "frontal" tasks in autism is robust (Ozonoff, Pennington, and Rogers 1991; Pennington and Ozonoff 1996). For instance, individuals with autism often fail to inhibit prepotent responses and to shift response categories (Hughes, Russell, and Robbins 1994). Poor performance on these tasks appears to be related to stereotyped and perseverative behavior in everyday life. The site of brain abnormality need not necessarily be in prefrontal cortex, but could be at different points in a distributed system underlying executive functions, for example the dopamine system (Damasio and Maurer 1978).

A second cognitive theory that attempts to address islets of ability and special talents that are present in a significant proportion of autistic individuals is the theory of weak central coherence (Frith and Happé 1994). This theory proposes that the observed performance peaks in tests such as block design and embedded figures, and the *savant syndrome,* shown for instance in outstanding feats of memory or exceptional drawing, are due to a cognitive processing style that favors segmental over holistic processing. Some evidence exists that people with autism process information in an unusually piecemeal fashion (e.g., start a drawing from an unusual detail). Likewise, they fail to integrate information so as to derive contextually relevant meaning. For instance, when reading aloud "the dog was on a long lead," they may pronounce the word *lead* as *led.*

Clearly, the explanation of autism will only be complete when the necessary causal links have been traced between gene, brain, mind and behavior. This is as yet a task for the future.

Autocatalysis

See SELF-ORGANIZING SYSTEMS

Automata

An *automaton* (pl. *automata*) was originally anything with the power of self-movement, then, more specifically, a *machine* with the power of self-movement, especially a figure that simulated the motion of living beings. Perhaps the most impressive such automata were those of Jacques de Vaucanson (1709–1782), including a duck that ate and drank with realistic motions of head and throat, produced the sound of quacking, and could pick up cornmeal and swallow, digest, and excrete it.

People acting in a mechanical, nonspontaneous way came to be called automata, but this begs the very question for which cognitive science seeks a positive answer: "Is the working of the human mind reducible to information processing embodied in the workings of the human brain?" that is, is human spontaneity and intelligence a purely material phenomenon? René DESCARTES (1596–1650) saw the functioning of nonhuman animals, and much of human function, as being explainable in terms of the automata of his day but drew the line at cognitive function. However, whereas Descartes's view was based on clockwork and hydraulic automata, most cognitive science is based on a view of automata as "information processing machines" (though there is now a welcome increase of interest in *embodied automata).*

The present article describes key concepts of information processing automata from 1936 through 1956 (the year of publication of *Automata Studies* by Shannon and McCarthy), including Turing machines, finite automata, automata for formal languages, McCulloch-Pitts neural networks, and self-reproducing automata.

TURING (1936) and Post (1936) introduced what is now called a *Turing machine* (TM), consisting of a control box containing a finite program; an indefinitely extendable tape divided lengthwise into squares; and a device for scanning

and then printing on one square of the tape at a time and subsequently moving the tape one square left or right or not at all. We start the machine with a finite sequence of symbols on the tape, and a program in the control box. The symbol scanned, and the instruction now being executed from the program, determine what new symbol is printed on the square, how the tape is moved, and what instruction is executed next.

We associate with a TM Z a numerical function f_Z by placing a number n encoded as a string $<n>$ on the tape and start Z scanning the leftmost square of $<n>$. If and when Z stops, we decode the result to obtain the number $f_Z(n)$. If Z never stops, we leave $f_Z(n)$ undefined. Just consider the program Z, which always moves right on its tape (new squares are added whenever needed), as an example of a machine that never stops computing, no matter what its input. More subtle machines might, for example, test to see whether n is prime and stop computing only if that is the case. (We can only associate f_Z with Z after we have chosen our encoding. Nonnumerical functions can be associated with a TM once we have a "straightforward" way of unambiguously coding the necessarily finite or countable input and output structures on the tape.)

Turing's Hypothesis (also called *Church's thesis*; see CHURCH-TURING THESIS) is that a function is effectively computable if and only if it is computable by some TM. This statement is informal, but each attempt to formalize the notion of effectiveness using finite "programs" has yielded procedures equivalent to those implementable by TMs (or a subclass thereof).

Because each TM is described by a finite list of instructions we may *effectively enumerate* the TMs as Z_1, Z_2, Z_3, . . .—given n we may effectively find Z_n, and given the list of instructions for Z, we may effectively find the n for which $Z = Z_n$. For example, we might list all the one-instruction programs first, then all those with two instructions, and so on, listing all programs of a given length in some suitable generalization of alphabetical order.

Turing showed that there is a *universal Turing Machine* that, given a coded description of Z_n on its tape as well as x, will proceed to compute $fz_n(x) = f_n(x)$, if it is defined. This is obvious if we accept Turing's hypothesis, for given n and x we find Z_n effectively, and then use it to compute $f_n(x)$, and so there should exist a TM to implement the effective procedure of going from the pair (n, x) to the value $f_n(x)$. More directly, we can program a Turing machine U that divides the data on its tape into two parts, that on the left providing the instructions for Z_n, and that on the right providing the string $x(t)$ on which Z_n would now be computing. U is programmed to place markers against the current instruction from Z_n and the currently scanned symbol of $x(t)$, and to move back and forth between instructions and data to simulate the effect of Z_n on x. For further details see Minsky (1967) and Arbib (1969), the second of which generalizes Turing machines to those that can work in parallel on multiple, possibly multidimensional tapes.

Is every function mapping natural numbers ($N = \{0, 1, 2, 3, . . .\}$) to natural numbers computable? Obviously not, for we have seen that the number of computable functions is countable, whereas the number of all functions is uncountable. To understand the latter claim, note that any real number between zero and one can be represented by an infinite decimal expansion $0.d_0d_1d_2d_3 . . . d_n . . .$ and thus as a function $f:N \to N$ with $f(n) = d_n$—and thus the uncountable set of these real numbers can be viewed as a subset of the set of all functions from N to N. However, the interest of computability theory is that there are "computationally interesting" functions that are not computable.

The following provides a simple example of an explicit proof of noncomputability. We define a *total* function h (i.e., $h(x)$ is defined for every x in N) as follows. Let $h(n) = n$ if f_n is itself total, while $h(n) = n_0$ if f_n is not total—where n_0 is a fixed choice of an integer for which f_{n_0} is a total computable function; h thus has the interesting property that a computable function f_n is total if and only if $n = h(m)$ for some m. h is certainly a well-defined total function, but is h a *computable* function? The answer is no. For if h were computable, then so too would be the function f defined by $f(n) = f_{h(n)}(n) + 1$, and f would also be total. Then f is total and computable, and so $f = f_{h(m)}$ for some m so that $f(m) = f_{h(m)}(m)$. But, by definition, $f(m) = f_{h(m)}(m) + 1$, a contradiction! This is one example of the many things undecidable by any effective procedure.

The most famous example—proved by an extension of the above proof—is that we cannot tell effectively for arbitrary (n, x) whether Z_n will stop computing for input x. Thus *the halting problem for TMs is unsolvable.*

Finite automata provide, essentially, the input-output behavior of the TM control box without regard for its interaction with the tape. A *finite automaton* is abstractly described as a quintuple $M = (X, Y, Q, \delta, \beta)$ where X, Y, and Q are finite sets of inputs, outputs, and states, and if at time t the automaton is in state q and receives input x, it will emit output $\beta(q)$ at time t, and then make the transition to state $\delta(q,x)$ at time $t + 1$.

Given this, we can view the control box of a Turing Machine as a finite automaton: let X be the set of tape symbols, Q the set of control-box instructions, and Y the set $X \times M$ of pairs (x, m) where x is symbol to be printed on the tape and m is a symbol for one of the three possible tape moves (left, right, or not at all).

Another special case of the finite automaton definition takes Y to be the set $\{0,1\}$—this is equivalent to dividing the set Q into the set F of designated *final* states for which $\beta(q) = 1$, and its complement—and then designates a specific state q_0 of Q to be the "initial state." In this case, interest focuses on the *language accepted* by M, namely the set of strings w consisting of a sequence of 0 or more elements of X (we use X^* to denote the set of such strings) with the property that if we start M in state q_0 and apply input sequence w, then M will end up in a state—denoted by $\delta^*(q_0,w)$—that belongs to F.

The above examples define two sets of "languages" (in the sense of subsets of X^*, i.e., strings on some specified alphabet): *finite-state languages* defined as those languages accepted by some finite automaton, and *recursively enumerable sets* that have many equivalent definitions, including "a set R is *recursively enumerable* if and only if there is a Turing machine Z such that Z halts computation on initial tape x if and only if x belongs to R." Without going into

details and definitions here, it is interesting to note that two intermediate classes of formal languages—the context-free languages and the context-sensitive languages—have also been associated with classes of automata. The former are associated with *push-down automata* and the latter with *linear-bounded automata*. Discussion of the relation of these language classes to human language was a staple topic for discussion in the 1960s (Chomsky and Miller 1963; Chomsky 1963; Miller and Chomsky 1963), and Chomsky has subsequently defined a number of other systems of formal grammar to account for human language competence. However, much work in PSYCHOLINGUISTICS now focuses on the claim that adaptive networks provide a better model of language performance than does any system based on using some fixed automaton structure which embodies such a formal grammar (e.g., Seidenberg 1995).

McCulloch and Pitts (1943) modeled the neuron as a logic element, dividing time into units so small that in each time period at most one spike can be initiated in the axon of a given neuron, with output 1 or 0 coding whether or not the neuron "fires" (i.e., has a spike on its axon). Each connection from neuron i to neuron j has an attached *synaptic weight*. They also associate a *threshold* with each neuron, and assume exactly one unit of delay in the effect of all pre-synaptic inputs on the cell's output. A McCulloch-Pitts neuron (MP-neuron) fires just in case the weighted value of its inputs at that time reaches threshold.

Clearly, a network of MP-neurons functions like a finite automaton, as each neuron changes state synchronously on each tick of the time scale. Conversely, it was shown, though inscrutably, by McCulloch and Pitts that any finite automaton can be simulated by a suitable network of MP-neurons—providing formal "brains" for the TMs, which can carry out any effective procedure. Knowledge of these results inspired VON NEUMANN's logical design for digital computers with stored programs (von Neumann, Burks, and Goldstine 1947–48).

Intuitively, one has the idea that a construction machine must build a simpler machine. But in biological systems, the complexity of an offspring matches that of the parent; and evolution may yield increasing biological complexity. Von Neumann (1951) outlined the construction of an automaton A that, when furnished with the description of any other automaton M (composed from some suitable collection of elementary parts) would construct a copy of M. However, A is *not* self-reproducing: A, supplied with a copy of its own description, will build a copy of A *without* its own description. The passage from a *universal constructor* to a *self-reproducing automaton* was spelled out in von Neumann (1966) in which the "organism" is a pattern of activity in an unbounded array of identical finite automata, each with only twenty-nine states. This was one root of the study of *cellular automata*.

As embodied humans we have far richer interactions with the world than does a TM; our "computations" involve all of our bodies, not just our brains; and biological neurons are amazingly more subtle than MP-neurons (Arbib 1995, pp. 4–11). A TM might in principle be able to solve a given problem—but take far too long to solve it. Thus it is not enough that something be computable—it must be *tractable,* that is,

computable with available resources (Garey and Johnson 1979). Distributed computation may render tractable a problem that a serial TM would solve too slowly. When some people say "the brain is a computer," they talk as if the notion of "computer" were already settled. However, a human brain is built of hundreds of regions, each with millions of cells, each cell with tens of thousands of connections, each connection involving subtle neurochemical processes. To understand this is to push the theory of automata—and cognitive science—far beyond anything available today. Our concepts of automata will grow immensely over the coming decades as we better understand how the brain functions.

Arbib (1987) provides much further information on neural nets, finite automata, TMs, and automata that construct as well as compute, as well as a refutation of the claim that Gödel's Incompleteness theorem (see GÖDEL'S THEOREMS) sets limits to the intelligence of automata. Many articles in Arbib (1995) and in the present volume explore the theme of connectionist approaches to cognitive modeling (see COGNITIVE MODELING, CONNECTIONIST).

Automatic Processing

See AUTOMATICITY

Automaticity

Automaticity is a characteristic of cognitive processing in which practiced consistent component behaviors are performed rapidly, with minimal effort or with automatic allocation of attention to the processing of the stimulus. Most skilled behavior requires the development of automatic processes (e.g., walking, READING, driving, programming). Automatic processes generally develop slowly, with practice over hundreds of trials. An example of an automatic process for the skilled reader is encoding letter strings into their semantic meaning. As your eyes fixate on the word "red," a semantic code representing a color and an acoustic image of the phonemes /r/ /e/ /d/ are activated. Automatic processes may occur unintentionally, such as the refocusing of your ATTENTION when you hear your name used in a nearby conversation at a party. Automatic processing can release unintentional behaviors, such as automatic capture errors (e.g., walking out of an elevator when the doors open on an unintended floor).

Automaticity develops when there is a consistent mapping (CM) between the stimuli and responses at some stage of processing. For example, in a letter search task, a subject responds to a set of letters called the "target set" and ignores the "distracter set." If certain letter stimuli are consistently the target set, they will be attended and responded to whenever they occur. Automatic processing will develop with practice and the consistent target letters will attract attention and activate response processes. Automatic targets can be found rapidly in cluttered displays with little effort. Automaticity does not develop when stimuli have a varied mapping (VM) (e.g., when a letter that is a target on one trial is a distracter on the next).

Automatic processing (AP) is often contrasted with controlled or attentive processing. Controlled processing (CP) occurs early in practice, is maintained when there is a varied mapping, and is relatively slow and effortful.

Automatic processing shows seven qualitatively and quantitatively different processing characteristics relative to controlled processing. Automatic processing can be much faster than controlled processing (e.g., 2 ms per category for AP versus 200 ms for CP). Automatic processing is parallel across perceptual channels, memory comparisons, and across levels of processing, whereas controlled processing is serial. Automatic processing requires minimal effort, which enables multitask processing. Automatic processing is robust and highly reliable relative to controlled processing despite fatigue, exhaustion, and the effects of alcohol. On the other hand, automatic processing requires substantial consistent practice, typically hundreds of trials for a single task before accuracy is attained, whereas controlled processing often attains accuracy for a single task in a few trials. Subjects have reduced control of automatic processing, which attracts attention or elicits responses if task demands change relative to the subject's previous consistent training. Automatic processing produces less memory modification than controlled processing, which causes a stimulus to be processed without MEMORY of the processing (e.g., Did you lock the door when leaving the car?).

Models of automaticity seek to account for the characteristics noted above and, in particular, for the contrasts between automatic and controlled processing. They divide into two kinds: incremental learning and instance-based. In the incremental learning models (e.g., James 1890/1950; Laberge 1975; Schneider, Dumais, and Shiffrin 1984), the strength of association between the stimulus and a priority of the signal increases each time a positive stimulus-response sequence occurs. After a sufficient number of such events occur, the priority of the response is sufficient to result in an output of that stage of processing with the minimal need for attention. Stimuli not consistently attended to do not obtain a high priority, hence do not produce an automatic response. In contrast, the instance-based model of Logan (1992), for example, assumes that all instances are stored and the response time is determined by a parallel memory access in which the first retrieved instance determines the reaction time. In this model, the importance of consistency is due to response conflict between the instances slowing the response.

The concept of automaticity has been widely applied to many areas of psychology to interpret processing differences. In the area of attentional processing, it has been applied to interpret effects of processing speed, effort, visual search, and interference effects. In skill acquisition, it has been applied to interpret changes in performance with practice and the development of procedural knowledge. In the understanding of human error, it has been applied to understand unintended automatic behaviors such as capture errors and workload-related errors for controlled processing. In clinical disorders such as schizophrenia, difficulties in maintaining attention can result from too frequent or too few automatic attention shifts, and preservative behavior can result from automatic execution of component skills or lack of memory modification for automatic behaviors. In addictions such as smoking, a major obstacle in breaking a habit is the difficulty of inhibiting automatic behaviors linked to social contexts. In the aging literature, there is evidence that automatic and controlled behaviors may develop and decline differentially with age and that the aged may have more difficulty learning and altering automatic behaviors.

The concept of automatic processing has had a long history in cognitive psychology. The topic of automaticity was a major focus in WILLIAM JAMES's *Principles of Psychology* (1890/1950). In modern times, automatic processing has

been an important issue in the attention literature (Posner and Snyder 1975; Schneider and Shiffrin 1977; Shiffrin 1988) and the skill acquisition literature (Laberge 1975), and the skill acquisition and memory literature (Anderson 1992; Schneider and Detweiler 1987; Logan 1992).

Autonomy of Psychology

Psychology has been considered an autonomous science in at least two respects: its subject matter and its methods. To say that its subject matter is autonomous is to say that psychology deals with entities—properties, relations, states—that are not dealt with or not wholly explicable in terms of physical (or any other) science. Contrasted with this is the idea that psychology employs a characteristic method of explanation, which is not shared by the other sciences. I shall label the two senses of autonomy "metaphysical autonomy" and "explanatory autonomy."

Whether psychology as a science is autonomous in either sense is one of the philosophical questions surrounding the (somewhat vague) doctrine of "naturalism," which concerns itself with the extent to which the human mind can be brought under the aegis of natural science. In their contemporary form, these questions had their origin in the "new science" of the seventeenth century. Early materialists like Hobbes (1651) and La Mettrie (1748) rejected both explanatory and metaphysical autonomy: Mind is matter in motion, and the mind can be studied by the mathematical methods of the new science just as any matter can. But while materialism (and therefore the denial of metaphysical autonomy) had to wait until the nineteenth century before becoming widely accepted, the denial of explanatory autonomy remained a strong force in empiricist philosophy. HUME described his *Treatise of Human Nature* (1739–1740) as an "attempt to introduce the experimental method of reasoning into moral subjects"—where "moral" signifies "human." And subsequent criticism of Hume's views, notably by KANT and Reid, ensured that the question of naturalism—whether there can be a "science of man"—was one of the central questions of nineteenth–century philosophy, and a question that hovered over the emergence of psychology as an independent discipline (see Reed 1994).

In the twentieth century, much of the philosophical debate over the autonomy of psychology has been inspired by the logical positivists' discussions of the UNITY OF SCIENCE (see Carnap 1932–1933; Feigl 1981; Oppenheim and Putnam 1958). For the positivists, physical science had a special epistemological and ontological authority: The other sciences (including psychology) must have their claims about the world vindicated by being translated into the language of physics. This extreme REDUCTIONISM did not survive long after the decline of the positivist doctrines which generated it—and it cannot have helped prevent this decline that no positivist actually succeeded in translating any psychological claims into the language of physics. Thus even though positivism was a major influence on the rise of postwar PHYSICALISM, later physicalists tended to distinguish their metaphysical doctrines from the more extreme positivist claims. J. J. C. Smart (1959), for example, asserted that mental and physical properties are identical, but denied that the psychological language we use to describe these properties can be translated into physical language. This is not yet to concede psychology's explanatory autonomy. That psychology employs a different *language* does not mean it must employ a different explanatory *method*. And Smart's iden-

tity claim obviously implies the denial of psychology's metaphysical autonomy.

On the other hand, many philosophers think that the possibility of *multiple realization* forces us to accept the metaphysical autonomy of psychology. A property is multiply realized by underlying physical properties when not all of the instances of that property are instances of the same physical property. This is contrasted with property *identity*, where a brain property being identical with a mental property, for example, entails that all and only instances of the one property are instances of the other. Hilary Putnam (1975) argued influentially that there are good reasons for thinking that psychological properties are multiply realized by physical properties, on the grounds that psychological properties are *functional* properties of organisms—properties identified by the causal role they play in the organism's psychological organization (see FUNCTIONALISM).

This kind of functionalist approach implies a certain degree of metaphysical autonomy: Because psychological properties are multiply realized, it seems that they cannot be identical with physical properties of the brain (but contrast Lewis 1994). It does not, however, imply a Cartesian dualist account of the mind, because all these properties are properties of physical objects, and the physical still has a certain ontological priority, sometimes expressed by saying that everything *supervenes* on the physical (see SUPERVENIENCE and MIND-BODY PROBLEM). The picture that emerges is a "layered world": The properties of macroscopic objects are multiply realized by more microscopic properties, eventually arriving at the properties which are the subject matter of fundamental physics (see Fodor 1974; Owens 1989).

With the exception of some who hold to ELIMINATIVE MATERIALISM, who see the metaphysical autonomy of commonsense (or "folk") psychological categories as a reason for rejecting the entities psychology talks about, the "layered world" picture is a popular account of the relationship between the subject matters of the various sciences. But what impact does this picture have on the question of the explanatory autonomy of psychology? Here matters become a little complex. The "layered world" picture does suggest that the theories of the different levels of nature can be relatively independent. There is also room for different *styles* of explanation. Robert Cummins (1983) argues that psychological explanation does not conform to the "covering law" pattern of explanation employed in the physical sciences (where to explain a phenomenon is to show it to be an instance of a law of nature). And some influential views of the nature of computational psychology treat it as involving three different levels of EXPLANATION (see Marr 1982). But in general, nothing in the "layered world" picture prevents psychology from having a properly scientific status; it is still the *subject matter* (psychological properties and relations) of psychology that ultimately sets it apart from physics and the other sciences. In short, the "layered world" conception holds that psychological explanation has its autonomy in the sense that it does not need to be reduced to physical explanation, but nonetheless it is properly scientific.

This view can be contrasted with Davidson's (1970) view that there are features of our everyday psychological explanations that prevent these explanations from ever becoming scientific. Davidson argues that psychological explanations attributing PROPOSITIONAL ATTITUDES are governed by normative principles: In ascribing a propositional attitude to a person, we aim to make that person's thought and action as reasonable as possible (for related views, see McDowell 1985; Child 1994). In natural science, no comparable normative principles are employed. It is this dependence on the "constitutive ideal of rationality" that prevents a psychology purporting to deal with the propositional attitudes from ever becoming scientific—in the sense that physics is scientific. According to Davidson, decision theory is an attempt to systematize ordinary explanations of actions in terms of belief and desire, by employing quantitative measures of degrees of belief and desire. But because of the irreducibly normative element involved in propositional attitude explanation, decision theory can never be a natural science (for more on this subject, see Davidson 1995). Where the "layered world" picture typically combines a defense of metaphysical autonomy with an acceptance of the properly scientific (or potentially scientific) nature of all psychological explanation, Davidson's ANOMALOUS MONISM combines strong explanatory autonomy with an identity theory of mental and physical events.

Bartlett, Frederic Charles

Frederic C. Bartlett (1886–1969) was Britain's most outstanding psychologist between the World Wars. He was a cognitive psychologist long before the cognitive revolution of the 1960s. His three major contributions to current cognitive science are a methodological argument for the study of "ecologically valid" experimental tasks, a reconstructive approach to human memory, and the theoretical construct of the "schema" to represent generic knowledge.

Receiving a bachelor's degree in philosophy from the University of London (1909), Bartlett carried out additional undergraduate work in the moral sciences at Cambridge University (1914), where he later became director of the Cambridge Psychological Laboratory (1922) and was eventually appointed the first Professor of Experimental Psychology at Cambridge (1931). He was made Fellow of the Royal Society in 1932 and knighted in 1948.

Bartlett's unique position in the development of psychology derived in part from his multidisciplinary background. At London and also later at Cambridge, Bartlett was influenced by the philosophy of James Ward and George Stout (Bartlett 1936), who developed systems that were antiatomist and antiassociationist, as opposed to the traditional British empiricist view. At Cambridge, Bartlett's major intellectual influences were C. S. Myers and W. H. R. Rivers. Although both had been trained as physicians, Myers was an experimental psychologist and Rivers a cultural and physical anthropologist when Bartlett studied with them there. It was Myers who introduced Bartlett to German laboratory psychology with a particular focus on PSYCHOPHYSICS.

His work with Rivers had a strong impact on Bartlett's thinking. He published a number of books and papers devoted to social issues and the role of psychology in anthropological research (Harris and Zangwill 1973). The anthropological study of the conventionalization of human cultural artifacts over time served as a principal source of Bartlett's ideas about schemata. Recently social constructivists (Costall 1992) have argued that if psychology had followed Bartlett's early writings on these topics, the field would now be much more of a social-based discipline than it is.

As a young faculty member, Bartlett had extensive interactions with the neurologist Henry Head. While Bartlett never directly concerned himself with neurophysiological research (Broadbent 1970; Zangwill 1972), he provided intellectual support for a number of students who went on to become the first generation of British neuropsychologists (e.g., Oliver Zangwill, Brenda Milner). Bartlett's discussions with Henry Head about physiological "schemata" (used to account for aspects of human posture) was another important source of Bartlett's thinking on the psychological construct of "schema" (cf. Bartlett 1932).

Through a complex series of events that occurred late in his career, Bartlett had a direct hand in initiating the information-processing framework that is a major component of current cognitive science. During World War II, a brilliant young student named Kenneth Craik came to Cambridge to work with Bartlett. Craik carried out early work on control engineering and cybernetics, only to be killed in a bicycle accident the day before World War II ended. Bartlett was able to see the importance of Craik's approach and took over its development. Donald BROADBENT, in his autobiography (1980), notes that when he arrived at Cambridge after the war, he was exposed to a completely original point of view about how to analyze human behavior. Broadbent went on to develop the first information-processing box models of human behavior (cf. Weiskrantz 1994).

Bartlett worked on applied problems throughout his career, believing that in an effort to isolate and gain control of psychological processes, much laboratory research in psychology missed important phenomena that occurred in more natural settings. This argument for ECOLOGICAL VALIDITY (e.g., Neisser 1978) makes up an important subtheme in current cognitive science (see also ECOLOGICAL PSYCHOLOGY).

Bartlett's methodological preference for ecologically valid tasks led him to reject the traditional approach to the study of human memory that involved learning lists of nonsense syllables. In his book *Remembering* (1932), Bartlett reported a series of memory studies that used a broader range of material, including texts of folktales from Native American cultures. Bartlett focused not on the number of correct words recalled, but on the nature of the changes made in the recalls. He found that individuals recalling this type of material made inferences and other changes that led to a more concise and coherent story (conventionalization). Overall, Bartlett concluded that human memory is not a reproductive but a reconstructive process. Although Bartlett's approach made little impact on laboratory memory research at the time, with the advent of the cognitive revolution (e.g., Neisser 1967), his ideas became an integral part of the study of human MEMORY, and by the early 1980s, his book *Remembering* was the second most widely cited work in the area of human memory (White 1983).

To account for his memory data, Bartlett developed the concept of the "schema" (see SCHEMATA). He proposed that much of human knowledge consists of unconscious mental structures that capture the generic aspects of the world (cf. Brewer and Nakamura 1984). He argued that the changes

he found in story recall could be accounted for by assuming that "schemata" operate on new incoming information to fill in gaps and rationalize the resulting memory representation. Bartlett's schema concept had little impact on memory research in his lifetime, and, in fact, at the time of his death, his own students considered it to have been a failure (Broadbent 1970; Zangwill 1972). However, the schema construct made an impressive comeback in the hands of computer scientist Marvin Minsky. In the early stages of the development of the field of artificial intelligence (AI), Minsky was concerned about the difficulty of designing computer models to exhibit human intelligence. He read Bartlett's 1932 book and concluded that humans were using top-down schema-based information to carry out many psychological tasks. In a famous paper, Minsky (1975) proposed the use of frames (i.e., schemata) to capture the needed top-down knowledge. In its new form, the schema construct has widely influenced psychological research on human memory (Brewer and Nakamura 1984) and the field of AI.

Basal Ganglia

The CEREBRAL CORTEX is massively interconnected with a large group of subcortical structures known as the "basal ganglia." In general, the basal ganglia can be described as a set of input structures that receive direct input from the cerebral cortex, and output structures that project back to the cerebral cortex via the THALAMUS. Thus a major feature of basal ganglia anatomy is their participation in multiple loops with the cerebral cortex, termed *cortico-basal ganglia-thalamo-cortical circuits* (see Alexander, DeLong, and Strick 1986, figure 1).

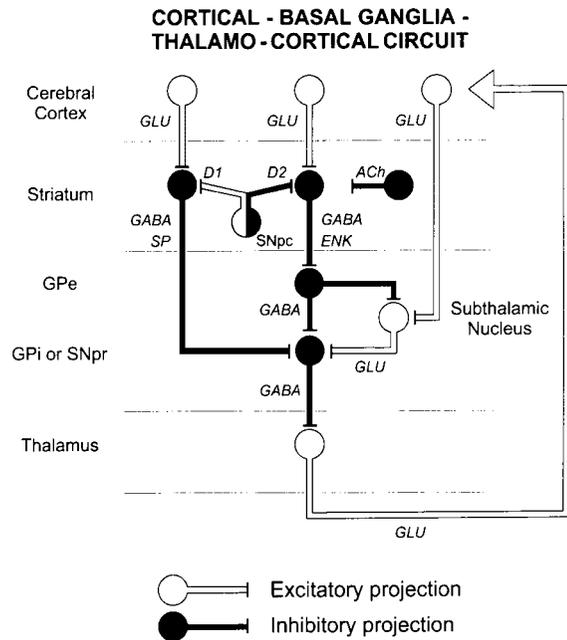
Although the term *basal ganglia* was first used to indicate the putamen and globus pallidus (Ringer 1879), it now refers to the striatum, globus pallidus, subthalamic nucleus (STN), and substantia nigra. The striatum has three subdivisions, the caudate, putamen, and ventral striatum, that together form the main input structures of the basal ganglia. The globus pallidus consists of an external segment (GPe) and an internal segment (GPi). The GPe and STN are thought to represent "intermediate" basal ganglia structures, although the STN also receives some direct cortical inputs. The substantia nigra comprises two major cell groups, the pars compacta (SNpc) and pars reticulata (SNpr). The SNpr and GPi are the major output structures of the basal ganglia.

There has been considerable progress in defining the intrinsic organization of basal ganglia circuits (see Parent and Hazrati 1995). Briefly, inputs from the cerebral cortex to the striatum use glutamate (GLU) as an excitatory neurotransmitter to synapse on medium-sized (12–20 μm) spiny stellate neurons, which are also the projection or output neurons of the striatum. Most of the cortical input terminates in striatal regions known as the "matrix," which contain high levels of acetylcholinesterase, the enzyme responsible for breaking down the neurotransmitter acetylcholine (Ragsdale and Graybiel 1981). Efferents from other cortical areas terminate in striatal regions termed "patches" or "striosomes," which have low levels of acetylcholinesterase. In addition to these differences in afferent input, the medium spiny stellate cells in the striosomes and matrix also have different efferent connections. Output cells in striosomes project to neurons in SNpc that produce the neurotransmitter dopamine. The axons of these SNpc cells project back to the striatum, where they release dopamine. The net effect of dopamine on striatal cells depends on the type of receptors present.

Output neurons in the matrix project to GPe, GPi, or SNpr. These striatal cells use the neurotransmitter gamma-aminobutyric acid (GABA) to inhibit their targets. The matrix cells projecting to GPi or SNpr express high levels of a neuropeptide called "substance P (SP)" and are excited by the action of dopamine on their D1 receptors. In contrast, matrix cells projecting to GPe express high levels of enkephalin (ENK) and are inhibited by the action of dopamine on their D2 receptors (figure 1).

Efferents from GPe project largely to the STN, GPi and SNpr and use GABA to inhibit their targets. Neurons in the STN project to GPi or SNpr where they use GLU to excite neurons in both structures (figure 1). There is also evidence

CORTICAL - BASAL GANGLIA - THALAMO - CORTICAL CIRCUIT

Excitatory projection
Inhibitory projection


for GPe projections to the reticular nucleus of the thalamus, but the significance of this projection is unknown.

Neurons in the GPi and SNpr are the principal outputs of the basal ganglia. These neurons innervate a specific set of thalamic nuclei and use GABA as an inhibitory transmitter. Output neurons in the thalamus that receive basal ganglia input use GLU as a neurotransmitter to excite their targets. Although some of these thalamic neurons project back to the striatum, and thus form a closed feedback loop with the basal ganglia, the major output from the basal ganglia is to thalamic neurons that in turn project to the cerebral cortex. This pathway forms the efferent limb of the cortico-basal ganglia-thalamocortical circuit. Output neurons in SNpr and GPi also project to brain stem nuclei such as the superior colliculus and pedunculopontine nucleus. The projection to the colliculus appears to play a role in the generation of eye and head movements. The function of the pedunculopontine projection is more obscure. Pedunculopontine neurons appear to largely project back upon SNpc, GPi, and STN.

Recently, there have been some dramatic changes in concepts about the function of basal ganglia loops with the cerebral cortex. These loops were thought to collect inputs from widespread cortical areas in the frontal, parietal, and temporal lobes and to "funnel" this information back to the primary motor cortex or other cortical motor areas for use in MOTOR CONTROL (Kemp and Powell 1971). New observations have led to the suggestion that basal ganglia loops are involved in a much more diverse range of behavior including MOTOR LEARNING and cognition. For example, Alexander, DeLong and Strick (1986) have proposed that basal ganglia output targeted at least five regions of the frontal lobe: two cortical areas concerned with skeletomotor and OCULOMOTOR CONTROL, and three regions of the prefrontal cortex involved in WORKING MEMORY, ATTENTION, and emotional behavior.

Subsequent experiments have supported this proposal and also suggested that basal ganglia-thalamocortical projections to the frontal lobe are topographically organized into discrete output channels (Hoover and Strick 1993; Middleton and Strick 1994). Furthermore, it is now apparent that basal ganglia output is directed to cortical areas outside the frontal lobe, including a region of the temporal lobe involved in visual processing (Middleton and Strick 1996a). Thus the anatomical substrate exists for basal ganglia output to influence multiple motor and nonmotor areas of the cerebral cortex. Consequently, current views of basal ganglia function emphasize the impact these subcortical nuclei may have on a broad spectrum of behavior.

Several lines of evidence implicate the basal ganglia in forms of "habit learning" that involve the creation of novel associations between stimuli and responses. For example, individuals with Parkinson's disease (PD) or Huntington's disease (HD) have been shown to be impaired in the performance of tasks that depend on habit learning (Knowlton, Mangels, and Squire 1996; Knowlton et al. 1996). Both PD and HD arise from the degeneration of specific cell groups in the basal ganglia (the SNpc and striatum, respectively). Interestingly, SINGLE-NEURON RECORDING studies in monkeys have shown that "tonically active neurons" in the striatum change their firing properties as an association is built between a specific sensory stimulus and an appropriate motor response (Aosaki et al. 1994). These neurons are thought to be large (50–60 μm) aspiny cholinergic interneurons. Similarly, some neurons in the SNpc are preferentially activated by appetitive rewards or stimuli that predict the occurrence of such rewards. Together, these striatal and nigral neurons may form part of the neural substrate underlying behavioral reinforcement (Schultz, Dayan, and Montague 1997).

Other forms of learning also appear to be influenced by the basal ganglia. Physiological studies have shown that portions of the striatum and pallidum are activated during the performance of tasks that require learning a sequence of movements (Jenkins et al. 1994; Mushiake and Strick 1995; Kermadi and Joseph 1995). Moreover, some patients with PD and HD are selectively impaired on motor learning tasks, but not on other forms of learning (Heindel et al. 1989). These observations suggest that the basal ganglia may play a critical role in what has been termed *procedural* or *motor-skill learning*.

There is also evidence to support the involvement of the basal ganglia in non-motor cognitive processes. First, some neurons in the basal ganglia display activity related to sensory and cognitive functions but not motor responses (Hikosaka and Wurtz 1983; Mushiake and Strick 1995; Brown, Desimone, and Mishkin 1996). Second, some individuals with PD and HD have striking cognitive and visual deficits, such as impaired recognition of faces and facial expressions, that actually precede the development of prominent motor symptoms (Jacobs, Shuren, and Heilman 1995a,b). Third, other patients with basal ganglia lesions exhibit profound cognitive, visual, and sensory disturbances. For example, lesions of the globus pallidus or SNpr have been reported to produce working memory deficits, obsessive-compulsive behavior, apathy, and visual hallucinations (Laplane et al.

1989; McKee et al. 1990). There is also growing evidence that alterations in the basal ganglia accompany disorders such as schizophrenia, depression, obsessive-compulsive disorder, Tourette's syndrome, AUTISM, and attention deficit disorder (for references, see Middleton and Strick 1996b; Castellanos et al. 1996). Finally, the current animal model of PD uses high doses of a neurotoxin called MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) to reproduce the neuropathology and motor symptoms of this disorder with remarkable fidelity. However, chronic low-dose treatment of monkeys with this compound has been shown to cause cognitive and visual deficits, without gross motor impairments (Schneider and Pope-Coleman 1995).

Taken together, existing anatomical, physiological, and behavioral data suggest that the basal ganglia are not only involved in the control of movement, but also have the potential to influence diverse aspects of behavior. Future research will be needed to determine the full extent of the cerebral cortex influenced by basal ganglia output, the physiological consequences of this influence, and the functional operations performed by basal ganglia circuitry.

Bayesian Learning

The Bayesian approach views all model learning—whether of parameters, structure, or both—as the reduction of a user's UNCERTAINTY about the model given data. Furthermore, it encodes all uncertainty about model parameters and structure as probabilities.

Bayesian learning has two distinct advantages over classical learning. First, it combines prior knowledge and data, as opposed to classical learning, which does not explicitly incorporate user or prior knowledge, so that ad hoc methods are needed to combine knowledge and data (see also MACHINE LEARNING). Second, Bayesian learning methods have a built-in Occam's razor—there is no need to introduce external methods to avoid overfitting (see Heckerman 1995).

To illustrate with an example taken from Howard 1970, consider a common thumbtack—one with a round, flat head that can be found in most supermarkets. If we toss the thumbtack into the air, it will come to rest either on its point *(heads)* or on its head *(tails)*. Suppose we flip the thumbtack $N + 1$ times, making sure that the physical properties of the thumbtack and the conditions under which it is flipped remain stable over time. From the first N observations, we want to determine the probability of heads on the $(N + 1)$th toss.

In a classical analysis of this problem, we assert that there is some true probability of heads, which is unknown. We *estimate* this true probability from the N observations using criteria such as low bias and low variance. We then use this estimate as our probability for heads on the $(N + 1)$th toss. In the Bayesian approach, we also assert that there is some true probability of heads, but we encode our uncertainty about this true probability using the rules of probability to compute our probability for heads on the $(N + 1)$th toss.

To undertake a Bayesian analysis of this problem, we need some notation. We denote a variable by an uppercase letter (e.g., X, X_i, Θ), and the state or value of a corresponding variable by that same letter in lowercase (e.g., x, x_i, θ). We denote a set of variables by a boldface uppercase letter (e.g., $\mathbf{X}$, $\mathbf{X_i}$, $\mathbf{\Theta}$). We use a corresponding boldface lowercase letter (e.g., $\mathbf{x}$, $\mathbf{x_i}$, $\mathbf{\theta}$) to denote an assignment of state or value to each variable in a given set. We use $p(X = x \,|\, \xi)$, or $p(x \,|\, \xi)$ as a shorthand, to denote the probability that $X = x$ of a person with state of information ξ. We also use $p(x \,|\, \xi)$ to denote the probability distribution for X (both mass functions and density functions). Whether $p(x \,|\, \xi)$ refers to a probability, a probability density, or a probability distribution will be clear from context.

Returning to the thumbtack problem, we define Θ to be a variable whose values θ correspond to the possible true values of the probability of heads. We express the uncertainty about Θ using the probability density function $p(\theta \,|\, \xi)$. In addition, we use X_1 to denote the variable representing the outcome of the lth flip, $l = 1, \ldots, N + 1$, and $D = \{X_1 = x_1, \ldots, X_N = x_N\}$ to denote the set of our observations. Thus, in Bayesian terms, the thumbtack problem reduces to computing $p(x_{N+1}|D,\xi)$ from $p(\theta \,|\, \xi)$.

To do so, we first use Bayes's rule to obtain the probability distribution for Θ given D and background knowledge ξ:

$$p(\theta|D, \xi) \;=\; \frac{p(\theta|\xi)p(D|\theta, \xi)}{p(D|\xi)} \tag{1}$$

where

$$p(D|\xi) \;=\; \int p(D|\theta, \xi)p(\theta|\xi) \; d\theta \tag{2}$$

Next, we expand the *likelihood* $p(D|\theta, \xi)$. Both Bayesians and classical statisticians agree on this term. In particular, given the value of Θ, the observations in D are mutually independent, and the probability of heads (tails) on any one observation is θ ($1-\theta$). Consequently, equation 1 becomes

$$p(\theta|D, \xi) = \frac{p(\theta|\xi)\theta^h(1-\theta)^t}{p(D|\xi)} \qquad (3)$$

where h and t are the number of heads and tails observed in D, respectively. The observations D represent a random sample from the binomial distribution parameterized by θ; the probability distributions $p(\theta | \xi)$ and $p(\theta | D, \xi)$ are commonly referred to as the "prior" and "posterior" for Θ, respectively; and the quantities h and t are said to be "sufficient statistics" for binomial sampling because they summarize the data sufficiently to compute the posterior from the prior.

To determine the probability that the $(N+1)$th toss of the thumbtack will come up heads, we use the expansion rule of probability to average over the possible values of Θ:

$$p(X_{N+1} = heads|D, \xi) \qquad (4)$$

$$= \int p(X_{N+1} = heads|(\theta, \xi)p(\theta|D, \xi)d\theta$$

$$= \int \theta p(\theta|D, \xi)d\theta \equiv E_{p(\theta|D, \xi)}(\theta)$$

where $E_{p(\theta|D, x)}(\theta)$ denotes the expectation of θ with respect to the distribution $p(\theta|D,\xi)$.

To complete the Bayesian analysis for this example, we need a method to assess the prior distribution for Θ. A common approach, usually adopted for convenience, is to assume that this distribution is a *beta distribution:*

$$p(\theta|\xi) = Beta(\theta|\alpha_h, \alpha_t) \equiv \qquad (5)$$

$$\frac{\Gamma(\alpha)}{\Gamma(\alpha_h)\Gamma(\alpha_t)}\theta^{\alpha_h-1}(1-\theta)^{\alpha_t-1}$$

where $\alpha_h > 0$ and $\alpha_t > 0$ are the parameters of the beta distribution, $\alpha = \alpha_h + \alpha_t$, and $\Gamma(\cdot)$ is the *gamma function* that satisfies $\Gamma(x + 1) = x\Gamma(x)$ and $\Gamma(1) = 1$. The quantities α_h and α_t are often referred to as "hyperparameters" to distinguish them from the parameter θ. The hyperparameters α_h and α_t must be greater than zero so that the distribution can be normalized. Examples of beta distributions are shown in figure 1.

The beta prior is convenient for several reasons. By equation 3, the posterior distribution will also be a beta distribution:

$$p(\theta|D, \xi) \qquad (6)$$

$$= \frac{\Gamma(\alpha + N)}{\Gamma(\alpha_h + h)\Gamma(\alpha_t + t)}\theta^{\alpha_h + h - 1}(1-\theta)^{\alpha_t + t - 1}$$

$$= Beta(\theta|\alpha_h + h, \alpha_t + t)$$

We term the set of beta distributions a *conjugate family of distributions* for binomial sampling. Also, the expectation of θ with respect to this distribution has a simple form:

$$\int \theta Beta(\theta|\alpha_h, \alpha_t)d\theta = \frac{\alpha_h}{\alpha} \qquad (7)$$

Hence, given a beta prior, we have a simple expression for the probability of heads in the $(N + 1)$th toss:

$$p(X_{N+1} = heads|D, \xi) = \frac{\alpha_h + h}{\alpha + N} \qquad (8)$$

Assuming $p(\theta|\xi)$ is a beta distribution, it can be assessed in a number of ways. For example, we can assess our probability for heads in the first toss of the thumbtack (e.g., using a probability wheel). Next, we can imagine having seen the outcomes of k flips, and reassess our probability for heads in the next toss. From equation 8, we have, for $k = 1$,

$$p(X_{N+1} = heads|\xi) = \frac{\alpha_h}{a_h + \alpha_t}$$

$$p(X_2 = heads|X_1 = heads, \varepsilon) = \frac{\alpha_2 + 1}{\alpha_h + \alpha_t + 1}$$

Given these probabilities, we can solve for α_h and α_t. This assessment technique is known as "the method of imagined future data." Other techniques for assessing beta distributions are discussed by Winkler (1967).

Although the beta prior is convenient, it is not accurate for some problems. For example, suppose we think that the thumbtack may have been purchased at a magic shop. In this case, a more appropriate prior may be a mixture of beta distributions—for example,

$$p(\theta|\xi)$$
$$= 0.4\ Beta\ (20, 1) + 0.4\ Beta\ (1, 20) + 0.2\ Beta\ (2, 2)$$

where 0.4 is our probability that the thumbtack is heavily weighted toward heads (tails). In effect, we have introduced an additional *hidden* or unobserved variable H, whose states correspond to the three possibilities: (1) thumbtack is biased toward heads, (2) thumbtack is biased toward tails, or (3) thumbtack is normal; and we have asserted that θ conditioned on each state of H is a beta distribution. In general, there are simple methods (e.g., the method of imagined future data) for determining whether or not a beta prior is an accurate reflection of one's beliefs. In those cases where the beta prior is inaccurate, an accurate prior can often be assessed by introducing additional hidden variables, as in this example.

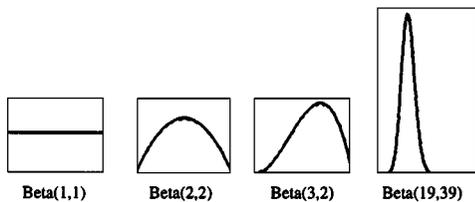
So far, we have only considered observations drawn from a binomial distribution. To be more general, suppose our problem domain consists of variables $\mathbf{X} = (X_1, \ldots, X_n)$. In addition, suppose that we have some data $D = (x_1, \ldots, x_N)$,


Figure 1. Several beta distributions.

Beta(1,1)   Beta(2,2)   Beta(3,2)   Beta(19,39)

which represent a random sample from some unknown (true) probability distribution for **X.** We assume that the unknown probability distribution can be encoded by some statistical model with structure **m** and parameters θ_m. Uncertain about the structure and parameters of the model, we take the Bayesian approach—we encode this uncertainty using probability. In particular, we define a discrete variable **M**, whose states **m** correspond to the possible true models, and encode our uncertainty about **M** with the probability distribution $p(\mathbf{m} \mid \xi)$. In addition, for each model structure **m**, we define a continuous vector-valued variable Θ_m, whose configurations θ_m correspond to the possible true parameters. We encode our uncertainty about Θ_m using the probability density function $p(\theta_m \mid \mathbf{m}.\xi)$.

Given random sample *D,* we compute the posterior distributions for each **m** and θ_m using Bayes's rule:

$$p(\mathbf{m}|D,\xi) = \frac{p(\mathbf{m}|\xi)p(D|\mathbf{m}, \xi)}{\Sigma_{m'}p(\mathbf{m}'|\xi)p(D|\mathbf{m}', \xi)} \qquad (9)$$

$$p(\theta_m|D, \mathbf{m}, \xi) = \frac{p(\theta_m|\mathbf{m}, \xi)p(D|\theta_m, \mathbf{m}, \xi)}{p(D|\mathbf{m}, \xi)} \qquad (10)$$

where

$$p(D|\mathbf{m}, \xi)\int p(D|\theta_m, \mathbf{m}, \xi)p(\theta_m|\mathbf{m}, \xi)d\theta_m \qquad (11)$$

is the *marginal likelihood.* Given some hypothesis of interest, *h,* we determine the probability that *h* is true given data *D* by averaging over all possible models and their parameters according to the rules of probability:

$$p(h|D, \xi) = \sum_m p(\mathbf{m}|D, \xi)p(h|D, \mathbf{m}, \xi) \qquad (12)$$

$$p(h|D, \mathbf{m}, \xi) = \int p(h|\theta_m, \mathbf{m}, \xi)p(\theta_m|D, \mathbf{m}, \xi)d\theta_m \quad (13)$$

For example, *h* may be the event that the next observation is x_{N+1}. In this situation, we obtain

$$p(x_{N+1}|D, \xi) \qquad (14)$$

$$= \sum_m p(\mathbf{m}|D, \xi)\int p(x_{N+1}|\theta_m, \mathbf{m}, \xi)p(\theta_m|D, \mathbf{m}, \xi)d\theta_m$$

where $p(\mathbf{x}_{N+1}|\theta_m, \mathbf{m}, \xi)$ is the likelihood for the model. This approach is often referred to as "Bayesian model averaging." Note that no single model structure is learned. Instead, all possible models are weighted by their posterior probability.

Under certain conditions, the parameter posterior and marginal likelihood can be computed efficiently and in closed form. For example, such computation is possible when the likelihood is given by a BAYESIAN NETWORK (e.g., Heckerman 1998) and several other conditions are met. See Bernardo and Smith 1994, Lauritzen 1996, and Heckerman 1998 for a discussion.

When many model structures are possible, the sums in equations 9 and 12 can be intractable. In such situations, we can search for one or more model structures with large posterior probabilities, and use these models as if they were exhaustive—an approach known as "model selection." Examples of search methods applied to Bayesian networks are given by Heckerman, Geiger, and Chickering (1995) and Madigan et al. (1996).

Bayesian Networks

Bayesian networks were conceptualized in the late 1970s to model distributed processing in READING comprehension, where both semantical expectations and perceptual evidence must be combined to form a coherent interpretation. The ability to coordinate bidirectional inferences filled a void in EXPERT SYSTEMS technology of the early 1980s, and Bayesian networks have emerged as a general representation scheme for uncertain knowledge (Pearl 1988; Shafer and Pearl 1990; Heckerman, Mamdani, and Wellman 1995; Jensen 1996; Castillo, Gutierrez, and Hadi 1997).

Bayesian networks are directed acyclic graphs (DAGs) in which the nodes represent variables of interest (e.g., the temperature of a device, the gender of a patient, a feature of an object, the occurrence of an event) and the links represent informational or causal dependencies among the variables. The strength of a dependency is represented by conditional probabilities that are attached to each cluster of parent-child nodes in the network.

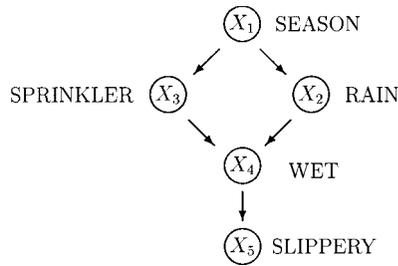
Figure 1 describes a simple yet typical Bayesian network: the causal relationships between the season of the year (X_1), whether rain falls (X_2) during the season, whether the sprinkler is on (X_3) during that season, whether the pavement would get wet (X_4), and whether the pavement would be slippery (X_5). Here the absence of a direct link between X_1 and X_5, for example, captures our understanding that the influence of seasonal variations on the slipperiness of the pavement is mediated by other conditions (e.g., wetness).


Figure 1. A Bayesian network representing causal influences among five variables.

As this example illustrates, a Bayesian network constitutes a model of the environment rather than, as in many other KNOWLEDGE REPRESENTATION schemes (e.g., rule-based systems and NEURAL NETWORKS), a model of the reasoning process. It simulates, in fact, the mechanisms that operate in the environment, and thus facilitates diverse modes of reasoning, including prediction, abduction, and control.

Prediction and abduction require an economical representation of a joint distribution over the variables involved. Bayesian networks achieve such economy by specifying, for each variable X_i, the conditional probabilities $P(x_i \mid pa_i)$ where pa_i is a set of predecessors (of X_i) that render X_i independent of all its other predecessors. Variables judged to be the direct causes of X_i satisfy this property, and these are depicted as the parents of X_i in the graph. Given this specification, the joint distribution is given by the product

$$P(x_1, \ldots, x_n) = \prod_i P(x_i \mid pa_i) \qquad (1)$$

from which all probabilistic queries (e.g., Find the most likely explanation for the evidence) can be answered coherently using probability calculus.

The first algorithms proposed for probabilistic calculations in Bayesian networks used message-passing architecture and were limited to trees (Pearl 1982; Kim and Pearl 1983). Each variable was assigned a simple processor and permitted to pass messages asynchronously with its neighbors until equilibrium was achieved. Techniques have since been developed to extend this tree propagation method to general networks. Among the most popular are Lauritzen and Spiegelhalter's (1988) method of join-tree propagation, and the method of cycle-cutset conditioning (see Pearl 1988, 204–210; Jensen 1996).

While inference in general networks is NP-hard, the COMPUTATIONAL COMPLEXITY for each of the methods cited above can be estimated prior to actual processing. When the estimates exceed reasonable bounds, an approximation method such as stochastic simulation (Pearl 1987; 1988, 210–223) can be used instead. Learning techniques have also been developed for systematically updating the conditional probabilities $P(x_i \mid pa_i)$ and the structure of the network, so as to match empirical data (see Spiegelhalter and Lauritzen 1990; Cooper and Herskovits 1990).

The most distinctive feature of Bayesian networks, stemming largely from their causal organization, is their ability to represent and respond to changing configurations. Any local reconfiguration of the mechanisms in the environment can be translated, with only minor modification, into an isomorphic reconfiguration of the network topology. For example, to represent a disabled sprinkler, we simply delete from the network all links incident to the node "Sprinkler." To represent the policy of turning the sprinkler off when it rains, we simply add a link between "Rain" and "Sprinkler" and revise $P(x_3 \mid x_1, x_2)$. This flexibility is often cited as the ingredient that marks the division between deliberative and reactive agents, and that enables deliberative agents to manage novel situations instantaneously, without requiring retraining or adaptation.

Organizing one's knowledge around stable causal mechanisms provides a basis for planning under UNCERTAINTY (Pearl 1996). Once we know the identity of the mechanism altered by the intervention and the nature of the alteration, the overall effect of an intervention can be predicted by modifying the corresponding factors in equation 1 and using the modified product to compute a new probability function. For example, to represent the action "turning the sprinkler ON" in the network of figure 1, we delete the link $X_1 \rightarrow X_3$ and fix the value of X_3 to ON. The resulting joint distribution on the remaining variables will be

$$P(x_1, x_2, x_4, x_5) \qquad (2)$$
$$= P(x_1)P(x_2 \mid x_1)P(x_4 \mid x_2, X_3 = \text{ON})P(x_5 \mid x_4)$$

Note the difference between the observation $X_3 = \text{ON}$, encoded by ordinary Bayesian conditioning, and the action $do(X_3 = \text{ON})$, encoded by conditioning a mutilated graph, with the link $X_1 \rightarrow X_3$ removed. This indeed mirrors the difference between seeing and doing: after observing that the sprinkler is ON, we wish to infer that the season is dry, that it probably did not rain, and so on; no such inferences should be drawn in evaluating the effects the contemplated action "turning the sprinkler ON."

One of the most exciting prospects in recent years has been the possibility of using Bayesian networks to discover causal structures in raw statistical data (Pearl and Verma 1991; Spirtes, Glymour, and Schienes 1993). Although any inference from association to CAUSATION is bound to be less reliable than one based on controlled experiment, we can still guarantee an aspect of reliability called "stability": Any alternative structure compatible with the data must be less stable than the structure inferred, which is to say, slight fluctuations in parameters will render that structure incompatible with the data. With this form of guarantee, the theory provides criteria for identifying genuine and spurious causes, with or without temporal information, and yields algorithms for recovering causal structures with hidden variables from empirical data.

In mundane decision making, beliefs are revised not by adjusting numerical probabilities but by tentatively accepting some sentences as "true for all practical purposes." Such sentences, called "plain beliefs," exhibit both logical and probabilistic character. As in classical LOGIC, they are propositional and deductively closed; as in probability, they are subject to retraction and to varying degrees of entrenchment. Bayesian networks can be adopted to model the

dynamics of plain beliefs by replacing ordinary probabilities with nonstandard probabilities, that is, probabilities that are infinitesimally close to either zero or one (Goldszmidt and Pearl 1996).

Although Bayesian networks can model a wide spectrum of cognitive activity, their greatest strength is in CAUSAL REASONING, which in turn facilitates reasoning about actions, explanations, counterfactuals, and preferences. Such capabilities are not easily implemented in neural networks, whose strengths lie in quick adaptation of simple motor-visual functions.

Some questions arise: Does an architecture resembling that of Bayesian networks exist anywhere in the human brain? If not, how does the brain perform those cognitive functions at which Bayesian networks excel? A plausible answer to the second question is that fragmented structures of causal organizations are constantly being assembled on the fly, as needed, from a stock of functional building blocks. For example, the network of figure 1 may be assembled from several neural networks, one specializing in the experience surrounding seasons and rains, another in the properties of wet pavements, and so forth. Such specialized networks are probably stored permanently in some mental library, from which they are drawn and assembled into the structure shown in figure 1 only when a specific problem presents itself, for example, to determine whether an operating sprinkler could explain why a certain person slipped and broke a leg in the middle of a dry season.

Thus Bayesian networks are particularly useful in studying higher cognitive functions, where the problem of organizing and supervising large assemblies of specialized neural networks becomes important.

Behavior-Based Robotics

Behavior-based robotics (BBR) bridges the fields of artificial intelligence, engineering, and cognitive science. The behavior-based approach is a methodology for designing autonomous agents and robots; it is a type of INTELLIGENT AGENT ARCHITECTURE. Architectures supply structure and impose constraints on the way robot control problems are solved. The behavior-based methodology imposes a general, biologically inspired, bottom-up philosophy, allowing for a certain freedom of interpretation. Its goal is to develop methods for controlling artificial systems (usually physical robots, but also simulated robots and other autonomous software agents) and to use robotics to model and better understand biological systems (usually animals, ranging from insects to humans).

Behavior-based robotics controllers consist of a collection of behaviors that achieve and/or maintain goals. For example, "avoid-obstacles" maintains the goal of preventing collisions; "go-home" achieves the goal of reaching some home destination. Behaviors are implemented as control laws (sometimes similar to those used in CONTROL THEORY), either in software or hardware, as a processing element or a procedure. Each behavior can take inputs from the robot's sensors (e.g., camera, ultrasound, infrared, tactile) and/or from other behaviors in the system, and send outputs to the robot's effectors (e.g., wheels, grippers, arm, speech) and/or to other behaviors. Thus, a behavior-based controller is a structured network of interacting behaviors.

BBR is founded on subsumption architecture (Brooks 1986) and other work in reactive robotics (RR). RR achieves rapid real-time responses by embedding the robot's controller in a collection of preprogrammed, concurrent condition-action rules with minimal internal state (e.g., "if bumped, stop," "if stopped, back up"; Brooks and Connell 1986; Agre and Chapman 1987). Subsumption architecture provides a layered approach to assembling reactive rules into complete control systems from the bottom up. Rules, and layers of rules, are added incrementally; lower layers can function independently of the higher ones, and higher ones utilize the outputs of the lower ones, but do not override them. For example, "avoid-collision" at the lowest level, and

"move-to-light" at a higher level, when combined, result in a robust light-chasing behavior; the higher-level rule never overrides the lower-level one, thus guaranteeing collision avoidance.

While robust, such reactive systems are limited by their lack of internal state; they are incapable of using internal representations and learning new behaviors. Behavior-based systems overcome this limitation because their underlying unit of representation, behaviors, can store state. The way state is represented and distributed in BBR is one of the sources of its novelty. Information is not centralized or centrally manipulated; instead, various forms of distributed representations are used, ranging from static table structures and networks to active, procedural processes implemented within the behavior networks.

In contrast to RR and BBR, both of which are structured and developed bottom-up, PLANNING-based deliberative control systems are top-down, and require the agent/robot to perform a sequence of processing sense-plan-act steps (e.g., "combine the sensory data into a map of the world, then use the planner to find a path in the map, then send steps of the plan to the robot's wheels"; Giralt, Chatila, and Vaisset 1983; Moravec and Elfes 1985; Laird and Rosenbloom 1990). Hybrid systems attempt a compromise between bottom-up and top-down by employing a reactive system for low-level control and a planner for high-level decision making (Firby 1987; Georgeoff and Lansky 1987; Arkin 1989; Payton 1990; Connell 1991). Often called "three-layer architectures," they separate the control system into three communicating but independent parts: (i) the planner, (ii) the reactive system, and (iii) the intermediate module, which reconciles the different time-scales and representations used by the other two and any conflicts between their outputs.

Behavior-based systems typically do not employ such a hierarchical division but are instead integrated through a homogeneous distributed representation. Like hybrid systems, they also provide both low-level control and high-level deliberation; the latter is performed by one or more distributed representations that compute over the other behaviors, often directly utilizing low-level behaviors and their outputs. The resulting system, built from the bottom-up, does not divide into differently represented and independent components as in hybrid systems, but instead constitutes an integrated computational behavior network. The power, elegance, and complexity of behavior-based systems all stem from the ways their constituent behaviors are defined and used.

Consequently, the organizational methodology of behavior-based systems differs from other control methods in its approach to modularity, the way in which the system is organized and subdivided into modules. Behavior-based philosophy mandates that the behaviors be relatively simple, added to the system incrementally, and not executed in a serial fashion. Subsets of behaviors are executed concurrently so that the system can exploit parallelism, both in the speed of computation and in the resulting dynamics that arise within the system itself (from the interaction among the behaviors) and with the environment (from the interaction of the behaviors with the external world). Behaviors can be designed at a variety of abstraction levels. In general they are higher than the robot's atomic actions (i.e., typically above "go-forward-by-a-small-increment," "turn-by-a-small-angle"), and they extend in time and space. Some implemented behaviors include: "go-home," "find-object," "get-recharged," "avoid-the-light," "aggregate-with-group," "pick-up-object," "find-landmark," etc. Because behaviors can be defined at different levels of abstraction and can represent various types of information, they are difficult to define precisely, but are also a rich medium for innovative interpretations.

Deciding what behavior to execute at a particular point in time is called *behavior arbitration,* and is one of the central design challenges of BBR. For simplicity, most implemented systems use a built-in, fixed priority for behaviors. More flexible solutions, which can be less computationally efficient and harder to analyze, are commonly based on computing some function of the behavior activation levels, such as a voting or activation spreading scheme (Maes 1989; Payton et al. 1992). Behavior-based systems are typically designed so the effects of the behaviors largely interact in the environment rather than internally through the system, taking advantage of the richness of interaction dynamics by exploiting the properties of SITUATEDNESS/EMBEDDEDNESS. These dynamics are sometimes called *emergent* behaviors because they *emerge* from the interactions and are not internally specified by the robot's program. Therefore, the internal behavior structure of a behavior-based system need not necessarily mirror its externally manifested behavior. For example, a robot that flocks with other robots may not have a specific internal "flocking" behavior; instead, its interaction with the environment and other robots may result in flocking, although its only behaviors may be "avoid collisions," "stay close to the group," and "keep going" (Matarić 1997).

Behavior-based robots have demonstrated various standard robotic capabilities, including obstacle avoidance, navigation, terrain mapping, following, chasing/pursuit, object manipulation, task division and cooperation, and learning maps, navigation and walking. They have also demonstrated some novel applications like large-scale group behaviors, including flocking, foraging, and soccer playing, and modeling insect and even human behavior (Agha and Bekey 1997; Webb 1994; Asada et al. 1994; Brooks and Stein 1994). Application domains have included MOBILE ROBOTS, underwater vehicles, space robotics, as well as robots capable of MANIPULATION AND GRASPING, and some WALKING AND RUNNING MACHINES.

Variations and adaptations of MACHINE LEARNING, and in particular REINFORCEMENT LEARNING, have been effectively applied to behavior-based robots, which have demonstrated learning to walk (Maes and Brooks 1990), navigate (Matarić 1992; Millan 1994), communicate (Yanco and Stein 1993), divide tasks (Parker 1993; Matarić 1997), behave socially (Matarić 1994), and even identify opponents and score goals in robot soccer (Asada et al. 1994). Methods from ARTIFICIAL LIFE, EVOLUTIONARY COMPUTATION, GENETIC ALGORITHMS, FUZZY LOGIC, VISION AND LEARNING, MULTIAGENT SYSTEMS, and many others continue to be actively explored and applied to behavior-based robots as their role in animal modeling and practical applications continues to develop.

Behaviorism

"Psychology is the Science of Mental Life, both of its phenomena and their conditions. The phenomena are such things as we call feelings, desires, cognitions, reasonings, decisions, and the like" (1890: 1). So said William JAMES in his *Principles of Psychology,* perhaps the most important and widely cited textbook in the history of psychology. James believed that psychology would have finished its job when it "ascertained the empirical correlation of the various sorts of thought or feeling with definite conditions of the brain" (1890: vi).

His own primary interest in conscious mental experience notwithstanding, James did predict that "the data assumed by psychology, like those assumed by physics and the other natural sciences, must some time be overhauled" (1890: vi). James did not, however, predict that only a few short years after publication of his *Principles,* just such a major overhaul would be in full swing. Nor did James foresee that the impact of this overhaul would be so revolutionary and controversial nearly a century later. *Behaviorism* is the name given to this dramatic shift away from psychology as the science of mental life and toward being the science of overt action.

John B. Watson is usually credited with beginning behaviorism; surely, his 1913 paper, "Psychology as the Behaviorist Views It," made the case for behaviorism in a most dramatic and forceful manner. But other scholars paved the way for behaviorism. Among them, H. S. Jennings, Watson's biologist colleague at Johns Hopkins University, more methodically and less polemically advocated a behavioristic approach for psychology in his 1906 book, *Behavior of the Lower Organisms.* Jennings's views on the science of psychology still serve as a fitting introduction to the premises and methods of behaviorism.

As did Watson, Jennings studied the behavior of nonhuman animals. Interest in nonhuman animals or even human infants poses very real limits on our readiest means for understanding the psychological phenomena of thinking and feeling: namely, INTROSPECTION, what Edward B. Titchener (1896) called the one distinctively psychological method. Without verbal report, how can we ever claim to have gained access to another organism's mental life? Indeed, just because we ask other people to report to us their private thoughts and feelings, why should we be sanguine that they are either willing or able to do so?

Jennings took a decidedly cautious stance concerning the private world of conscious thoughts and feelings. "The conscious aspect of behavior is undoubtedly most interesting. But we are unable to deal directly with this by the methods of observation and experiment. . . . Assertions regarding consciousness in animals, whether affirmative or negative, are not susceptible of verification" (1906: v). Contrary to the claims of their critics, most behaviorists, like Jennings, deny neither the existence nor the importance of CONSCIOUSNESS; rather, they hold that private data cannot be the subject of public science.

Having judged that the introspective investigation of consciousness is an unworkable methodology for objective science, Jennings offered a new alternative to a science of mental life—a science of overt action. "Apart from their relation to the problem of consciousness and its development, the objective processes in behavior are of the highest interest in themselves" (1906: v).

Jennings noted that behavior has historically been treated as the neglected stepsister of consciousness. The treatment of behavior as subsidiary to the problem of consciousness has tended to obscure the fact that in behavior we have the most marked and perhaps the most easily studied of the organic processes. Jennings observed that "in behavior we

are dealing with actual objective processes (whether accompanied by consciousness or not), and we need a knowledge of the laws controlling them, of the same sort as our knowledge of the laws of metabolism" (1906: v). Discovering general laws of behavior—in both human and nonhuman animals—with the methods of natural science is the aim of a behavioristic psychology.

Jennings's consideration of nonhuman animal behavior (what we now call COMPARATIVE PSYCHOLOGY) was a key extension of psychological science, an extension that was effectively precluded through introspective investigation but was made possible by behavioristic study. This extension was controversial because it had important implications for our understanding of human behavior. "From a discussion of the behavior of the lower organisms in objective terms, compared with a discussion of the behavior of man in subjective terms, we get the impression of a complete discontinuity between the two" (1906: 329). Jennings believed that this dualistic view of human and nonhuman psychology offered centuries earlier by DESCARTES was stale and incorrect; a fresh and proper answer to the question of whether humans differed fundamentally from all other animals required examining their behavior from a common and objective vantage point. "Only by comparing the objective factors can we determine whether there is a continuity or a gulf between the behavior of lower and higher organisms (including man), for it is only these factors that we know" (1906: 329).

Based on that objective evidence, Jennings agreed with Charles DARWIN and his theory of EVOLUTION through natural selection that "there is no difference in kind, but a complete continuity between the behavior of lower and of higher organisms [including human beings]" (1906: 335). Indeed, many years of assiduous study convinced Jennings that, "if Amoeba were a large animal, so as to come within the everyday experience of human beings, its behavior would at once call forth the attribution to it of states of pleasure and pain, of hunger, desire, and the like, on precisely the same basis as we attribute these things to the dog" (1906: 336), however problematical for an objective psychology these anthropomorphic attributions of MOTIVATION and EMOTION might be.

Jennings's exhortation for us to limit our consideration of both human and nonhuman behavior to objective factors underscores the key imperative of behaviorism. "The ideal of most scientific men is to explain behavior in terms of matter and energy, so that the introduction of psychic implications is considered superfluous" (1906: 329). Mentalism was to play no part in this new psychological science of the twentieth century, although it is at the core of the current, but arguably (see Blumberg and Wasserman 1995) reactionary school of nonhuman animal behavior, COGNITIVE ETHOLOGY, founded by the biologist Donald R. Griffin (1976).

Critics of behaviorism nevertheless argue that excluding the realm of private experience from psychological science is misguided. Doesn't a behavioristic account omit most if not all of the truly interesting and important aspects of psychological functioning? No, said Jennings. What is advocated is simply an objective analysis of psychological processes. With remarkable sophistication and some thirty

years before Edward C. Tolman (1936) did so more prominently, Jennings urged the operationalization of psychological terms and phenomena so as to make their study completely objective and permit their exact experimental investigation—even in nonhuman animals and human infants. (Clark L. Hull 1952, B. F. Skinner 1945, and Kenneth W. Spence 1956 later developed behaviorism in very different ways to deal with ideation and thinking.)

Take, for example, one of James's favorite psychological notions—ATTENTION. For Jennings, attention is not a conscious mental state. Rather, "at the basis of *attention* lies objectively the phenomenon that the organism may react to only one stimulus even though other stimuli are present which would, if acting alone, likewise produce a response" (1906: 330). The organism can then be said to attend to the particular stimulus to which it responds. Or, take what to many is the hallmark of mental life—choice or DECISION MAKING. For Jennings, choice is not a conscious mental process. Instead, "*choice* is a term based objectively on the fact that the organism accepts or reacts positively to some things, while it rejects or reacts negatively or not at all to others" (1906: 330). In these and many other cases, Jennings explained that "we shall not attempt to take into consideration the scholastic definitions of the terms used, but shall judge them merely from the objective phenomena on which they are based" (1906: 329).

What then are the limits of a behavioristic approach to psychological phenomena? This key question has not yet been answered, but it has been vigorously debated. Watson believed that the matter would eventually be decided by experimental study. "As our methods become better developed it will be possible to undertake investigations of more and more complex forms of behavior. Problems which are now laid aside will again become imperative, but they can be viewed as they arise from a new angle and in more concrete settings" (1913: 175).

A case study for looking at psychological issues from a new angle and in a concrete setting is recent research into CATEGORIZATION and conceptualization by nonhuman animals. Building on powerful experimental methods pioneered by Skinner (1938) and his student Richard J. Herrnstein (1990), my colleagues and I have trained pigeons to categorize complex visual stimuli such as colored photographs and detailed line drawings into different classes, ranging from basic-level CONCEPTS (like cats, flowers, cars, and chairs), to superordinate concepts (like mammals, vegetables, vehicles, and furniture), to abstract concepts (like same versus different). In all three cases, the pigeons not only acquired the visual discriminations through reinforcement learning, but they also generalized those discriminations to completely novel stimuli (Wasserman 1995); such generalization is the hallmark of conceptualization. Additional extensions of behavioristic methods and analyses have been made to visual IMAGERY (Rilling and Neiworth 1987) and to the reporting of interoceptive stimuli induced by the administration of drugs (Lubinski and Thompson 1993). Here too, pigeons were taught with purely behavioral methods to engage in behaviors which, when performed by people, are conventionally considered to be the product of conscious mental states and processes. Behaviorists, like

Skinner, take a different tack and ask, Isn't it more productive and parsimonious to attribute these behaviors to the contingencies of reinforcement (which can be specified and experimentally manipulated) than to mental entities and psychic machinations (which cannot)?

Some firmly resist this maneuver and emphatically say no. Empirical demonstrations such as these have done little to convert behaviorism's most trenchant critics, such as Noam Chomsky (1959). These individuals argue that behaviorism is formally unable to explain complex human behavior, especially LANGUAGE AND COMMUNICATION.

These critics note, for instance, that human verbal behavior exhibits remarkable variability and temporal organization. They contend that CREATIVITY and grammar are properties of linguistic performance that are in principle beyond behavioristic explanation, and they instead argue that these properties of language uniquely implicate the operation of creative mental structures and processes. In response, behaviorists note that all behaviors—from the simplest acts like button pressing to the most complex like reciting poetry—involve intricate and changing topographies of performance. In fact, variability itself is a property of behavior that research (Eisenberger and Cameron 1996) has shown is modifiable through the systematic delivery of reinforcement and punishment, in much the same way as other properties of behavior like frequency, amplitude, and duration are conditioned by reinforcement contingencies. As to the temporal organization of behavior, even nonhuman animals like pigeons and monkeys have been taught to recognize and to produce structured sequences of stimuli and responses (Terrace 1993; Weisman et al. 1980). Such complex performances were again the result of elementary LEARNING processes brought about by familiar CONDITIONING techniques.

More famously and directly, Skinner offered a behavioristic account of human language in his 1957 book, *Verbal Behavior.*

Many theorists therefore conclude that behaviorism is the strongest alternative to a mentalistic account of human and nonhuman behavior. Far from being run out of business by the premature proclamations of their mentalistic critics, behaviorists have steadfastly proceeded with the task of experimentally analyzing many of the most complex and vexing problems of behavior using the most effective and current tools of natural science.

Bilingualism and the Brain

In recent years, there has been growing interest in the cognitive neuroscience of bilingualism. The two central questions in this literature have been: (1) Does a bilingual speaker represent each language in different areas of the brain? (2) What effect does age of second language acquisition have on brain representation? These questions have been considered by using electrophysiological and functional neuroimaging measures as well as by looking at bilinguals who suffer strokes affecting the areas responsible for language processing in the brain. We will begin by considering the effects of age of acquisition before considering the localization of the first and second language in the brain.

What effects does age of second language acquisition have on brain representation? Researchers in cognitive science have considered whether there is a critical period for learning a language (*see also* LANGUAGE ACQUISITION). This topic is also of interest to those learning a second language. Specifically, investigators have inquired about the differences between early and late second language learners. Recent work using event-related potentials (ERP) supports

previous behavioral findings suggesting that second language learning is better in those who learn their second language early. Mclaughlin and Osterhout (1997) found that college students learning French progressively improve from chance to near-native performance on lexical decision (i.e., deciding if a letter string is a word or not); however, electrophysiological indices revealed sensitivity to French words after only a few weeks of instruction. An increased N400 (a waveform that indexes lexical-semantic processing) for words preceded by semantically unrelated words (coffee-dog) was found as the number of years of exposure to French increased, but it never approached the levels seen in native French speakers. Weber-Fox and Neville (1996) have found differences in the N400 to semantic violations, but only for those who learned a second language after the age of eleven. Changes in ERPs to grammatical violations, however, appeared even for those who learned their second language before the age of four. Perani et al. (1996), using POSITRON EMISSION TOMOGRAPHY (a measure of localized brain activity), have found that listening to passages in a first language results in an activation of areas that is not apparent in the second language for late second language learners (e.g., increased activation in the left and right temporal pole, the left inferior frontal gyrus, and the left inferior parietal lobe). Thus age of acquisition has an effect on electrophysiological measures of brain activity as well as on the neuroanatomical areas that are involved in second language processing.

Does a bilingual speaker represent each language in different areas of the brain? Researchers have long wondered whether cognitive functions are processed by separate areas of the brain (*see* CORTICAL LOCALIZATION, HISTORY OF). A similar question has been asked with respect to the cortical localization of the two languages in bilingual speakers. One way to answer this question is to look at the effects of brain lesions on the processing of a bilingual's two languages. Brain lesions that affect one language and not the other would lead to the conclusion that languages are represented in different areas of the brain. Indeed, there is evidence of different degrees of recovery in each language after a stroke (Junque, Vendrell and Vendrell 1995; Paradis 1977). Extreme cases have shown postoperative impairment in one language with spontaneous recovery after eight months (Paradis and Goldblum 1989). A more recent case has been used to suggest that there is a clear neuroanatomical dissociation between the languages (Gomez-Tortosa et al. 1995). Others, however, suggest that there are a number of other explanations for these data (see Paradis 1996 and Hines 1996 for further discussion).

The notion that bilinguals' two languages are represented in overlapping brain areas has also been supported with other methodologies. Ojemann and Whitaker (1978) found that electrical stimulation of certain areas in the cortex interrupted naming in both languages, whereas stimulation of other areas interrupted naming in only one language. More recent work using measures that look at activation as a measure of blood flow have come to similar conclusions. Klein et al. (1994), using PET, found that naming pictures in a second language vs. naming pictures in a first language resulted in activation in the putamen, a subcortical area that

has been associated with phonological processing. Other studies have found that bilinguals show activity in left frontal areas of the brain for semantic and phonological analyses of words in both their languages (Klein et al. 1995; Wagner et al. 1996). Taken together these findings suggest that whereas naming in L2 involves activation in areas that are not involved in L1, lexical and semantic judgments of words activate mostly overlapping areas of the brain. Although there are some dissociations when surface tasks such as naming are used, these dissociations disappear when semantic tasks are used.

Having two linguistic systems that overlap presents an interesting challenge for theories of bilingual language processing. If these two languages are located on overlapping tissue, how do bilinguals manage to keep these languages from constantly interfering with each other? A recent study by Hernandez et al. (1997) was designed to look at this issue using functional MAGNETIC RESONANCE IMAGING (fMRI) for Spanish–English bilinguals. Participants were asked to name a picture in their first language, second language, or to alternate between each language on successive trials. Results revealed slower reaction times and an increase in the number of cross-language errors in the alternating condition relative to the single-language condition (Kohnert-Rice and Hernandez forthcoming). In the fMRI study, there was no difference when comparing activation for naming in the first and second language. However, activation in the prefrontal cortex increased significantly when participants were asked to alternate between languages. Thus it appears that the left prefrontal cortex may also act to reduce the amount of interference between languages (as indexed by slower reaction times and increased cross-language errors; *see also* WORKING MEMORY, NEURAL BASIS OF).

Languages can be represented across syntactic, phonological, orthographic, semantic, pragmatic, and DISCOURSE dimensions. These distinctions can vary depending on the two languages. For example, Chinese and English are very different orthographically and phonologically. However, some aspects of SYNTAX are very similar (e.g., the lack of morphological markers and the use of word order to indicate the agent of a sentence). Contrast this with Spanish and English, which are more similar orthographically but are very different in syntax in that the former uses a very large number of morphological markers. Despite the progress that has been made in addressing the relationship between bilingualism and brain representation, and although strides have been made in the PSYCHOLINGUISTICS and cognitive neuroscience of bilingualism, much work remains to be done. This research will necessarily involve behavior and the brain. Clearly the issue of bilingual brain bases involves both a rich multidimensional information space as well as a rich cerebral space. Understanding how the former maps onto the latter is a question that should keep researchers occupied into the next century and beyond.

Binding by Neural Synchrony

Neuronal systems have to solve immensely complex combinatorial problems and require efficient binding mechanisms in order to generate representations of perceptual objects

and movements. In the context of cognitive functions, combinatorial problems arise from the fact that perceptual objects are defined by a unique constellation of features, the diversity of possible constellations being virtually unlimited (cf. BINDING PROBLEM). Combinatorial problems of similar magnitude have to be solved for the acquisition and execution of motor acts. Although the elementary components of motor acts, the movements of individual muscle fibers, are limited in number, the spatial and temporal diversity of movements that can be composed by combining the elementary components in ever-changing constellations is again virtually infinite. In order to establish neuronal representations of perceptual objects and movements, the manifold relations among elementary sensory features and movement components have to be encoded in neural responses. This requires binding mechanisms that can cope efficiently with combinatorial complexity. Brains have acquired an extraordinary competence to solve such combinatorial problems, and it appears that this competence is a result of the evolution of the CEREBRAL CORTEX.

In the primary visual cortex of mammals, relations among the responses of retinal ganglion cells are evaluated and represented by having the output of selected arrays of ganglion cells converge in diverse combinations onto individual cortical neurons. Distributed signals are bound together by selective convergence of feed forward connections (Hubel and Wiesel 1962). This strategy is iterated in prestriate cortical areas in order to generate neurons that detect and represent more complex constellations of features including whole perceptual objects.

However, this strategy of binding features together by recombining input connections in ever-changing variations and representing relations explicitly by responses of specialized cells results in a combinatorial explosion of the number of required binding units. It has been proposed, therefore, that the cerebral cortex uses a second, complementary strategy, commonly called assembly coding, that permits utilization of the same set of neurons for the representation of different relations (Hebb 1949). Here, a particular constellation of features is represented by the joint and coordinated activity of a dynamically associated ensemble of cells, each of which represents explicitly only one of the more elementary features that characterize a particular perceptual object. Different objects can then be represented by recombining neurons tuned to more elementary features in various constellations (assemblies). For assembly coding, two constraints need to be met. First, a selection mechanism is required that permits dynamic, context dependent association of neurons into distinct, functionally coherent assemblies. Second, grouped responses must get labeled so that they can be distinguished by subsequent processing stages as components of one coherent representation and do not get confounded with other unrelated responses. Tagging responses as related is equivalent with raising their salience jointly and selectively, because this assures that they are processed and evaluated together at the subsequent processing stage. This can be achieved in three ways. First, nongrouped responses can be inhibited; second, the amplitude of the selected responses can be enhanced; and third, the selected cells can be made to discharge in precise temporal synchrony. All three mechanisms enhance the relative impact of the grouped responses at the next higher processing level. Selecting responses by modulating discharge rates is common in labeled line coding where a particular cell always signals the same content. However, this strategy may not always be suited for the distinction of assemblies because it introduces ambiguities, reduces processing speed, and causes superposition problems (von der Malsburg 1981; Singer et al. 1997). Ambiguities could arise because discharge rates of feature-selective cells vary over a wide range as a function of the match between stimulus and receptive field properties; these modulations of response amplitude would not be distinguishable from those signalling the relatedness of responses. Processing speed would be reduced because rate coded assemblies need to be maintained for some time in order to be distinguishable. Finally, superposition problems arise, because rate coded assemblies cannot overlap in time within the same processing stage. If they did, it would be impossible to distinguish which of the enhanced responses belong to which assembly. Simultaneous maintenance of different assemblies over perceptual time scales is required, however, to represent composite objects.

Both the ambiguities and the temporal constraints can be overcome if the selection and labeling of responses is achieved through synchronization of individual discharges (Gray et al. 1989; Singer and Gray 1995). Synchronicity can be adjusted independently of rates, and so the signature of relatedness, if expressed through synchronization, is independent of rate fluctuations. Moreover, synchronization enhances only the salience of those discharges that are precisely synchronized and generate coincident synaptic potentials in target cells at the subsequent processing stage. Hence the selected event is the individual spike or a brief burst of spikes. Thus, the rate at which different assemblies can follow one another within the same neuronal network without getting confounded is much higher than with rate coding. It is only limited by the duration of the interval over which synaptic potentials summate effectively. If this interval is in the range of 10 or 20 ms, several different assemblies can alternate within preceptually relevant time windows.

If synchronization serves as a selection and binding mechanism, neurons must be sensitive to coincident input. Moreover, synchronization must occur rapidly and show a relation to perceptual phenomena.

Although the issue of *coincidence detection* is still controversial (König, Engel, and Singer 1996; Shadlen and Newsome 1994), evidence is increasing that neurons can evaluate temporal relations with precision among incoming activity (see e.g., Carr 1993). That cortical networks can handle temporally structured activity with high precision and low dispersion follows from the abundant evidence on the oscillatory patterning and precise synchronization of neuronal responses in the γ-frequency range (Singer and Gray 1995; König, Engel, and Singer 1996). Synchronization at such high frequencies is only possible if integration time constants are short. Precise synchronization over large distances is usually associated with an oscillatory patterning of responses in the β- and γ-frequency range, suggesting a causal relation (König, Engel, and Singer 1995). This oscillatory patterning

is associated with strong inhibitory interactions (Traub et al. 1996), raising the possibility that the oscillations contribute to the shortening of integration time constants.

Simulations with spiking neurons reveal that networks of appropriately coupled units can undergo very rapid transitions from uncorrelated to synchronized states (Deppisch et al. 1993; Gerstner 1996). Rapid transitions from independent to synchronized firing are also observed in natural networks. In visual centers, it is not uncommon that neurons engage in synchronous activity, often with additional oscillatory patterning, at the very same time they increase their discharge rate in response to the light stimulus (Neuenschwander and Singer 1996; Gray et al. 1992). One mechanism is coordinated spontaneous activity that acts like a dynamic filter and causes a virtually instantaneous synchronization of the very first discharges of responses Fries et al. 1997b). The spatio-temporal patterns of these spontaneous fluctuations of excitability reflect the architecture and the actual functional state of intracortical association connections. Thus, grouping by synchronization can be extremely fast and still occur as a function of both the prewired associational dispositions and the current functional state of the cortical network.

Evidence indicates that the probability and strength of response synchronization reflects elementary Gestalt criteria such as continuity, proximity, similarity in the orientation domain, colinearity, and common fate (Gray et al. 1989; Engel, König, and Singer 1991; Engel et al. 1991; Freiwald, Kreiter, and Singer 1995; Kreiter and Singer 1996). Most importantly, the magnitude of synchronization exceeds that expected from stimulus-induced rate covariations of responses, indicating that it results from internal coordination of spike timing. Moreover, synchronization probability does not simply reflect anatomical connectivity but changes in a context-dependent way (Gray et al. 1989; Engel, König, and Singer 1991; Freiwald, Kreiter, and Singer 1995; Kreiter and Singer 1996), indicating that it is the result of a dynamic and context-dependent selection and grouping process. Most of the early experiments on response synchronization have been performed in anesthetized animals, but more recent evidence from cats and monkeys indicates that highly precise, internally generated synchrony occurs also in the awake brain, exhibits similar sensitivity to context (Kreiter and Singer 1996; Fries et al. 1997a; Gray and Viana Di Prisco 1997), and is especially pronounced when the EEG is desynchronized (Munk et al. 1996) and the animals are attentive (Roelfsema et al. 1997). Direct relations between response synchronization and perception have been found in cats who suffered from strabismic amblyopia, a developmental impairment of vision associated with suppression of the amblyopic eye, reduced visual acuity, and disturbed perceptual grouping (crowding) in this eye. Quite unexpectedly, the discharge rates of individual neurons in the primary visual cortex fail to reflect these deficits (see Roelfsema et al. 1994 for references). The only significant correlate of amblyopia is the drastically reduced ability of neurons driven by the amblyopic eye to synchronize their responses (Roelfsema et al. 1994), and this accounts well for the perceptual deficits: by reducing the salience of responses, disturbed synchronization could be responsible for the suppression of signals from the amblyopic eye, and by impairing binding, it could reduce visual acuity and cause crowding.

Another close correlation between response synchronization and perception has been found in experiments on binocular rivalry (Fries et al. 1997a). A highly significant correlation exists between changes in the strength of response synchronization in primary visual cortex and the outcome of rivalry. Cells mediating responses of the eye that won in interocular competition increased the synchronicity of their responses upon presentation of the rival stimulus to the other, losing eye, while the reverse was true for cells driven by the eye that became suppressed.

These results support the hypothesis that precise temporal relations between the discharges of spatially distributed neurons matter in cortical processing and that synchronization may be exploited to jointly raise the salience of the responses selected for further processing, that is, for the dynamic binding of distributed responses into coherent assemblies.

The example of rivalry also illustrates how synchronization and rate modulation depend on each other. The signals from the suppressed eye failed to induce tracking EYE MOVEMENTS, indicating that the vigorous but poorly synchronized responses in primary visual areas eventually failed to drive the neurons responsible for the execution of eye movements. Thus, changes of synchronicity result in changes of response amplitudes at subsequent processing stages. This convertibility provides the option to use both coding strategies in parallel in order to encode complementary information.

Binding Problem

Binding is the problem of representing conjunctions of properties. It is a very general problem that applies to all types of KNOWLEDGE REPRESENTATION, from the most basic perceptual representations to the most complex cognitive representations. For example, to visually detect a vertical red line among vertical blue lines and diagonal red lines, one must visually bind each line's color to its orientation (see Treisman and Gelade 1980). Similarly, to understand the statement, "John believes that Mary's anger toward Bill stems from Bill's failure to keep their appointment," one must bind *John* to the agent role of *believes,* and the structure *Bill's failure to keep their appointment* to the patient role of *stems from* (see THEMATIC ROLES). Binding lies at the heart of the capacity for symbolic representation (cf. Fodor and Pylyshyn 1988; Hummel and Holyoak 1997).

A binding may be either *static* or *dynamic.* A static binding is a representational unit (such as a symbol or a node in a neural network) that stands for a specific conjunction of properties. For example, a neuron that responds to vertical red lines at location x, y in the visual field represents a static binding of *vertical, red,* and *location x, y.* Variants of this approach have been proposed in which bindings are coded as patterns of activation distributed over sets of units (rather than the activity of a single unit; e.g., Smolensky 1990). Although this approach to binding appears very different from the localist (one-unit-one-binding) approach, the two are equivalent in all important respects. In both cases, binding is carried in the units themselves, so different bindings of the same properties are represented by separate units. In a static binding, the capacity to represent how elements are bound together trades off against the capacity to represent the elements themselves (see Holyoak and Hummel forthcoming). In an extreme case, the units coding, say, red diagonal lines may not overlap at all with those representing red vertical lines.

Dynamic binding represents conjunctions of properties as bindings of units in the representation. That is, representational units are *tagged* with regard to whether they are bound together or not. For example, let red be represented by unit *R,* vertical by *V,* and diagonal by *D,* and let us denote a binding with the tag "+." A red diagonal would be represented as $R + D$ and a red vertical as $R + V$. Dynamic binding permits a given unit (here, *R*) to participate in multiple bindings, and as a result (unlike static binding), it permits a representation to be isomorphic with the structure it represents (see Holyoak and Hummel forthcoming).

Dynamic binding permits greater representational flexibility than static binding, but it also has a number of properties that limit its usefulness. First, it is not obvious how to do dynamic binding in a neural (or connectionist) network. The most popular proposed binding tag is based on temporal synchrony: if two units are bound, then they fire in synchrony with one another; otherwise they fire out of synchrony (cf. Gray and Singer 1989; Hummel and Biederman 1992; Hummel and Holyoak 1997; Milner 1974; Shastri and Ajjanagadde 1993; von der Malsburg 1981). Although controversial (see Tovee and Rolls 1992), there is

evidence for this type of binding in biological nervous systems (see König and Engel 1995). A more important limitation of dynamic binding is that it is impractical as a basis for binding in long-term MEMORY. For example, we may remember where we parked our car last Tuesday, but it is unlikely that the neurons representing our car have been firing in synchrony with those representing our parking space continuously since then. (The memory might be coded by, say, synaptic links between those neurons, and those links may have been created at the time we parked the car, but such links do not constitute dynamic bindings in the sense discussed here; see Holyoak and Hummel forthcoming.) A third limitation of dynamic binding is that it requires more ATTENTION and WORKING MEMORY than static binding (see Hummel and Holyoak 1997; Stankiewicz, Hummel and Cooper 1998; Treisman and Gelade 1980; Treisman and Schmidt 1982). Although there is no theoretical limit on the number of conjunctive units (i.e., static bindings) that may be active at a given time, there are likely to be strong limits on the number of distinct tags available for dynamic binding. In the case of synchrony, for example, only a finite number of groups of neurons can be active and mutually out of synchrony with one another. Attention may serve, in part, to control the allocation of this finite dynamic binding resource (see Hummel and Stankiewicz 1996).

To the extent that a process exploits dynamic binding, it will profit from the isomorphism between its representations and the represented structures, but it will be demanding of processing resources (attention and working memory); to the extent that it binds properties statically, it will be free to operate in parallel with other processes (i.e., demanding few resources), but the resulting representations will not be isomorphic with the represented structures. These properties of static and dynamic binding have important implications for human perception and cognition. For example, these (and other) considerations led Hummel and Stankiewicz (1996) to predict that attended object images will visually prime both themselves and their left-right reflections, whereas ignored images will prime themselves but not their reflections. In brief, the reason is that dynamic binding (of features into object parts and object parts to spatial relations) is necessary to generate a left-right invariant structural description from an object's image (Hummel and Biederman 1992), and attention is necessary for dynamic binding (Treisman and Gelade 1980); attention should therefore be necessary for left-right invariant structural description. Stankiewicz, Hummel, and Cooper (1998) tested this prediction and the results were exactly as predicted. Apparently, the human visual system uses both static and dynamic codes for binding in the representation of object shape, and these separate codes manifest themselves, among other ways, as differing patterns of priming for attended and ignored object images. Similar tradeoffs between the strengths of static and dynamic binding are also apparent in aspects of human memory and thinking (cf. Hummel and Holyoak 1997).

Binding Theory

Binding theory is the branch of linguistic theory that explains the behavior of sentence-internal anaphora, which is labeled "bound anaphora" (see ANAPHORA). To illustrate the problem, the sentences in (1) each contain an anaphoric expression (*she, herself*), and a potential antecedent (*Lucie* or *Lili*).

(1) a. Lucie thought that Lili hurt her.
    b. Lucie thought that Lili hurt herself.
    c. *Lucie thought that herself hurt Lili.

The two anaphoric expressions have different anaphora options: In (1a), only *Lucie* can be the antecedent; in (1b), only *Lili;* in (1c), neither can. This pattern is universal. All languages have the two anaphoric types in (2), though not all have both anaphors. English does not have an SE anaphor; the Dravidian languages of India do not have a SELF anaphor; Germanic and many other languages have both.

(2) *Types of anaphoric expressions*
    Pronouns: *(she, her)*
    Anaphors:
    a. complex SELF anaphors (*herself*)
    b. SE (Simplex Expression) anaphors (*zich*, in Dutch)

The core restrictions on binding are most commonly believed to be purely syntactic. It is assumed that bound anaphora is possible only when the antecedent C-Commands the anaphoric expression. (Node A C-Commands node B iff the first branching node dominating A also dominates B; Reinhart 1976.) In (1b), *Lili* C-Commands *herself,* but in the illicit (1c), it does not.

The central problem, however, is the different distribution of the two anaphoric types. It was discovered in the seventies (Chomsky 1973) that the two anaphora types correspond to the two types of syntactic movement described below.

(3) *WH-movement:* Who$_i$ did you suggest that we invite t$_i$?

(4) *NP-movement*
    a. Felix$_i$ was invited t$_i$.
    b. Felix$_i$ seems [t$_i$ happy].

NP-movement is much more local than WH-MOVEMENT. Chomsky's empirical generalization rests on observing the relations between the moved NP and the trace left in its original position: in the syntactic domain in which a moved NP can bind its trace, an NP can bind an anaphor, but it cannot bind a pronoun, as illustrated in (5) and (6). Where an anaphor cannot be bound, NP movement is excluded as well, as in (7).

(5) a. Felix$_i$ was invited t$_i$
    b. Felix$_i$ invited himself$_i$
    c. *Felix$_i$ invited him$_i$

(6) a. Felix$_i$ was heard [t$_i$ singing]
    b. Felix$_i$ heard [himself$_i$ sing]
    c. Felix$_i$ hoorde [zich$_i$ zingen] (Dutch)
    d. *Felix$_i$ heard [him$_i$ sing]

(7) a. *Lucie$_i$ believes that we should elect herself$_i$
    b. *Lucie$_i$ is believed that we should elect t$_i$

In the early implementations of binding theory (Chomsky 1981), this was captured by defining NP-traces as anaphors. Thus, the restrictions on NP-movement were believed to follow from the binding conditions. Skipping the technical defi-

nition of a local domain, these are given in (8), where "bound" means coindexed with a C-Commanding NP.

(8) *Binding conditions*
    Condition A: An anaphor must be bound in its local domain.
    Condition B: A pronoun must be free in its local domain.

(5c) and (6d) violate condition B. (7a, b) and (1c) violate condition A. The others violate neither, hence are permitted.

Later developments in SYNTAX enabled a fuller understanding of what this generalization follows from. A crucial difference between WH-traces and NP-traces is that NP-traces cannot carry case. The conditions in (8) alone cannot explain why this should be so; what is required is an examination of the concept "argument." *An argument of some predicative head P is any constituent realizing a grammatical function of P (thematic role, case, or grammatical subject).* However, arguments can be more complex objects than just a single NP. In the passive sentence (5a), there is, in fact, just one argument, with two links. Arguments, then, need to be defined as chains: roughly, *An A(rgument)-chain is a sequence of (one or more) coindexed links satisfying C-Command, in a local domain* (skipping, again, the definition of the local domain, which requires that there are no "barriers" between any of the links).

If *A*-chains count as just one syntactic argument, they cannot contain two fully independent links. Specifically, coindexation that forms an *A*-chain must satisfy (9).

(9) *The A-chain condition*:
    An *A*-chain must contain exactly one link that carries structural case (at the head of the chain).

Condition (9) is clearly satisfied in (5a) and (6a), where the trace gets no case. Turning to anaphoric expressions, Reinhart and Reuland (1993) argue that while pronouns are fully Case-marked arguments, anaphors, like NP-traces, are Case-defective. Consequently, it turns out that the binding conditions in (8) are just entailments of (9) (Fox 1993; Reinhart and Reuland 1993). If a pronoun is bound in the local domain, as in (5c) and (6d), an *A*-chain is formed. But since the chain contains two Case-marked links, (9) rules this out, as did condition *B* of (8). In all the other examples in (5) and (6), the *A*-chains satisfy (9), because they are tailed by a caseless link (NP-trace or anaphor). If an anaphor is not bound in the local domain, it forms an *A*-chain of its own. For example, in (7a) *Lucie* and *herself* are two distinct *A*-chains (i.e., two arguments, rather than one). The second violates (9), because it does not contain even one case. Hence, (9) filters out the derivation, as did condition *A* of (8). Condition *A*, then, is just a reflex of the requirement that arguments carry case, while condition *B* is the requirement that they do not carry more than one case, both currently stated in (9).

Recall that only arguments are required to have case. So (9) does not prevent an anaphor from occurring unbound in a nonargument position. For example, the only difference between (7) and (10) is that the anaphor in (10) is embedded in an argument, but is not an argument itself.

(7) *Lucie*$_i$ believes that we should elect herself$_i$.

(10) Lucie$_i$ believes that we should elect Max and herself$_i$.

Anaphors that are not part of a chain are commonly labeled "logophoric," and the question when they are preferred over pronouns is dependent on DISCOURSE—rather than syntax—conditions (Pollard and Sag 1992; Reinhart and Reuland 1993).

There is, however, an aspect of bound local anaphora that is not covered by (8) or (9). Regarding case, SE and SELF anaphors are alike. Nevertheless, while both can occur in (6c), repeated in (11), SE is excluded in (12), which does not follow from (9). The difference is that in (12) a reflexive predicate is formed, because the anaphor and *Max* are co-arguments. But in (11) the anaphor is the subject of the embedded predicate. The same contrast is found in many languages.

(11) Max$_i$ hoorde [zich$_i$/zichzelf$_i$ zingen] (Dutch)

(12) a. Max$_i$ hoorde zich$_i$.
    b. Max$_i$ hoorde zichzelf$_i$. (Max heard himself.)

Reinhart and Reuland argue that, universally, the process of reflexivization requires morphological licensing. Thus, another principle is active here:

(13) *Reflexivity Condition*:
    A reflexive predicate must be reflexive-marked.

A predicate can be reflexive-marked either on the argument, with a SELF anaphor, or on the predicate. (In the dravidian language Kannada, the reflexive morpheme *kol* is used on the verb.) Because *zich* is not a reflexive-marker, (12a) violates (13).

Blindsight

In 1905, the Swiss neurologist L. Bard demonstrated residual visual functions, in particular an ability to locate a source of light, in cortically blind patients. The phenomenon was termed blindsight by Weiskrantz and colleagues (1974) and has been extensively studied both in human patients and in monkeys with lesions of the primary visual cortex (V1, striate cortex). The cortical blindness that results from the visual cortex's destruction or deafferentation is complete if the lesion destroys V1 in both hemispheres. The more common partial blindness (a field defect) always affects the contralesional visual hemifield. Its extent ("quadrantanopia," "hemianopia"), position ("to the left"), and density ("relative," "absolute") is perimetrically assessed. Density refers to the degree to which conscious vision is lost: in a relative defect, conscious vision is reduced and qualitatively altered; often, only fast-moving, high-contrast stimuli are seen (Riddoch 1917). In an absolute defect, no conscious vision remains.

Cortical blindness differs from blindness caused by complete destruction of the eye, the retina, or the optic nerve: the latter lesions destroy the visual input into the brain, while destruction of the striate cortex spares the retinofugal pathways that do not project (exclusively or at all) to this structure. These pathways form the extra-geniculo-striate cortical visual system that survives the effects of the V1-lesion and the ensuing degeneration of the lateral geniculate nucleus and the partial degeneration of the retinal ganglion cell layer. Physiological recordings in monkeys and functional neuroimaging in patients has shown that this system, which includes extrastriate visual cortical areas, remains visually responsive following inactivation or destruction of V1 (Bullier, Girard, and Salin 1993; Stoerig et al. 1997).

The discovery of residual visual functions that were demonstrable in patients who consistently claimed not to see the stimuli they nevertheless responded to (Pöppel, Frost, and Held 1973; Richards 1973; Weiskrantz et al. 1974) was met with a surprise that bordered on disbelief. It seemed inconceivable that human vision could be blind, nonphenomenal, and not introspectable. At the same time, the remaining visual responsivity of extensive parts of the visual system renders remaining visual functions likely to the point where one wonders how to explain that the subjects are blind.

These puzzling residual functions that have increasingly attracted attention from philosophers (e.g., Nelkin 1996; see consciousness) include neuroendocrine and reflexive responses that can even be demonstrated in unconscious (comatose) patients. In contrast, the nonreflexive responses that are the hallmark of blindsight are only found in conscious patients with cortical visual field defects. They have been uncovered with two types of approach that circumvent the blindness the patients experience. The first approach requires the patient to respond to a stimulus presented in the normal visual field, for instance by pressing a response key or by describing the stimulus. In part of the trials, unknown to the patient, the blind field is additionally stimulated. If the additional stimulus significantly alters the reaction time to the seen stimulus (Marzi et al. 1986), or if it alters its appearance, for instance by inducing perceptual completion (Torjussen 1976), implicit processing of the unseen stimulus has been demonstrated. The second type of approach requires the patients to respond directly to stimulation of the blind field. Commonly, forced-choice guessing paradigms are used, and the patients are asked to guess where a stimulus has been presented, whether one has been presented, or which one of a small number of possible stimuli has been presented. Saccadic and manual localization, detection, and discrimination of stimuli differing in dimensions ranging from speed and direction of motion to contrast, size, flux, spatial frequency, orientation, disparity, and wavelength have been demonstrated in this fashion (see Stoerig and Cowey 1997 for review). Whether a patient's performance is at chance level, moderately significant, or close to perfect depends on many variables. Among others they include (a) the stimulus properties: changes in on- and off-set characteristics, size, wavelength, adaptation level, and speed can all cause significant changes in performance (Barbur, Harlow, and Weiskrantz 1994); (b) the stimulus position: when the stimulus is stabilized using an eye-tracking device, at least in some patients stimuli are detectable at some positions and not at others (Fendrich, Wessinger, and Gazzaniga 1992); (c) the response: a spontaneous grasping response may yield better discriminability than a verbal one (Perenin and Rossetti 1996); (d) the training: performance in identical conditions may improve dramatically with practice (Stoerig and Cowey 1997); (e) the lesion: although a larger lesion does not simply imply less residual function (Sprague 1966), evidence from hemidecorticated patients indicates that at least the direct responses require extrastriate visual cortical mediation (King et al. 1996).

Monkeys with striate cortical ablation show very similar residual visual responses. In both humans and monkeys, compared to the corresponding retinal position in the normal hemifield, the residual sensitivity is reduced by 0.4–1.5 log units (Stoerig and Cowey 1997). It is important to note that detection based on straylight, determined with the stimulus positioned on the optic disc of normal observers or in the field defects of patients who are asked to respond by indicating whether they can notice light emanating from this area, requires stimulus intensities 2–3 log units above those needed in the normal field. Blindsight is thus consid-

erably more sensitive and cannot be explained as an artifact of light scattered into the normal visual field (Stoerig and Cowey 1991). The relatively small loss in sensitivity that distinguishes blindsight from normal vision is remarkable in light of the patients' professed experience of blindness. Interestingly, hemianopic monkeys, when given the chance to indicate "no stimulus" in a signal detection paradigm, responded to stimuli they detected perfectly in a localization task as if they could not see them (Cowey and Stoerig 1995). This indicates that it may not just be the patients who deny seeing the stimuli and claim that they are only guessing, but that both species have blindsight: nonreflexive visual functions in response to stimuli that are not consciously seen.

That the visual functions that remain in absolute cortical blindness are indeed blind is one of the most intriguing aspects of the phenomenon. Like other implicit processes that have been described in patients with amnesia, achromatopsia, or prosopagnosia, they may help us understand which neuronal processes and structures mediate implicit as opposed to consciously represented processes. As ipsilesional as well as contralesional extrastriate cortical responsivity to visual stimulation remains in patients and monkeys with blindsight, it appears insufficient to generate the latter (Bullier, Girard, and Salin 1993; Stoerig et al. 1997). This hypothesis gains further support from a recent functional magnetic resonance imaging study that compared within the same patient with a relative hemianopia the activation patterns elicited with a consciously perceived fast moving stimulus and a slow moving one that the patient could only detect in an unaware mode: in both modes, extrastriate visual cortical areas were activated (Sahraie et al. 1997). Further exploration along these lines may help pin down the neuronal substrate(s) of conscious vision, and studies of what can and cannot be done on the basis of blind vision alone can throw some light on the function as well as the nature of conscious representations.

Bloomfield, Leonard

Leonard Bloomfield (1887–1949) is, together with Edward Sapir, one of the two most prominent American linguists of the first half of the twentieth century. His book *Language* (Bloomfield 1933) was the standard introduction to linguistics for thirty years. Together with his students, particularly Bernard Bloch, Zellig Harris, and Charles Hockett, Bloomfield established the school of thought that has come to be known as American structural linguistics, which dominated the field until the rise of GENERATIVE GRAMMAR in the 1960s.

Throughout his career, Bloomfield was concerned with developing a general and comprehensive theory of language. His first formulation (Bloomfield 1914) embedded that theory within the conceptualist framework of Wilhelm Wundt. In the early 1920s, however, Bloomfield abandoned that in favor of a variety of BEHAVIORISM in which the theory of language took center stage: "The terminology in which at present we try to speak of human affairs—. . . 'consciousness,' 'mind,' 'perception,' 'ideas,' and so on— . . . will be discarded . . . and will be replaced . . . by terms in linguistics . . . . Non-linguists . . . constantly forget that a speaker is making noise, and credit him, instead, with the possession of impalpable 'ideas.' It remains for the linguist to show, in detail, that the speaker has no 'ideas' and that the noise is sufficient" (Bloomfield 1936: 322, 325; page numbers for Bloomfield's articles refer to their reprintings in Hockett 1970).

In repudiating the existence of all mentalist constructs, Bloomfield also repudiated the classical view that the structure of language reflects the structure of thought. For Bloomfield, the structure of language was the central object of linguistic study, and hence of cognitive science, had that term been popular in his day.

Bloomfield maintained that all linguistic structure could be determined by the application of analytic procedures starting with the smallest units that combine sound (or "vocal features") and meaning (or "stimulus-reaction features"), called *morphemes* (Bloomfield 1926: 130). Having shown how to identify morphemes, Bloomfield went on to show how to identify both smaller units (i.e., phonemes, defined as minimum units of "distinctive" vocal features) and larger ones (words, phrases, and sentences).

Bloomfield developed rich theories of both MORPHOLOGY and SYNTAX, much of which was carried over more or less intact into generative grammar. In morphology, Bloomfield paid careful attention to phonological alternations of various sorts, which led to the development of the modern theory of *morphophonemics* (see especially Bloomfield 1939). In syntax, he laid the foundations of the theory of constituent structure, including the rudiments of XBAR-THEORY (Bloomfield 1933: 194–195). Bloomfield generated so much enthusiasm for syntactic analysis that his students felt that they were doing syntax for the first time in the history of linguistics (Hockett 1968: 31).

Bloomfield did not develop his theory of semantics to the same extent as he did his theories of PHONOLOGY, morphology, and syntax, contenting himself primarily with naming the semantic contributions of various types of linguistic units.

For example, he called the semantic properties of morphemes "sememes," those of grammatical forms "epistememes," etc. (Bloomfield 1933: 162, 166). Bloomfield contended that whereas the phonological properties of morphemes are analyzable into parts (namely phonemes), sememes are unanalyzable: "There is nothing in the structure of morphemes like *wolf, fox,* and *dog* to tell us the relation between their meanings; this is a problem for the zoölogist" (1933: 162). Toward the end of the heyday of American structural linguistics, however, this view was repudiated (Goodenough 1956; Lounsbury 1956), and the claim that there are submorphemic units of meaning was incorporated into early theories of generative grammar (Katz and Fodor 1963).

Bloomfield knew that for a behaviorist theory of meaning such as his own to be successful, it would have to account for the semantic properties of nonreferential linguistic forms such as the English words *not* and *and.* Bloomfield was aware of the difficulty of this task. His attempt at defining the word *not* is particularly revealing. After initially defining it as "the linguistic *inhibitor* [emphasis his] in our speech-community," he went on to write: "The utterance, in a phrase, of the word *not* produces a phrase such that simultaneous parallel response to both this phrase and the parallel phrase without *not* cannot be made" (Bloomfield 1935: 312). In short, what Bloomfield is attempting to do here is to reduce the logical law of contradiction to a statement about possible stimulus-response pairs.

However, such a reduction is not possible. No semantic theory that contains the law of contradiction as one of its principles is expressible in behaviorist terms. Ultimately, American structural linguistics failed not for its inadequacies in phonology, morphology, and syntax, but because behaviorism does not provide an adequate basis for the development of a semantic theory for natural languages.

Boas, Franz

Franz Boas (1858–1942) was the single most influential anthropologist in North America in the twentieth century. He immigrated to the United States from Germany in the 1880s, taught briefly at Clark University, then in 1896 took a position at Columbia University, where he remained for the rest of his career. He was trained originally in physics and geography, but by the time he came to this country his interests had already turned to anthropology.

He was a controversial figure almost from the start, in part because of his debates with the cultural evolutionists about the course of human history (*see* CULTURAL EVOLUTION). According to the evolutionists, the pattern of history is one of progress, whereby societies develop through stages of savagery, barbarism, and eventually civilization. In this view, progress is guided by human reason, and societies differ because some have achieved higher degrees of rationality and therefore have produced more perfect institutions than others. According to Boas, however, the dominant process of change is culture borrowing or diffusion. All societies invent only a small fraction of their cultural inventory, for they acquire most of their cultural material from other peoples nearby. The process of diffusion is a result not of reason but of historical accident, and each culture is a unique amalgamation of traits and has a unique historical past.

Boas's concept of culture changed radically in the context of these ideas about history, for he came to view culture as a body of patterns that people learn through interactions with the members of their society. People adhere to such patterns as hunting practices and marriage rules not because they recognize that these help to improve their lives, as the evolutionists thought, but because the members of society absorb the cultural forms of their social milieu. By this view, these historically variable patterns largely govern human behavior and thus are the most important component of the human character. Furthermore, most of culture is emotionally grounded and beyond the level of conscious awareness. Whereas the evolutionists assumed that people are consciously oriented by patterns of rationality and that reason itself is universal and not local—although different societies exhibit different degrees of it—from Boas's perspective people are oriented by a body of cultural patterns of which they are largely unaware. These include such features as linguistic rules, values, and assumptions about reality (see LANGUAGE AND CULTURE). These patterns are emotionally grounded in that people become attached to the ways of life they have learned and adhere to them regardless of rational or practical considerations.

Boas's thinking also had significant implications for the concept of race. People behave the way they do not because of differences in racial intelligence, but because of the cultural patterns they have learned through enculturation. Boas was an outspoken proponent of racial equality, and publication of his book *The Mind of Primitive Man* in 1911 was a major event in the development of modern racial thought. Furthermore, Boas's culture concept had important relativistic implications (*see* CULTURAL RELATIVISM). He proposed that values are historically conditioned, in the same way as pottery styles and marriage patterns, and consequently the standards that a person uses in judging other societies reflect the perspective that he or she has learned. Boas and his students developed a strong skepticism toward cross-cultural value judgments.

Boas's work was epistemologically innovative, and he elaborated an important version of cognitive relativism (*see* RATIONALISM VS. EMPIRICISM). In his view, human beings experience the world through such forms as linguistic patterns and cultural beliefs, and like all other aspects of culture these are influenced by the vicissitudes of history. Consequently, people experience the world differently according to the cultures in which they are raised. For example, the linguistic rules that a person learns have the capacity to lead that individual to mis-hear speech sounds that he or she is not accustomed to hearing, while the same person has no difficulty hearing minute differences between other speech sounds that are part of his or her native tongue. Thus this segment of experience is comprehended through a complex of unconscious linguistic forms, and speakers of different languages hear these sounds differently.

Yet in important respects Boas was not a relativist. For instance, while he argued that the speakers of different languages hear the same speech sounds differently, he also assumed that the trained linguist may discover this happening, for, with effort, it is possible to learn to hear sounds as they truly are. In a sense, the linguist is able to experience speech sounds outside of his or her own linguistic framework, and to avoid the cognitive distortions produced by culture. Boas held similar views about science. While reality is experienced through cultural beliefs, it is possible to move outside of those beliefs into a sphere of objective neutrality, or a space that is culture-free, in doing scientific research. Thus Boas's anthropological theory contained a version of cognitive relativism at one level but rejected it at another. Relativism applies when human beings think and perceive in terms of their learned, cultural frameworks, but it is possible for cognitive processes to operate outside of those frameworks as well.

Bounded Rationality

Bounded rationality is rationality as exhibited by decision makers of limited abilities. The ideal of RATIONAL DECISION MAKING formalized in RATIONAL CHOICE THEORY, UTILITY THEORY, and the FOUNDATIONS OF PROBABILITY requires choosing so as to maximize a measure of expected utility that reflects a complete and consistent preference order and probability measure over all possible contingencies. This requirement appears too strong to permit accurate description of the behavior of realistic individual agents studied in economics, psychology, and artificial intelligence. Because rationality notions pervade approaches to so many other issues, finding more accurate theories of bounded rationality constitutes a central problem of these fields. Prospects appear poor for finding a single "right" theory of bounded rationality due to the many different ways of weakening the ideal requirements, some formal impossibility and tradeoff theorems, and the rich variety of psychological types observable in people, each with different strengths and limitations in reasoning abilities. Russell and Norvig's 1995 textbook provides a comprehensive survey of the roles of rationality and bounded rationality notions in artificial intelligence. Cherniak 1986 provides a philosophical introduction to the subject. Simon 1982 discusses numerous topics in economics; see Conlisk 1996 for a broad economic survey.

Studies in ECONOMICS AND COGNITIVE SCIENCE and of human DECISION MAKING document cases in which everyday and expert decision makers do not live up to the rational ideal (Kahneman, Slovic, and TVERSKY 1982; Machina 1987). The ideal maximization of expected utility implies a comprehensiveness at odds with observed failures to consider alternatives outside those suggested by the current situation. The ideal probability and utility distributions imply a degree of LOGICAL OMNISCIENCE that conflicts with observed inconsistencies in beliefs and valuations and with the frequent need to invent rationalizations and preferences to cover formerly unconceived circumstances. The theory of BAYESIAN LEARNING or conditionalization, commonly taken as the theory of belief change or learning appropriate to rational agents, conflicts with observed difficulties in assimilating new information, especially the resistance to changing cognitive habits.

Reconciling the ideal theory with views of decision makers as performing computations also poses problems. Conducting the required optimizations at human rates using standard computational mechanisms, or indeed any physical system, seems impossible to some. The seemingly enormous information content of the required probability and utility distributions may make computational representations infeasible, even using BAYESIAN NETWORKS or other relatively efficient representations.

The search for realistic theories of rational behavior began by relaxing optimality requirements. Simon (1955) formulated the theory of "satisficing," in which decision makers seek only to find alternatives that are satisfactory in the sense of meeting some threshold or "aspiration level" of utility. A more general exploration of the idea of meeting specific conditions rather than unbounded optimizations also stimulated work on PROBLEM SOLVING, which replaces expected utility maximization with acting to satisfy sets of goals, each of which may be achieved or not. Simon (1976) also emphasized the distinction between "substantive" and "procedural" rationality, concerning, respectively, rationality of the result and of the process by which the result was obtained, setting procedural rationality as a more feasible aim than substantive rationality. Good (1952, 1971) urged a related distinction in which "Type 1" rationality consists of the ordinary ideal notion, and "Type 2" rationality consists of making ideal decisions taking into account the cost of deliberation. The Simon and Good distinctions informed work in artificial intelligence on control of reasoning (Dean 1991), including explicit deliberation about the conduct of reasoning (Doyle 1980), economic decisions about reasoning (Horvitz 1987, Russell 1991), and iterative approximation schemes or "anytime algorithms" (Horvitz 1987, Dean and Boddy 1988) in which optimization attempts are repeated with increasing amounts of time, so as to provide an informed estimate of the optimal choice no matter when deliberation is terminated. Although reasoning about the course of reasoning may appear problematic, it can be organized to avoid crippling circularities (see METAREASONING), and admits theoretical reductions to nonreflective reasoning (Lipman 1991). One may also relax optimality by adjusting the scope of optimization as well as the process. Savage (1972) observed the practical need to formulate decisions in terms of "small worlds" abstracting the key elements, thus removing the most detailed alternatives from optimizations. The related "selective rationality" of Leibenstein (1980) and "bounded optimality" of Horvitz (1987) and Russell and Subramanian (1995) treat limitations stemming from optimization over circumscribed sets of alternatives.

Lessening informational requirements constitutes one important form of procedural rationality. Goal-directed problem solving and small world formulations do this directly by basing actions on highly incomplete preferences and probabilities. The extreme incompleteness of information represented by these approaches can prevent effective action, however, thus requiring means for filling in critical gaps in reasonable ways, including various JUDGMENT HEURISTICS based on representativeness or other factors (Kahneman, Slovic, and TVERSKY 1982). Assessing the expected value of information forms one general approach to filling these gaps. In this approach, one estimates the change in utility of the decision that would stem from filling specific information gaps, and then acts to fill the gaps offering the largest expected gains. These assessments may be made of policies as well as of specific actions. Applied to policies about how to reason, such assessments form a basis for the nonmonotonic or default reasoning methods appearing in virtually all practical inference systems (formalized as various NONMONOTONIC LOGICS and theories of belief revision) that fill routine gaps in rational and plausible ways. Even when expected deliberative utility motivates use of a nonmonotonic rule for adopting or abandoning assumptions, such rules typically do not involve probabilistic or preferential information directly, though they admit natural interpretations as either statements of extremely high probability (infinitesimally close to 1), in effect licensing reasoning about magnitudes of probabilities without requiring quantitative comparisons, or as expressions of preferences over beliefs and other mental states of the agent, in effect treating reasoning as seeking mental states that are Pareto optimal with respect to the rules (Doyle 1994). Nonmonotonic reasoning methods also augment BAYESIAN LEARNING (conditionalization) with direct changes of mind that suggest "conservative" approaches to reasoning that work through incremental adaptation to small changes, an approach seemingly more suited to exhibiting procedural rationality than the full and direct incorporation of new information called for by standard conditionalization.

Formal analogs of Arrow's impossibility theorem for social choice problems and multiattribute UTILITY THEORY limit the procedural rationality of approaches based on piecemeal representations of probability and preference information (Doyle and Wellman 1991). As such representations dominate practicable approaches, one expects any automatic method for handling inconsistencies amidst the probability and preference information to misbehave in some situations.

Brentano, Franz

Franz Brentano (1838–1917), German philosopher and psychologist, taught in the University of Vienna from 1874 to 1894. He is the author of *Psychology from an Empirical Standpoint* (first published in 1874), and is principally remembered for his formulation of the so-called Brentano thesis or doctrine of intentionality, according to which what is characteristic of mental phenomena is their INTENTIONALITY or the "mental inexistence of an object."

For Brentano, intentionality is to be understood in psychological (or in what might today be called methodologically solipsistic) terms. To say that a mental act is "directed toward an object" is to make an assertion about the interior structure or representational content of the act. Brentano's primary aim is to provide a taxonomy of the different kinds of basic constituents of mental life and of the different kinds of relations between them. Unlike more recent cognitive psychologists, Brentano takes as his main instrument in analyzing these basic constituents and relations not logic but a sophisticated ontological theory of part and whole, or "mereology." Where standard mereology is extensional, however, treating parts and wholes by analogy with Venn diagrams, Brentano's mereology is enriched by topological elements (Brentano 1987) and by a theory of the different sorts of dependence relations connecting parts together into unitary wholes of different sorts. A theory of "mereotopology" along these lines was first formalized by Husserl in 1901 in the third of his *Logical Investigations* (1970), and its application by Husserl to the categories of language led to the development of CATEGORIAL GRAMMAR in the work of Leśniewski and in Ajdukiewicz (1967).

The overarching context of all Brentano's writings is the psychology and ontology of Aristotle. Aristotle conceived perception and thought as processes whereby the mind abstracts sensory and intelligible forms from external substances. Impressed by the successes of corpuscularism in physics, Brentano had grown sceptical of the existence of any external substances corresponding to our everyday cognitive contents. He thus suspended belief in external substances but retained the Aristotelian view of cognition as a process of combining and separating forms within the mind. It is in these terms that we are to understand his view that "[e]very mental phenomenon includes something as object within itself" (1973).

Brentano distinguishes three sorts of ways in which a subject may be conscious of an object:

1. In presentation. Here the subject is conscious of the object or object-form, and has it before his mind, without taking up any position with regard to it, whether in sensory experience or via concepts.
2. In judgment. Here there is added to presentation one of two diametrically opposed modes of relating cognitively to the object: modes of acceptance and rejection or of belief and disbelief. Perception, for Brentano, is a combination of sensory presentation and positive judgment.
3. In phenomena of interest. Here there is added to presentation one of two diametrically opposed modes of relating conatively to the object: modes of positive and negative interest or of "love" and "hate." Judgment and interest are analogous in that there is a notion of correctness applying to each: the correctness of a judgment (its truth) serves as the objective basis of logic, the correctness of love and hate as the objective basis of ethics.

Brentano's theory of part and whole is presented in his *Descriptive Psychology* (1995). Many of the parts of con-

sciousness are "separable" in the sense that one part can continue to exist even though another part has ceased to exist. Such separability may be either reciprocal—as in a case of simultaneous seeing and hearing—or one-sided—as in the relation of presentation and judgment, or of presentation and desire: a judgment or desire cannot as a matter of necessity exist without some underlying presentation of the object desired or believed to exist.

The relation of one-sided separability imposes upon consciousness a hierarchical order, with *ultimate* or *fundamental acts,* acts having no further separable parts, constituting the ground floor. Such basic elements are for Brentano always acts of sensation. Even among basic acts, however, we can still in a certain sense speak of further parts. Thus in a sensation of a blue patch we can distinguish a color determination and a spatial determination as "distinctional parts" that mutually pervade each other. Another sort of distinctional part is illustrated by considering what the sensation of a blue patch and the sensation of a yellow patch share in common: they share, Brentano holds, the form of coloredness as a logical part. Brentano's account of the range of different sorts of distinctional parts of cognitive phenomena, and especially of the tree structure hierarchies manifested by different families of logical parts, covers some of the ground surveyed by later studies of "ontological knowledge" (Keil 1979).

Brentano's students included not only Sigmund Freud and T. G. Masaryk, but also Edmund Husserl, Alexius Meinong, Christian von Ehrenfels, and Carl Stumpf. Each went on to establish schools of importance for the development of different branches of cognitive science within this century (Smith 1994). Husserl's disciples founded the so-called phenomenological movement; Meinong founded the Graz School of "Gegenstandstheorie" (ontology without existence assumptions); and it was students of Ehrenfels and Stumpf in Prague and Berlin who founded the school of GESTALT PSYCHOLOGY (the term "Gestalt" having been first used by Ehrenfels as a technical term of psychology in 1890; see Ehrenfels 1988; MacNamara and Boudewijnse 1995). The representatives of each of these schools and movements attempted to transform Brentano's psychological doctrine of intentionality into an ontological theory of how cognizing subjects are directed toward objects in the world. The influence of Brentano's philosophical ideas is alive today in the work of analytic philosophers such as Roderick Chisholm (1982), and it has been especially prominent in twentieth-century Polish logic and philosophy (Woleński and Simons 1989).

Broadbent, Donald E.

After years of behaviorist denial of mental terms, DONALD HEBB (1949) admonished: "We all know that attention and set exist, so we had better get the skeleton out of the closet and see what can be done with it." Donald E. Broadbent (1926–1993), more than anyone, deserves the credit for shedding scientific light on this "skeleton." Through his own empirical contributions and his careful analyses of the findings of others, Broadbent demonstrated that experimental psychology could reveal the nature of cognitive processes. In his hands, an information processing approach to understanding ATTENTION, perception, MEMORY, and performance was exceptionally illuminating, and helped initiate and fuel the paradigm shift known as the "cognitive revolution."

Broadbent joined the Royal Air Force in 1944. Noting equipment poorly matched to the human pilot, the importance of practice, and the possibility of measuring individual differences, he envisaged a career in psychology. Under the leadership of Sir Frederic BARTLETT, the Psychology Department at Cambridge University was engaged in solving precisely the kind of real world problems that excited Broadbent. Upon graduation in 1949, Broadbent went straight into research as a staff member at the Medical Research Council's Applied Psychology Unit (APU) in Cambridge.

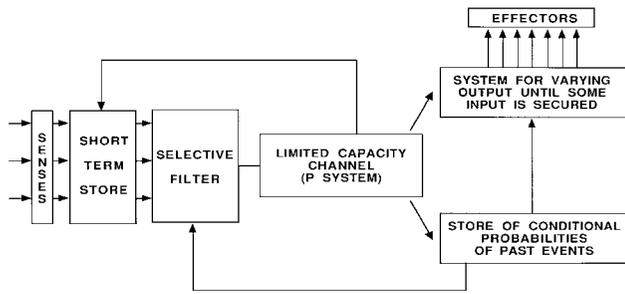
Broadbent's early research and thinking were strongly influenced by the APU's first two directors, Bartlett and Kenneth Craik. Bartlett (1932) emphasized that people were active, constructivist processors; Craik (1943) pioneered the use of engineering concepts (cybernetics) to explain human performance. At the time, communication theory (Shannon 1948), with its information metric and concept of a communication channel with a limited capacity for information transmission, was being applied to psychological phenomena. Broadbent induced the key principles of his "filter" theory from three basic findings on selective listening (e.g., Cherry 1953): (1) People are strictly limited in their ability to deal with multiple messages (sources of sensory information); (2) the ability to focus on one message while ignoring


Figure 1. Broadbent's (1958) filter theory asserts that there exists a limited capacity stage of perception (P-system), that this stage is preceded by parallel analysis of simple stimulus features, and that access to the P-system is controlled by a selective filter. Short-term and long-term (store of conditional probabilities of past events) memory systems were postulated and integrated into the information processing system. (This figure is modeled on Broadbent 1958: 297.)

another, irrelevant one is greatly improved if the messages differ in a simple physical property such as location or pitch; and, (3) the consequence of focusing on one message is that the content of the ignored message is unreportable (though simple physical properties can be picked up).

These and other findings, and the theoretical framework Broadbent induced from them, were described in his first major work, *Perception and Communication* (1958). The information processing architecture of Broadbent's famous filter theory (fig. 1) quickly became the most influential model of human cognitive activity cast in information processing terms. Thirteen years later, when Broadbent published his second major work, *Decision and Stress* (1971), it was shown how the 1958 model needed modification: new mechanisms for selection (pigeon-holing and categorizing) that operated later in the processing sequence were added to filtering and an emphasis on the statistical nature of evidence accumulation and decision making was incorporated.

In light of their growing popularity it might be suggested that artificial NEURAL NETWORK models will replace the information processing approach. While acknowledging the value of models cashed out in neural network terms, Broadbent (1985) points out (cf. MARR 1982) that such models are at a different level of analysis (implementation) than information processing models (computation); the appropriate level depends on the nature of the problem to be solved. Considering the problem of designing human-machine systems for data-rich environments, Moray suggests an enduring role for models like Broadbent's: "Whatever the deep structure of attention may be, its surface performance is, in the vast majority of cases, well described by a single, limited capacity channel, which is switched discretely among the various inputs" (1993: 113).

Donald Broadbent was attracted to psychology because he believed that the application of psychological principles could benefit people. It is fitting, then, that in 1958 he was selected to direct the APU, which he did for sixteen years. During this time the APU—already widely respected—would become one of the world's preeminent facilities for

pure and applied psychological research. After this period of steadfast administrative service, Broadbent—who never held an academic appointment—stayed on the Medical Research Council's scientific staff while moving to Oxford. Although Broadbent is, and will continue to be, best known for his empirical and theoretical work on attention, his endorsement of applied psychology never waned. Thus, in contrast to an emphasis on the cognitive "hardware" implicit in his filter theory, Broadbent's belief in the importance of cognitive "software" (task variables and individual differences in strategy selection), led him to predict: "In the long run, psychology will, like computer science, become an ever-expanding exploration of the merits and disadvantages of alternative cognitive strategies" (1980: 69).

Broadbent (1980) was genuinely ambivalent about what he called "academic psychology," and although he recognized the importance of theory, unlike many of his contemporaries, he rejected the hypothetico-deductive approach as inefficient, advocating instead experiments whose results could discriminate between classes of theory (1958: 306) and generate a solid, empirical foundation (Broadbent 1973). In light of these attitudes, it is somewhat ironic that Broadbent would have such a great impact on academic psychology (wherein his theoretical language helped foster the cognitive revolution) and that his theory of attention would become the benchmark against which all subsequent theories are compared.

Broca, Paul

During the 1850s Paul Broca (1824–1880) became an important and respected member of the French scientific establishment, sufficient to overcome noteworthy political obstacles and to found the Société d'Anthropologie in 1859 and remain its secretary until his death (Schiller 1979). In a series of papers published between 1861 and 1866 employing the clinico-pathological correlation technique to analyze a loss of speech (aphemia), Broca persuaded a majority of his colleagues that there was a relatively circumscribed center, located in the posterior and inferior convolutions of the left frontal lobe, that was responsible for speech (*langage articulé*). His conclusions have been enshrined in the eponyms Broca's Area and Broca's APHASIA. Whether or not Broca's conclusions constituted a scientific discovery, and whether or not he merits priority in this matter, has been debated ever since (Moutier 1908; Souques 1928; Schiller 1979; Joynt and Benton 1964; Young 1970; Whitaker and Selnes 1975; Henderson 1986; Cubelli and Montagna 1994; Eling 1994; Whitaker 1996). What is not in doubt is that cognitive neuroscience irrevocably changed after the publication of Broca's papers; the cortical localization of language, and by implication other cognitive functions, was now a serious, testable scientific hypothesis.

Broca's sources of knowledge about brain, intelligence, and language functions included François Leuret and Louis P. Gratiolet (1839–1857) and Gratiolet (1854), in which the history of cerebral localization was well described. Gratiolet, a member of the anthropology society, argued from comparative anatomy the importance of the frontal lobes. Bouillaud, who had been influenced by Gall, argued for language localization in the frontal lobe on clinical evidence. Broca knew Bouillaud personally, had been to his house, and even had considered studying internal medicine with him (Schiller 1979: 172). In early 1861 meetings of the anthropology society, Auburtin led a discussion on the question of localizing mental functions to distinct parts of the brain, specifically on localizing speech to the frontal lobe.

Broca participated in that debate (1861a), and his April 1861 report noted the relevance of case Leborgne, alias "tan" (1861b). He chose the older, more prestigious anatomical society as the venue for publishing this case (1861c), stating his belief in cerebral localization in the convolutions, outlining his views regarding regional structural differences of the convolutions (prefiguring cytoarchitectonics) and suggesting that Leborgne's left frontal lesion and loss of speech furnished evidence in support of these views. Broca's second case of loss of speech, patient Lelong, was also published in the same bulletin (1861d); he expressed surprise that the lesion was in the same place as in the previous case—left posterior frontal lobe—and again noted the compatibility with the theory of localization.

The role of the left versus the right hemisphere in language officially arose in 1863 when Gustave Dax deposited for review a report that his father, Marc Dax, had presented to the Montpellier medical society in 1836. In this report the clinico-pathological correlations of forty cases of aphasia suggested that language function resided in the left hemisphere. While the existence of the 1836 Marc Dax mémoire is not absolutely proven, the version written by his son Gustave Dax existed on 24 March 1863, when it was deposited for review (it was published in 1865). The record also shows that Broca's own publication suggesting the special role of the left hemisphere did not appear until 2 April 1863. The priority issue, Dax or Broca, is ably discussed by Schiller (1979), Joynt and Benton (1964), and Cubelli and Montagna (1994); what is not in dispute is that by 1865 the lateralization of language had become an empirical question.

Broca's work was one more part of the ongoing debate on cerebral localization initiated by Gall and Bouillaud in the early nineteenth century; "What Broca seems to have contributed was a demonstration of this localization at a time when the scientific community was prepared to take the issue seriously" (Young 1970: 134–135). Less often appreciated is the fact that every component of Broca's analysis had been published before, between 1824 and 1849. In 1824, Alexander Hood, an obscure Scottish general practitioner who believed in phrenological doctrine, published a case of what would later be called Broca's Aphasia. Hood distinguished between the motor control of the vocal tract musculature, speech output control, and lexical-semantic representation, albeit not in those terms, and assigned each a different left frontal lobe locus. Bouillaud (1825), discussing cases presented earlier by François Lallemand, clearly presented classic clinico-pathological correlation techniques as applied to expressive language. Marc Dax observed (1836/1863) that Lallemand's case histories documented that aphasia-producing lesions were in the left hemisphere. The historical question is to explain why Paul Broca in the 1860s was suddenly able to focus neuroscience on brain localization and lateralization of language.

One must acknowledge that Gall's craniology (Spurzheim's phrenology) had stigmatized research on cerebral localization. The doctrine of (brain) symmetry, persuasively articulated by Xavier Bichat at the beginning of the century, posed a major theoretical hurdle. Jean-Pierre Flourens (1794–1867), an influential member of France's scientific establishment, opposed the cortical localization of

cognitive functions. Finally, language was considered as verbal expression, as speech or as an output function primarily motoric in nature. What we today recognize as language comprehension fell under the rubric of intelligence or general intellectual functions. Much of the clinical evidence that had been marshaled against Bouillaud came from patients with posterior left hemisphere lesions who manifested aphasia; with no theoretical construct of language comprehension such data could only be interpreted as counter-evidence. The same arguments were offered against Broca, of course. It was the work of Theodor Meynert (1867), Henry Charlton Bastian (1869), and finally Carl Wernicke (1874) on disorders of comprehension that completed the model of language localization, thus setting the stage for the development of modern neurolinguistics and creating a historical niche for Paul Broca.

Cajal, Santiago Ramón y

Santiago Ramón y Cajal (1852–1934) was one of the most outstanding neuroscientists of all time. He was born in Petil-la de Aragón, a small village in the north of Spain. He studied medicine in the Faculty of Medicine in Zaragoza. In 1883, Cajal was appointed in 1892 as chair of Descriptive and General Anatomy at the University of Valencia. In 1887, he moved to the University of Barcelona, where he was appointed to the chair of Histology and Pathological Anatomy. At the University of Madrid, where he remained until retirement, he was appointed to the chair of Histology and Pathological Anatomy. Dr. Cajal received numerous prizes, honorary degrees, and distinctions, among the most important being the 1906 Nobel Prize for physiology or medicine. To describe the work of Cajal is rather a difficult task, because, unlike other great scientists, he is not known for one discovery only, but for his many and important contributions to our knowledge of the organization of the nervous system. Those readers interested in his life should consult his autobiography (Cajal 1917), where there is also a brief description of his main discoveries and theoretical ideas.

The detailed study of the nervous system began in the middle of the last century. Before Cajal's discoveries, very little was known about the neuronal elements of the nervous system, and knowledge about the connections between its different parts was purely speculative. The origin of nerve fibers was a mystery, and it was speculated that they arose from the gray matter independently of the nerve cells (neurons). This lack of knowledge was due mainly to the fact that appropriate methods for visualizing neurons were not available; the early methods of staining only permitted the visualization of neuronal cell bodies, a small portion of their proximal processes, and some isolated and rather poorly stained fibers. It was in 1873 that the method of Camillo GOLGI (1843–1926) appeared; for the first time, neurons were readily observed in histological preparations with all their parts: soma, dendrites, and axon. Furthermore, Golgi-stained cells displayed the finest morphological details with an extraordinary elegance, which led to the characterization and classification of neurons, as well as to the study of their possible connections. In 1906 Golgi was awarded the Nobel Prize for physiology or medicine for discovering this technique. Cajal shared the Nobel Prize with Golgi in the same year, for his masterful interpretations of his preparations in which he applied the method of Golgi.

Cajal was not introduced to a scientific career under the direction of any scientist, as then usually occurred with most scientists, but rather he became a prominent neurohistologist on his own. The career of Cajal can be divided into three major phases (DeFelipe and Jones 1991).

The first phase extended from the beginning in 1877 until 1887, when he was introduced to Golgi's method. During this period he published a variety of histological and microbiological studies, but they were of little significance.

The second phase (1887–1903) was characterized by very productive research, in which he exploited the Golgi method in order to describe in detail almost every part of the central nervous system. These descriptions were so accurate that his classic book *Histologie* (Cajal 1909, 1911), in which these studies are summarized, is still a reference book in all neuroscience laboratories. Also, during the first few years of this second phase, Cajal found much evidence in favor of the neuron doctrine, which contrasted with the other more commonly accepted reticular theory. The neuron doctrine, the fundamental organizational and functional principle of the nervous system, states that the neuron is the anatomical, physiological, genetic, and metabolic unit of the nervous system, whereas for the reticular theory the nervous system consists of a diffuse nerve network formed by the anastomosing branches of nerve cell processes (either both dendritic and axonal, or only axonal), with the cell somata having mostly a nourishing role (for review, see Shepherd 1991; Jones 1994).

The third phase of Cajal's career began in 1903, with his discovery of the reduced silver nitrate method, and ended with his death in 1934; this period was devoted mainly to the investigation of traumatic degeneration and regeneration of the nervous system. He published numerous scientific papers about this subject that were of great relevance, and which were summarized in another classic book, *Degeneration and Regeneration* (Cajal 1913–1914). During this phase, Cajal also published some important papers on the structure of the RETINA and optic centers of invertebrates.

Interestingly, Golgi, as well as most neurologists, neuroanatomists, and neurohistologists of his time, was a fervent believer in the reticular theory of nerve continuity. However, for Cajal the neuron doctrine was crystal clear. Microphotography was not well developed at that time, and virtually the only way to illustrate observations was by means of drawings, which were open to skepticism (DeFelipe and Jones 1992). Some of Cajal's drawings were considered artistic interpretations rather than accurate copies of his preparations. Nevertheless, examination of Cajal's preparations, housed in the Cajal Museum at the Cajal Institute, proves the exactness of his drawings (DeFelipe and Jones 1988, 1992). Although Cajal had the same microscopes and produced similar histological preparations with comparable quality of staining as the majority of the neurohistologists of his time, he *saw* differently than they did. This was the genius of Cajal.

Case-Based Reasoning and Analogy

Case-based reasoning (CBR) refers to a style of designing a system so that thought and action in a given situation are guided by a single distinctive prior case (precedent, prototype, exemplar, or episode). Historically and philosophically,

CBR exists as a reaction to rule-based reasoning: in CBR, the emphasis is on the case, not the rule.

CBR works with a set of past cases, a case base. CBR seeks to determine a "source case" relevant to a given "target case". All CBR systems separate their reasoning into two stages: (1) finding the appropriate source case (retrieving); and (2) determining the appropriate conclusions in the target case (revising/reusing). All CBR systems must have some way of augmenting their case base or learning new cases, even if this simply involves appending to a list of stored cases. Retrieval is described as finding the "most similar" past case or the "nearest neighbor"; this just begs the question of what is the appropriate similarity or distance metric.

To reason about an Italian automobile, consider past examples of automobiles. If the most similar retrieved case is a European automobile, this is a better source of information than a past example of an American automobile, all things being equal.

A set of cases might be viewed as a corpus from which rules could potentially be gleaned, but the appropriate generalizations of which have not yet been performed. In this view, CBR is a postponement of INDUCTION. The advantage of the raw cases, in this view, is that revision of the rule base can better be performed because the original cases remain available; they have not been discarded in favor of the rules that summarize them.

To guide deliberation in a situation, a case-based reasoner represents and transforms the rationale of a precedent or the etiology of a prior case. By hypothesis, a single case suffices for guidance if it is the appropriate case and it is transformed properly. In contrast, rule-based reasoners (e.g., EXPERT SYSTEMS and DEDUCTIVE REASONING) apply a rule to a situation with no transformation.

In both rule-based and case-based reasoning, managing the interaction of multiple sources of guidance is crucial. In CBR, different cases can suggest conflicting conclusions; in rule-based reasoning, several rules might conflict. In one, choose a case; in the other, choose a rule. Nonmonotonic reasoning is fundamentally concerned with both kinds of choice.

In practice, the separation of CBR from other forms of reasoning is imperfect. An interplay of rules and cases is unavoidable. A case can almost always be viewed as a compact representation of a set of rules. CBR is just one form of *extensional programming* (other examples are PATTERN RECOGNITION AND FEEDFORWARD NETWORKS, MACHINE LEARNING, and statistical learning) though CBR performs its generalizations on-line, while others preprocess their generalizations.

Nevertheless, CBR is a distinctly different paradigm. The emphasis is on the unique properties of each case, not the statistical properties of numerous cases. CBR differs from induction because induction derives its power from the aggregation of cases, from the attempt to represent what *tends* to make one case like or unlike another. CBR derives its power from the attempt to represent what *suffices* to make one case like or unlike another. CBR emphasizes the structural aspects of theory formation, not the statistical aspects of data.

Case-based reasoning is usually associated with work that has been called "scruffy": work that aims at the design of software systems and that takes its main themes and inspiration from psychology (e.g., Rosch and Lloyd 1978). Roger Schank (1982) imposes the view that case-based reasoning mimics human MEMORY. He refers to cases as "memories," retrieval of cases as "remindings," and representation of cases as "memory organization." Systems that owe their origin to this school of thought are considerable in scope and ability. There are case-based planners, case-based problem-solvers, case-based diagnosticians, case-based financial consultants, case-based approaches to learning (including EXPLANATION-BASED LEARNING), and case-based illuminations of search.

Research in this style tends to taxonomize issues and approaches. There are qualitative and quantitative metrics of similarity; there are approaches that seek to understand the causality underlying a case, and approaches that do not. The literature contains both a rich conceptual cartography and some of the most accessible polemics on the importance of a nonstatistical approach to the logging of past cases.

A good example of a case-based system is Katia Sycara's PERSUADER, which reasons about labor-management negotiations. It uses past agreements between similarly situated parties to suggest proposals that might succeed in the current negotiation. Past and present situations are compared on features such as wage rates and market competitiveness, and include structural models of how changing one feature affects another. Past agreements can be transformed according to the differences between past and present, possibly including numerically scaling the size of settlements.

Case-based reasoning moved to the center of AI when the logical issues of postponing rule formation were separated from the psychological issues of stuctural ANALOGY. Stuart Russell (1989) defined precisely the "logical problem of analogy" so that it could be studied with precision in the philosophical tradition. Russell proposed that there were relations between predicates, called "determinations," that would permit a single co-occurrence of P and Q to lead to the rule "if $P(x)$ then $Q(x)$." Thus, a person's nationality determines that person's language, but does not determine marital status. The logical formulation showed clearly what would be needed to formally justify analogy. Analogy is either presumptuous (thus, fallible, defeasible, or otherwise susceptible to discount and revision), or else it brings knowledge to bear that permits a single case to skew an entire (statistical) reference class. Like Nelson Goodman's (1972) paradox of "grue," which raises the question of justified projection with many cases, "determinations" raise the question of justified projection from a single case.

Kevin Ashley (1990) showed how cases are used in legal reasoning. Cases and precedents are fundamental to philosophy of law; AI and law have been equally concerned with the proper modeling of cases. Ashley noted that some features describing cases are inherently proplaintiff or pro–defendant. Understanding this distinction permits deeper comparisons of similarity. CBR appears in moral and legal philosophy under the name "casuistry."

Earlier researchers defended CBR by citing contemporary psychology. Ashley and Russell connected CBR to immense literatures that were historically concerned with the significance of the single case. Current work on CBR

continues to revolve around these two foci: psychology-inspired themes for systems design, and the precise understanding of reasoning with the single case.

Categorial Grammar

The term Categorial Grammar (CG) refers to a group of theories of natural language syntax and semantics in which the main responsibility for defining syntactic form is borne by the LEXICON. CG is therefore one of the oldest and purest examples of a class of lexicalized theories of grammar that also includes HEAD-DRIVEN PHRASE STRUCTURE GRAMMAR, LEXICAL FUNCTIONAL GRAMMAR, Tree-adjoining grammar, Montague grammar, RELATIONAL GRAMMAR, and certain recent versions of the Chomskean theory.

The various modern versions of CG are characterized by a much freer notion of derivational syntactic structure than is assumed under most other formal or generative theories of grammar. All forms of CG also follow Montague (1974) in sharing a strong commitment to the Principle of COMPOSITIONALITY—that is, to the assumption that syntax and interpretation are homomorphically related and may be derived in tandem. Significant contributions have been made by Categorial Grammarians to the study of SEMANTICS, SYNTAX, MORPHOLOGY, intonational phonology, COMPUTATIONAL LINGUISTICS, and human SENTENCE PROCESSING.

There have been two styles of formalizing the grammar of natural languages since the problem was first articulated in the 1950s. Chomsky (1957) and much subsequent work in GENERATIVE GRAMMAR begins by capturing the basic facts of English constituent order exemplified in (1) in a Context-free Phrase Structure grammar (CFPSG) or system of rewrite rules or "productions" like (2), which have their origin in early work in recursion theory by Post, among others.

(1) Dexter likes Warren.

(2) $S \rightarrow NP\ VP$
$VP \rightarrow TV\ NP$
$TV \rightarrow \{\ likes,\ sees,\ \ldots\ \}$

Categorial Grammar (CG), together with its close cousin Dependency Grammar (which also originated in the 1950s, in work by Tesnière), stems from an alternative approach to the context-free grammar pioneered by Bar-Hillel (1953) and Lambeck (1958), with earlier antecedents in Ajdukiewicz (1935) and still earlier work by Husserl and Russell in category theory and the theory of types. Categorial Grammars capture the same information by associating a functional type or category with all grammatical entities. For example, all transitive verbs are associated via the lexicon with a category that can be written as follows:

(3) likes := $(S\backslash NP)/NP$

The notation here is the "result leftmost" notation according to which α/β and $\alpha\backslash\beta$ represent functions from β

into α, where the slash determines that the argument β is respectively to the right (/) or to the left (\) of the functor. Thus the transitive verb (3) is a functor over NPs to its right-yielding predicates, or functors over NPs to the left, which in turn yield *S*. (There are several other notations for categorial grammars, including the widely used "result on top" notation of Lambek 1958 and much subsequent work, according to which the above category is written *(NP\S)/NP*. The advantage of the present notation for cognitive scientists is that semantic type can be read in a consistent left-right order, regardless of directionality.)

In "pure" context-free CG, categories can combine via two general function application rules, which in the present notation are written as in (4), to yield derivations, written as in (5a), in which underlines indexed with right and left arrows indicate the application of the two rules.

(4) *Functional application*
    a. *X/Y*   *Y* $\Rightarrow$ *X*
    b. *Y*   *X\Y* $\Rightarrow$ *X*

(5) a. <u>Dexter</u> <u>likes</u> <u>Warren</u>   b. Dexter likes Warren
    NP (S\NP)/NP NP   NP   V   NP
          S\NP   VP
            S   S

Such derivations are equivalent to traditional trees like (5b) in CFPSG. However, diagrams like (5a) should be thought of as derivations, delivering a compositional interpretation directly, rather than a purely syntactic structure. The identification of derivation with interpretation becomes important when we consider the extensions of CG that take it beyond weak equivalence with CFPSG.

A central problem for any theory of grammar is to capture the fact that elements of sentences that belong together at the level of semantics or interpretation may be separated by much intervening material in sentences, the most obvious example in English arising from the relative clause construction. All theories of grammar respond to this problem by adding something such as the transformationalists' WH-MOVEMENT, GPSG feature-passing, ATN HOLD registers, or whatever to a context-free core. Usually, such additions increase automata-theoretic power. To the extent that the constructions involved seem to be quite severely constrained, and that certain kinds of long-range dependencies seem to be universally prohibited, there is clearly some explanatory value in keeping such power to a minimum.

All of the generalizations of categorial grammar respond to this problem by adding various *type-driven combinatory operators* to pure CG. The many different proposals for how to do this fall under two quite distinct approaches. The first, *rule-based,* approach, pioneered by Lyons (1968), Bach (1976), and Dowty (1979), among other linguists, and by Lewis (1970) and Geach (1972), among philosophical logicians, starts from the pure CG of Bar-Hillel, and adds rules corresponding to simple operations over categories, such as "wrap" (or commutation of arguments), "type-raising," (which resembles the application of traditional nominative, accusative, etc. case to NPs, etc.) and functional composi-

tion. One possible derivation of a complex relative clause comes out as follows in one fairly typical version, "Combinatory" Categorial Grammar (CCG), discussed at length by the present author (see "Further Reading"), in which type-raising and composition are for historical reasons indicated by **T** and **B**, respectively.

(6) a woman whom   Dexter thinks that Warren likes
    (N\N)/(S/NP) S/(S\NP) (S\NP)/S' S'/S S/(S\NP) (S\NP)/NP
                         S/S'   **B**
                          S/S   **B**
                            S/(S\NP)   **B**
                              S/NP   **B**
                   N\N

Notice that this analysis bears no resemblance to a traditional right-branching clause structure modified by structure-preserving movement transformations.

The alternative, *deductive*, style of Categorial Grammar, pioneered by van Benthem (1986) and Moortgat (1988), takes as its starting point Lambek's syntactic calculus. The Lambek system embodies a view of the categorial slash as a form of logical implication for which a number of axioms or inference rules define a proof theory. (For example, functional application corresponds to the familiar classical rule of *modus ponens* under this view). A number of further axioms give rise to a deductive calculus in which many but not all of the rules deployed by the alternative rule-based generalizations of CG are theorems. For example, the derivation (6) corresponds to a proof in the Lambek calculus using type-raising and composition as lemmas.

The differences between these approaches make themselves felt when the grammars in question are extended beyond the weak context-free power of the Lambek calculus and the combinatory rules that are theorems thereof, as they must be to capture natural language in an explanatory fashion. The problem is that almost any addition of axioms corresponding to the non-Lambek combinatory rules that have been proposed in the rule-based framework causes a collapse of the calculus into "permutation completeness"—that is, into a grammar that accepts all permutations of the words of any sentence it accepts. This forces the advocates of the Lambek calculus into the "multimodal" systems involving many distinct slashes encoding multiple notions of implication (Morrill 1994), and forces the advocates of rule-based systems to impose type restrictions on their rules. (Nevertheless, Joshi, Vijay-Shanker, and Weir 1991 show that certain rule-based CGs remain of low automata-theoretic power.)

These two styles of CG are reviewed and compared at length by Moortgat (1988) (with a deductive bias), and Wood (1993) (with a rule-based bias) (see Further Readings). To some extent the same biases are respectively exhibited in the selection made in two important collections of papers edited by Buszkowski, Marciszewiski, and van Benthem (1988) and Oehrle, Bach, and Wheeler (1988) (see Further Readings), which include several of the papers cited here.

The differences are less important for the present purpose than the fact that all of these theories have the effect of

engendering derivational structures that are much freer than traditional surface structures, while nonetheless guaranteeing that the nonstandard derivations deliver the same semantic interpretation as the standard ones. For example, because all of these theories allow the residue of relativization *Dexter thinks that Warren likes* in example (6) to be a derivational constituent of type *S/NP*, they also all allow a nonstandard analysis of the canonical sentence *Dexter thinks that Warren likes these flowers* in terms of an identically derived constituent followed by an object NP:

(7) [[Dexter thinks that Warren likes]$_{S/NP}$ [these flowers]$_{NP}$]$_S$

This is a surprising property, because it seems to flout all received opinion concerning the surface constituency of English sentences, suggesting that a structure in which objects—even embedded ones—dominate subjects is as valid as the standard one in which subjects dominate objects. The implication is that the BINDING THEORY (which must explain such facts as that in every language in the world you can say the equivalent of *Warren and Dexter shave each other* but not *Each other shave Dexter and Warren*) must be regarded as a property of semantic interpretation or LOGICAL FORM rather than of surface structure as such (cf. Dowty 1979; Szabolcsi 1989; Chierchia 1988; Hepple 1990; Jacobson 1992).

These proposals also imply that there are many semantically equivalent surface derivations for every traditional one, a problem that is sometimes misleadingly referred to as "spurious ambiguity," and which appears to make parsing more laborious. However, this problem can be eliminated using standard chart-parsing techniques with an equivalence check on Logical Forms associated with constituents, as proposed by Karttunen (1989) and other advocates of unification-based computational realizations of CG—see Carpenter 1997 for a review.

Flexible or combinatory Categorial Grammars of all kinds have real advantages for capturing a number of phenomena that are problematic for more traditional theories of grammar. For example, as soon as the analysis in (7) is admitted, we explain why similar fragments can behave like constituents for purposes of coordination:

(8) [[I dislike]$_{S/NP}$, but [Dexter thinks that Warren likes]$_{S/NP}$ [these flowers]$_{NP}$]$_S$

(Other even more spectacular coordinating nonstandard fragments are discussed in Dowty 1988.)

We also explain why intonation seems similarly able to treat such fragments as phrasal units in examples like the following, in which % marks an intonational boundary or break, and capitalization indicates STRESS (cf. Oehrle et al. 1985; Prevost 1995):

(9) [Q:] I know who YOU like, but who does DEXTER like?
     [A:] [DEXTER likes]$_{S/NP}$ % [WARREN]$_{NP}$

Moreover, the availability of semantic interpretations for such nonstandard constituents appears under certain plausible assumptions about the relation of the competence grammar to the processor to simplify the problem of explaining the availability to human sentence processors of semantic interpretations for fragments like *the flowers sent for*, as evidenced by the effect of this content in (b) below in eliminating the "garden-path" effect of the ambiguity in (a), discussed by Crain and Steedman (1985) and Altman (1988).

(10) a. The doctor sent for the patient died.
      b. The flowers sent for the patient died.

All of these phenomena imply that the extra structural ambiguity engendered by generalized categorial grammars is not "spurious," but a property of competence grammar itself.

Categorization

Categorization, the process by which distinct entities are treated as equivalent, is one of the most fundamental and pervasive cognitive activities. It is fundamental because categorization permits us to understand and make predictions about objects and events in our world. People (necessarily) make use of only the tiniest fraction of the possible categorization schemes, but even a modest-sized set of entities can be grouped in a limitless number of ways. Therefore, a fundamental question is why we have the categories we have and not others. Further, what do our categorization schemes allow us to do that other schemes would not?

There has been a plethora of work on the structure of categories, mostly examining natural object categories (see Smith and Medin 1981; Rips 1990; Komatsu 1992 for reviews). A powerful but controversial idea is that SIMILARITY is an organizing principle. Within this framework, there are important distinctions concerning just how similarity operates, but we will not be concerned with them here (see Medin 1989 for a review). Simply stated, this view suggests that we put things in the same categories because they are similar to each other. A robin and a hawk (both birds) seem obviously more similar than a robin and an elephant (not a bird); elephants are not birds because they are not sufficiently similar to them. A natural consequence of this similarity view is that the world is organized for us and our categories map onto this reality (e.g., Rosch and Mervis 1975).

Why is this notion that categories are defined by some "objective" similarity controversial? The main criticism has been that the notion of similarity is too unconstrained to be useful as an explanatory principle (Goodman 1972; Murphy and Medin 1985). Similarity is usually defined in terms of shared properties, but Goodman argued that any two things share an unlimited number of properties (e.g., robins and elephants can move, weigh more than an ounce, weigh more than two ounces, take up space, can be thought about, etc.). Given this apparent flexibility, it may be that we see things as similar *because* they belong to the same category and not vice versa. That is, maybe we can explain similarity in terms of categories.

An alternative to the similarity view of categorization is that *theories* provide conceptual coherence (Carey 1985; Keil 1989; Medin 1989; Rips 1989; Hirschfeld and Gelman 1994). The theory-based explanation of categorization is consistent with the idea that CONCEPTS are comprised of features or properties. By concept, we mean the mental representation of a category that presumably includes more than procedures for identifying or classifying. These explanations go beyond similarity models in arguing that underlying principles (often causal) determine which features are relevant and how they might be interrelated (Komatsu 1992; see also Billman and Knutson 1996).

In current cognitive science theorizing, similarity has a role to play but a limited one that, in many respects, changes its character. Researchers who focus on similarity (e.g., Nosofsky 1988) use models of selective feature weighting such that similarity is, in part, a byproduct of category learning. Other researchers derive a role for similarity from an analysis of how categories might be used to satisfy human goals such as in drawing inferences (e.g., Anderson 1991). Finally, investigators who argue that categories are organized around knowledge structures (e.g., Wisniewski and Medin 1994) allow theories to determine the very notion of what a feature is.

Is there a single set of principles that applies to all categories? Evidence suggests that there may be important differences among them. First of all, a great deal of attention has been directed to the hierarchical component of categories. Objects can be categorized at different levels of abstraction; for example, your pet Fido can be categorized as a living thing, an animal, a mammal, a dog, or a poodle. Work by Eleanor Rosch and her colleagues (Rosch et al. 1976; see Berlin, Breedlove, and Raven 1973 for related work in anthropology) has shown that one level in this hierarchy,

dubbed the "basic level," seems to be psychologically privileged. In our example, *dog* would be a basic level term, and Rosch et al. found that a number of measures of privilege all converged on this level. The basic level is the level preferred in naming by adults, is the first learned by children, and is the level at which adults can categorize most rapidly. It may be that similarity plays a bigger role in categorization at the basic level than for more superordinate levels. Currently, investigators are actively pursuing issues such as whether the basic level might change with expertise (e.g., Tanaka and Taylor 1991) or vary across cultures (Berlin 1992; Coley, Medin, and Atran 1997). These questions bear on the respective roles of mind and world in categorization (variability with culture or expertise would tend to support the former).

Other researchers have attempted to extend this hierarchical structure to social categories (e.g., race, gender, occupation, etc.). There has been some work applying Rosch's measures of basic levels to the domains of person concepts and routine social events with moderate success (Cantor and Mischel 1979; Morris and Murphy 1990). Note, however, that many social categories are nonhierarchical and categories at the same level of abstractness may be overlapping rather than mutually exclusive. For example, a person can be categorized as a woman, an ethnic minority member, a millionaire, and a celebrity all at the same time. None of these categories are subordinate or superordinate to any other. This raises a new set of questions about which categories are activated in a given situation and how the corresponding concepts are updated with experience. There is even evidence that alternative social categories may compete and inhibit one another (Macrae, Bodenhausen, and Milne 1995). In short, there may be major differences between object and social categories (see Wattenmaker 1995 for a further example).

Goal-derived categories also differ from common taxonomic categories. Barsalou (1983, 1985) has shown that categories activated in the service of goals (e.g., things to take on a camping trip, things to eat when on a diet) may follow different processing principles. For instance, goodness of example for many object categories seems to be based on having typical properties (a robin is judged to be a very typical bird because it looks and acts like many other birds; ostriches are not typical for the opposite reason; see Rosch and Mervis 1975), but for goal-derived categories, goodness of example seems to be based on ideals or extremes. More specifically, the best example of a diet food is one with zero calories, even though zero may not be typical.

Still other researchers have suggested that categorization principles show DOMAIN SPECIFICITY. For example, some have suggested that biological categories constitute a distinct (and innate) domain and that people universally assume that biological categories have an underlying essence that makes things the way they are (Atran 1990). Domain-specificity is a topic that is currently receiving much attention (see chapters in Hirschfeld and Gelman 1994).

Categorization touches on many important applied and theoretical questions. How does the perception of social groups lead to stereotypes (see STEREOTYPING) and other forms of bias? What is the role of language in categorization and conceptual development? To what extent do people who categorize the same way also have the same concept? These are but a small sample of the fascinating issues associated with research on categorization.

Causal Reasoning

Knowing that all pieces of butter have always melted when heated to 150°F, one would probably be willing to conclude that if the next solid piece of butter is heated to 150°F, it will melt. In contrast, knowing that all coins in Nelson Goodman's pockets, up to this point, were silver, one would be reluctant to conclude that if a copper coin were put in his pocket, it would become silver (examples adapted from Goodman 1954/1983). Why is it that one is willing to believe that heating causes butter to melt, but unwilling to believe that Goodman's pocket causes coins to be silver? These contrasting examples point to the kinds of questions that psychologists who study causal reasoning have asked and to the approaches taken in their answers. The central question is: What makes some sequences of events causal, thus licensing inference involving similar events, and other sequences noncausal?

The problem of causal INDUCTION as posed by David HUME (1739/1987) began with the observation that causal relations are neither deducible nor explicit in the reasoner's sensory input (where such input includes introspection as well as external sensory input). Given that sensory input is the ultimate source of all information that a reasoner has, it follows that all acquired causal relations must have been computed from (noncausal) sensory input in some way. A fundamental question therefore arises for such relations: How does a reasoner come to know that one thing, or type of thing, causes another? In other words, what is the mapping from observable events as input to causal relations as output?

The solution Hume (1739/1987) proposed is that causal relations are inferred from the spatial and temporal contiguity of the candidate cause *c* and the effect *e*, the temporal priority of *c*, and the constant conjunction between *c* and *e*. For the butter example, Hume's regularity approach might explain that one concludes that heating causes butter to melt from the fact that the heat is close to the butter, melting follows soon after heating, and whenever butter is heated to 150°F, its melting follows. Similarly, this approach might explain that one is reluctant to believe that Goodman's

pocket causes coins to be silver, because his pocket probably did not come into existence before the coins did. If his pocket did predate all the coins in it, however, Hume's solution would fail: the coins were close to his pocket and they were silver whenever they were in his pocket, including soon after they were in his pocket.

One approach to the psychology of causal inference inherited the problem posed by Hume and extended his *regularity* solution. A branch of this approach was adopted by Kelley's (1973) ANOVA model and subsequent variants of it in social psychology (e.g., Hilton and Slugoski 1986). To illustrate contemporary statistical variants of Hume's solution, consider the contrasting examples again. Cheng and Holyoak's (1995) model would explain that a reasoner concludes that heating causes butter to melt because heating occurs before melting and melting occurs more often when the butter is heated to 150°F than when it is not, when other plausible influences on melting such as the purity of the butter are controlled. In contrast, a reasoner does not conclude that Goodman's pocket causes coins to be silver because one knows of alternative causes of coins being silver that might be uncontrolled. For example, Goodman might have selectively kept only silver coins in his pocket, whereas there is no such selection for coins outside his pocket.

As these examples illustrate, the regularity approach requires specific knowledge about alternative causes. But how does such knowledge come about in the first place? Unless one first knows *all* alternative causes, normative inference regarding a candidate cause seems impossible. Yet such inferences occur everyday in science and daily life. For example, without assuming that one knows all the alternative causes of butter melting, it is nonetheless possible to feel convinced, after observing the heating and subsequent melting of butter, that heating causes butter to melt.

An independent branch of the regularity approach begun in Pavlovian CONDITIONING, culminating in Rescorla and Wagner's (1972) connectionist model and its variants, and has been adopted to apply to human causal reasoning (e.g., Dickinson, Shanks, and Evenden 1984). This branch modifies Hume's solution in a manner similar to the statistical approach, but in addition provides algorithms for computing causal output from observational input. These connectionist variants of the regularity approach explain a wide range of empirical findings but have their shortcomings, such as a failure to explain the causal analog of the extinction of conditioned inhibition (for reviews, see Cheng 1997; Miller, Barnet, and Grahame 1995). A common source of these shortcomings may be the inability of these variants to represent causal power as an explicit variable existing independently of its value (*see* BINDING PROBLEM).

A second approach rejects all regularity solutions, and claims to offer an alternative solution to causal inference: one infers a relation to be causal when one perceives or knows of a causal mechanism or causal power underlying the relation (e.g., Koslowski 1996; Michotte 1963; Shultz 1982; White 1995). Because *power* theorists do not explicitly define causal "power" or causal "mechanism," it is unclear whether heating, for example, qualifies as a causal mechanism for substances melting. Assuming that it does, then power theorists would predict that heating should be

understood to cause butter to melt. In contrast, reasoners do not know of any mechanism involving Goodman's pocket that would cause coins to be silver, and therefore would not believe that his pocket causes coins to be silver. Power theorists attempt to refute the regularity view by demonstrating that knowledge regarding specific causal powers influence causal judgments.

To regularity theorists, it is unclear what question the power approach seeks to answer; that question, however, is definitely not the one posed by Hume (Cheng 1993). If it is "What kind of causal inference do people, including infants, typically make in their everyday life?" then the answer is that they often make inferences based on prior causal knowledge (e.g., previously acquired knowledge that heating causes substances to melt). Regularity theorists, however, have no objection to the use of prior causal knowledge, as long as not all of that knowledge is innate; the kind of evidence offered by power theorists is therefore compatible with the regularity view (Cheng 1993; see Morris and Larrick 1995 for an example of an application of prior causal knowledge using a statistical approach). If the power solution were to be regarded as an answer to Hume's problem, then it begs the question: How does acquired knowledge about the *causal* nature of mechanisms (e.g., heating as a cause of melting) come about? That is, how does a reasoner infer a *causal* mechanism from *noncausal* observations? The answer to this question (the same question that the regularity view attempts but fails to answer) is what ultimately explains why one believes that one relation is causal and another not.

In addition to their other problems, neither the regularity nor the power approach can explain the boundary conditions for causal inference (see Cheng 1997 for a review). For example, neither explains why controlling for alternative causes allows a regularity to imply causality.

A third approach to the psychology of causal inference inherited Hume's problem, but modified his regularity solution radically by adding a Kantian framework that assumes an a priori notion of causal power. This notion differs critically from the causal knowledge presupposed by traditional power theorists in that it is general rather than specific (see INFANT COGNITION for assumptions regarding specific causal knowledge). According to this approach, the reasoner innately postulates that there exist such things as causes that have the power to produce an effect and causes that have the power to prevent an effect, and determines whether a regularity is causal by attempting to generate it with such general possible powers. By integrating the two previous approaches, this new power approach claims to explain a wide range of findings regarding causal inference, overcoming many problems that cripple earlier approaches (Cheng 1997). The same basic approach has been adopted by computer scientists and philosophers in the last decade to study how it is possible in principle to draw inferences about causal networks from patterns of probabilities (BAYESIAN NETWORKS; Pearl 1995; Spirtes, Glymour, and Scheines 1993). Although psychological work has begun on aspects of causal networks (Busemeyer, McDaniel, and Byun 1997; Spellman 1997), how humans and other animal species infer causal networks remains to be investigated.

Causation

Basic questions in the philosophy of causation fall into two main areas. First, there are central metaphysical questions concerning the nature of causation, such as the following: What are causal laws? What is it for two states of affairs to be causally related? Which are primary—causal relations between states of affairs, or causal laws? How are causal facts related to noncausal facts? How can one explain the formal properties of causation—such as irreflexivity, asymmetry, and transitivity? What is the ground of the direction of causation?

Second, there are issues concerning the epistemology of causation. Can causal relations be directly observed? How can the existence of causal laws be established? What statistical methods can be used to confirm causal hypotheses, and how can those methods be justified?

Such metaphysical and epistemological issues first came sharply into focus as a result of David Hume's penetrating scrutiny of causation, and the theses that he defended (Hume 1739–40, 1748). On the metaphysical side, HUME argued for the view that causal facts are reducible to noncausal facts, while, on the epistemological side, Hume argued that causal relations between events, rather than being directly observable, can only be known by establishing the existence of "constant conjunctions," or general laws.

The major metaphysical choice is between realist and reductionist approaches to causation. According to the latter, all causal facts are logically supervenient upon the totality of noncausal states of affairs. It is logically impossible, then, for two possible worlds to disagree with respect to some causal fact while agreeing completely with respect to all noncausal facts.

Reductionist approaches to causation have dominated the philosophical landscape since the time of Hume, and many different accounts have been advanced. Three types of approaches are, however, especially important. First, there are approaches that start out from the general notion of a law of nature, then define the ideas of necessary and sufficient nomological conditions, and, finally, employ the latter concepts to explain what it is for one state of affairs to cause another (Mackie 1965). Second, there are approaches that employ subjunctive conditionals in an attempt to give a counterfactual analysis of causation (Lewis 1973, 1979, 1986). Third, there are probabilistic approaches, where the central idea is that a cause must, in some way, make its effect more likely (Reichenbach 1956; Good 1961–62; Suppes 1970; Eells 1991; Mellor 1995).

Each of these three types of approaches faces difficulties specific to it. The attempt to analyze causation in terms of nomological conditions, for example, is hard pressed to pro-vide any account of the direction of causation—a problem that quickly becomes evident when one notices that one state of affairs may be a nomologically sufficient condition for another either because the former is causally sufficient for the latter, or because, on the contrary, the latter is causally necessary for the former.

In the case of counterfactual approaches to causation, a crucial problem is that traditional analyses of subjunctive conditionals employ causal notions. Alternative accounts have been proposed, involving similarity relations over possible worlds. But these alternative accounts are exposed to decisive objections.

Finally, there are also specific problems for probabilistic accounts, two of which are especially important. First, probabilistic accounts have struggled to find an interpretation of their central claim—that causes must, in some way, make their effects more likely—that is not open to counterexamples. Second, probabilistic approaches to causation typically involve the very counterintuitive consequence that a completely deterministic world could not contain any causally related events (Tooley 1987).

There are also other objections, however—of a very serious sort—that tell against all reductionist approaches. First, one can show that some worlds with probabilistic laws may agree with respect to all causal laws and all noncausal facts, yet differ with respect to causal relations between events. So some causal facts not only are not logically supervenient upon the totality of noncausal states of affairs, they are not even supervenient upon the combination of that totality together with all causal laws (Carroll 1994; Tooley 1987).

Second, there are arguments showing that no reductionist approach to causation can account for the direction of causation. One problem, for example, is that very simple worlds containing causally related events may be devoid of all of the noncausal features upon which reductionist accounts rely to define the direction of causation—such as increasing entropy and the presence of open causal forks. Another problem is that, given deterministic laws of an appropriate sort—such as, for example, the laws of Newtonian physics—one can show that, corresponding to some worlds where a reductionist account assigns the correct direction to causation, there will be inverted worlds where the direction of causation is opposite to that specified by any reductionist account (Tooley 1990b).

Given these difficulties, it is natural to explore realist alternatives, and the most plausible form of realism involves viewing causation as a theoretical relation between states of affairs. The development of this type of approach, however, presupposed solutions to two problems that confronted realist interpretations of theories in general. First, there was the semantical problem of how one could even make sense of a realist interpretation of theoretical terms. Second, there was the epistemological problem of how one could justify any statement containing theoretical terms when those terms were interpreted as referring to unobservable states of affairs.

It is not surprising, then, that until those obstacles were surmounted, reductionist approaches to causation held sway. Now, however, satisfactory answers to the above problems are available. Thus, in the case of the semantical

problem, one promising approach involves the use of existential quantification ranging over properties and relations to assign a realist interpretation to theoretical terms (Lewis 1970), while, as regards the epistemological problem, there is now widespread acceptance of a type of inductive reasoning—variously referred to as the method of hypothesis, abduction, hypothetico-deductive reasoning, and inference to the best explanation—that will allow one to justify theoretical claims realistically construed.

These philosophical developments have made it possible, then, to take seriously the idea that causation is a theoretical relation. To construct such an account, however, one needs to set out an analytically true theory of causation, and, at present, only one such theory has been worked out in any detail (Tooley 1987, 1990a). It seems likely, however, both that more theories will be proposed in the near future, and that, given the difficulties that reductionism faces, an account of the nature of causation along realist lines will turn out to be correct.

Some philosophers have maintained that causation is a basic and unanalyzable relation that is directly observable (Anscombe 1971; Fales 1990). That view, however, is exposed to some very serious objections (Tooley 1990a). Of these, one of the most important concerns the fact that causal beliefs are often established on the basis of statistical information—using methods that, especially within the social sciences, are very sophisticated. But if causation is a basic and unanalyzable relation, how can non-causal, statistical information possibly serve to establish causal hypotheses?

Recently, this question of how causal hypotheses can be established using statistical information has been the subject of intense investigation. The basic approach has been, first, to identify fundamental principles relating causation to probability. Two such principles that have been suggested as very important, for example, derive from the work of Hans Reichenbach (1949, 1956):

The Screening Off Principle: If A causes C only via B, then, given B, A and C are statistically independent.

The Common Cause Principle: If A and B are statistically dependent, and neither causes the other, then there is a common cause of A and B.

Then, second, one attempts to show that those principles can be used to justify algorithms that will enable one to move from information about statistical relationships to conclusions about causal relations (Glymour et al. 1987; Glymour, Spirtes, and Scheines 1991; Spirtes, Glymour, and Scheines 1993)

This is an interesting and important research program. In its present form, however, it suffers from certain defects. First, some of the principles employed are unsound. Reichenbach's common cause principle, for example, is shown to be false by the inverted worlds objection to causal reductionism mentioned above. Second, if reductionism is false, then it is a mistake to look for algorithms that will specify, for some set of statistical relationships, what the relevant causal relations must be, as given a realist view of causation, different causal relations may underlie a given set of statistical relationships. A sound algorithm, accordingly,

will generate only a probability distribution over possible causal relations.

The basic conclusion, in short, is that an investigation into the epistemology of causation cannot proceed in isolation from consideration of the metaphysics of causation, and if it turns out that a reductionist view of causation is untenable, then one needs to employ a realist account that connects causation to probability, and then isolate algorithms that can be justified on the basis of such an account.

Cerebellum

The cerebellum constitutes 10 to 15 percent of the entire brain weight, about 140 grams in humans. Rollando (1809; see Dow and Moruzzi 1958) was the first who, by observing motor disturbances in an animal with a lesioned cerebellum, related the cerebellum to movement. Careful analyses of the motor disturbances so induced led Flourens (1824; see Dow and Moruzzi 1958) to conclude that the cerebellum is neither an initiator nor an actuator, but instead serves as a coordinator of movements. An animal with a damaged cerebellum still initiates and executes movement, but only in a clumsy manner. Flourens (1842) and Luciani (1891; see Dow and Moruzzi 1958) observed that motor disturbances caused in an animal by a partial lesion of the cerebellum were gradually compensated for due to the functional plasticity of cerebellar tissues. According to the current knowledge cited below, this plasticity is an expression of a learning capability of the cerebellum, which normally plays a role in MOTOR LEARNING, as in the cases of practicing sports and acquiring skilled movements. Early in the twentieth century, neurologists defined the unique symptoms, such as dysmetria and motor incoordination, of cerebellar diseases. Based on these classic observations, it has been thought that the major function of the cerebellum is to enable us to learn to perform movements accurately and smoothly. The extensive studies that have been performed over the past four decades have facilitated the formulation of comprehensive views on the structure of the cerebellum, what processes occur there, and what roles it plays not only in bodily but also in cognitive functions, even though some of the views are still hypothetical.

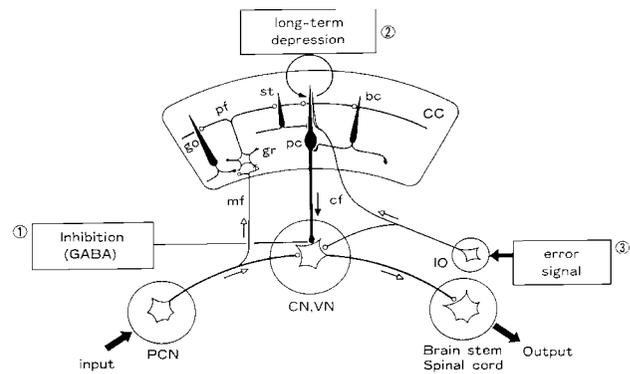
The cerebellar cortex contains an elaborate neuronal circuit composed of five types of cells: Purkinje, basket, strellate, Golgi, and granule cells (fig. 1; Eccles, Ito, and Szentagothai 1967). With respect to their synaptic action, these cells are inhibitory except for the granule cells, which are excitatory. Afferent signals from various precer-


Figure 1. Neuronal circuitry of the cerebellum. ebellar nuclei reach the cerebellar cortex and are relayed to the granule cells via mossy fibers, and to the dendrites of the Purkinje cells and other inhibitory cells via the axons of the granule cells, that is, parallel fibers. Afferent signals from the inferior olive in the medulla oblongata pass directly to the Purkinje cells via climbing fibers. L-glutamate is the neurotransmitter for the vast majority of mossy fibers and all granule cells, while GABA is the neurotransmitter for all inhibitory neurons.

The major signal flows in the cerebellum pass from the cells of origin for mossy fibers (PCN in fig. 1), granule cells (gr), and Purkinje cells (pc). Marr (1969), Albus (1971), and other theorists proposed that if climbing fiber signals modify granule cell-to-Purkinje cell synapses, the three-neuron structure would operate as a learning machine in the same way as the simple perceptron described by Rosenblatt (1962). It was a decade before long-term depression (LTD) was discovered to occur at parallel fiber-to-Purkinje cell synapses after conjunctive activation of these synapses together with climbing fiber-to-Purkinje cell synapses (Ito, Sakurai, and Tongroach 1982; Ito 1989). LTD occurs as a result of complex chemical processes involving a number of receptors and second messengers, eventually leading to the phosphorylation of glutamate receptors (Nakazawa et al. 1995).

The cerebellar cortex contains numerous small longitudinal microzones (Oscarsson 1976). Each microzone is paired with a small distinct group of neurons in a cerebellar or vestibular nucleus (CN, VN in fig. 1) to form a corticonuclear microcomplex that hereafter is referred to as a cerebellar chip or a chip (Ito 1984). In a cerebellar chip, input signals from various precerebellar nuclei activate the nuclear neurons that produce the output signals of the chip. This major signal path across a chip is attached with a sidepath through a microzone that receives input signals via mossy fibers and relays Purkinje cell signals to the nuclear neurons. Climbing fibers convey signals representing errors in the performance of the chip, as detected through various sensory pathways, which induce LTD in Purkinje cells. The LTD induction changes the signal flow through the microzone sidepath, thereby altering the signal flow across the chip. A cerebellar chip thus behaves as an adaptive unit in which input-output

relationships are adaptively altered by error signals conveyed by climbing fibers.

The cerebellum is divided into the flocculonodular lobe and the corpus cerebelli, the latter being further divided into vermis, paravermis (intermediate part), and hemisphere. Cerebellar chips in the flocculonodular lobe, vermis, and paravermis are connected to the brain stem and spinal cord, and confer adaptiveness on reflexes (not only motor but also autonomic; for the vestibuloocular reflex, see Robinson 1976; Ito 1984; for eye-blink conditioned reflex, see Thompson 1987) and compound movements (for locomotion, see Yanagihara and Kondo 1996), which by themselves are stereotyped and nonadaptive. The role of the evolutionary old part of the cerebellum is therefore to ensure the adaptiveness of the spinal cord and brain stem control functions in order to enable animals to survive in ever-changing environments.

With respect to cerebral control functions, cerebellar chips appear to play a different role, that is, the formation of an internal model of a controller or a control object. If, while a chip and the system to be modeled are supplied with common input signals, differences in their output signals are returned to the chip as error signals, the chip will gradually assume dynamic characteristics equivalent to those of the system to be modeled.

Cerebellar chips located in the paravermis are connected to the cerebral motor cortex in such a way that these chips constitute a model that mimics the dynamics of the skeletomuscular system (Ito 1984). The motor cortex thus becomes capable of performing a learned movement with precision by referring to the model in the cerebellum and not to the skeletomuscular system. Dysmetria, the failure to perform a precise reaching movement without visual feedback, could be due to the loss of such internal models. Another possibility is that a chip located in the cerebellar hemisphere forms a model that acts as a controller in place of the motor cortex (Kawato, Furukawa, and Suzuki 1987; Shidara et al. 1995). Learned movements could then be controlled unconsciously, yet accurately, by the cerebellum. These two model systems, one eliminating the need for sensory feedback and the other awareness from learned voluntary movement control, appear to represent different phases of motor learning conducted in different cerebellar areas.

Based on the parallel development of the cerebral association cortex and cerebellar hemispheres in primates, Leiner, Leiner, and Dow (1986) suggested that the lateralmost part of the cerebellar hemisphere is involved in cognitive rather than motor functions. Thought may occur as a result of the prefrontal association cortex acting as a controller upon images, ideas, or concepts encoded in the parietolateral association cortex as a control object. During thought repetition, a cerebellar chip may form a model of the parietolateral cortex or the prefrontal cortex. A repeatedly learned thought may thus be performed quickly yet accurately even without reference to the consequences of the thought or without conscious attention. Evidence suggesting such roles of the cerebellum as this is accumulating from studies on the human cerebellum using noninvasive techniques (see Schmahmann 1997).

Cerebral Cortex

The cerebral cortex is a paired structure in the forebrain that is found only in mammals and that is largest (relative to body size) in humans (Herrick 1926; Jerison 1973). Its most distinctive anatomical features are (i) the very extensive internal connections between one part and another part, and

(ii) its arrangement as a six-layered sheet of cells, many of which cells are typical *pyramidal cells*. Although the crumpled, folded surface of this sheet is responsible for the very characteristic appearance of the brains of large mammals, the cortex of small mammals tends to be smooth and unfolded. Where folds occur, each fold, or *gyrus,* is about 1/2 cm in width (Sarnat and Netsky 1981).

Imagine the crumpled sheet expanded to form a pair of balloons with walls 2.5 mm thick, each balloon with a diameter of 18 cm and a surface area close to 1000 cm2. The pair weighs about 500 grams, contains about 2×10^{10} cells connecting with each other through some 1014 *synapses,* and through a total length of about 2×10^{6} km of nerve fiber—more than five times the distance to the moon (Braitenberg and Schuz, 1991). The two balloons connect to each other through the *corpus callosum*, a massive tract of nerve fibers. Almost all the synapses and nerve fibers connect cortical neurons to each other, but it is of course the connections with the rest of the animal that allow the cortex to control the animal's highest behavior. The main connections are as follows.

The olfactory input from the nose probably represents the input to the primordial structure from which the cortex evolved. It goes directly to layer 1, the outermost layer, of a special region at the edge of the cortical sheet. Touch, hearing, and vision relay through *thalamic nuclei* that are situated near what would be the necks of the balloons, and these nuclei receive a large number of feedback connections from the cortical sheet as well as inputs from the sense organs. An important output pathway comes from the *motor area,* which is the region believed to be responsible for voluntary movement. The CEREBELLUM should be mentioned here because it is also concerned with the regulation and control of muscular movement; it has profuse connections to and from the cortex, and enlarged with it during evolution. It has recently become clear that it is concerned with some forms of CONDITIONING (Yeo, Hardiman, and Glickstein 1985; Thompson 1990).

The second set of pathways in and out of the cortex pass through two adjacent regions of modified cortical sheet called the *archicortex* and *paleocortex* that flank the six-layered *neocortex* (Sarnat and Netsky 1981). Paleocortex lies below the necks of the balloons and contains the *rhinencephalon* (nose brain), where smell information enters; it connects with other regions thought to be concerned with mood and EMOTION. Archicortex developed into the HIPPOCAMPUS, and is thought to be concerned with the laying down of memories. Like the paleocortex, it has connections with regions involved in mood, emotion, and endocrine control.

The words used to describe the higher mental capacities of animals with a large neocortex include CONSCIOUSNESS, *free will*, INTELLIGENCE, *adaptability*, and *insight,* but animals with much simpler brains learn well, so LEARNING should not be among these capacities (Macphail 1982). The comparative anatomists Herrick and Jerrison emphasize that neocortically dominated animals show evidence of having acquired extensive general knowledge about the world, but laboratory learning experiments are usually designed to prevent previously acquired knowledge from influencing results, and are therefore not good tests for stored general knowledge. The evidence for such knowledge is that cortically dominant animals take advantage of the enormously complicated associative structure of their environments, and this could come about in two ways. A species could have genetically determined mechanisms, acquired through evolutionary selection, for taking advantage of the regular features of the environment, or they could have learned through direct experience. It seems most likely that animals with a dominant neocortex have a combination of the two means—they have the best of both worlds by combining genetic and individual acquisition of knowledge about their environments (Barlow 1994).

Neuropsychologists who have studied the defects that result from damage and disease to the cerebral cortex emphasize localization of function (Phillips, Zeki, and Barlow 1984): cognitive functions are disrupted in a host of different ways that can, to some extent, be correlated with the locus of the damage and the known connections of the damaged part. But there can be considerable recovery of a function that has been lost in this way, particularly following damage in infancy or childhood: in the majority of adults the left hemisphere is absolutely necessary for speech and language, but these capacities can develop in the right hemisphere following total loss of the left hemisphere in childhood.

Neurophysiologists have recorded the activity of individual nerve cells in the cortical sheet. This work leads to the view that the cortex represents the sensory input and the animal is receiving, processes it for OBJECT RECOGNITION, and selects an appropriate motor output. Neurons in the *primary visual cortex* (also called *striate cortex* or *V1*) are selectively responsive to edge orientation, direction of MOTION, TEXTURE, COLOR, and disparity. These are the local properties of the image that, according to the laws of GESTALT PERCEPTION, lead to *segregation* of figure from ground. The neurons of V1 send their axons to adjacent *extra-striate visual cortex,* where the precise *topographic mapping* of the visual field found in V1 becomes less precise and information is collected together according to parameters (such as direction and velocity of motion) of the segregating features (Barlow 1981). These steps can account for the first stages of object recognition, but what happens at later stages is less clear.

Although there are considerable anatomical differences between the different parts of the cortical sheet, there are also great similarities, and its evolution as a whole prompts one to seek a similar function for it throughout. Here the trouble starts, for it is evident that comparative anatomists say it does one thing, neuropsychologists another, and neurophysiologists yet something else (Barlow 1994). These divergences result partly from the different spatial and time scales of the observations and experiments in different fields, for neurophysiology follows the activity of individual neurons from second to second, neuropsychologists are concerned with chronic, almost permanent defects resulting from damage to cortical areas containing several million cells, and behavioral observation is concerned with functions of the whole animal over intermediate periods of seconds and minutes. But the cells everywhere have an unusual

and similar form, which suggests they have a common function; an attractive hypothesis is that this is *prediction.*and

Sense organs are slow, but an animal's competitive survival often depends upon speedy response; therefore, a representation that is up to the moment, or even ahead of the moment, would be of very great advantage. Prediction depends upon identifying a commonly occurring sequential pattern of events at an early stage in the sequence and assuming that the pattern will be completed. This requires knowledge of the spatio-temporal sequences that commonly occur, and the *critical* or *sensitive periods,* which neurophysiologists have studied in the visual cortex (Hubel and Wiesel 1970; Movshon and Van Sluyters 1981) but which are also known to occur in the development of other cognitive systems, may be periods when spatio-temporal sequences that occur commonly encourage the development of neurons with a selectivity of response to these patterns. If such *phase sequences,* as HEBB (1949) called them, were recognized by individual cells, one would have a computational unit that, with appropriate connections, would be of selective advantage in an enormous range of circumstances. The survival value of neurons with the power of prediction could have led to the explosive enlargement of the neocortex that culminated in the human brain.

Chess, Psychology of

Historically, chess has been one of the leading fields in the study of EXPERTISE (see De Groot and Gobet 1996 and Holding 1985 for reviews). This popularity as a research domain is explained by the advantages that chess offers for studying cognitive processes: (i) a well-defined task; (ii) the presence of a quantitative scale to rank chess players (Elo 1978); and (iii) cross-fertilization with research on game-playing in computer science and artificial intelligence.

Many of the key chess concepts and mechanisms to be later developed in cognitive psychology were anticipated by Adriaan De Groot's book *Thought and Choice in Chess* (1946/1978). De Groot stressed the role of selective search, perception, and knowledge in expert chess playing. He also perfected two techniques that were to be often used in later research: recall of briefly presented material from the domain of expertise, and use of thinking-aloud protocols to study problem-solving behavior. His key empirical findings were that (i) world-class chess grandmasters do not search more, in number of positions considered and in depth of search, than weaker (but still expert) players; and (ii) grandmasters and masters can recall and replace positions (about two dozen pieces) presented for a few seconds almost perfectly, while weaker players can replace only a half dozen pieces.

De Groot's theoretical ideas, based on Otto Selz's psychology, were not as influential as his empirical techniques and results. It was only about twenty-five years later that chess research would produce a theory with a strong impact on the study of expertise and of cognitive psychology in general. In their chunking theory, Simon and Chase (1973) stressed the role of perception in skilled behavior, as did De Groot, but they added a set of elegant mechanisms. Their key idea was that expertise in chess requires acquiring a large collection of relatively small chunks (each at most six pieces) denoting typical patterns of pieces on the chess board. These chunks are accessed through a discrimination net and act as the conditions of a PRODUCTION SYSTEM: they evoke possible moves in this situation. In other respects, chess experts do not differ from less expert players: they

have the same limits in memory (a short-term memory of about seven chunks) and learning rate (about eight seconds are required to learn a chunk). In chess, as well as in other domains, the chunking theory explains experts' remarkable memory by their ability to find more and larger chunks, and explains their selective search by the fact that chunks evoke potentially good actions. Some aspects of the theory were implemented in a computer program by Simon and Gilmartin (1973). Simulations with this program gave a good fit to the behavior of a strong amateur and led to the estimation that expertise requires the presence of a large number of chunks, approximately between 10,000 and 100,000.

A wealth of empirical data was gathered to test the chunking theory in various domains of expertise. In chess, five directions of research may be singled out as critical: importance of perception and pattern recognition, relative role of short-term and long-term memories, evidence for chunks, role of higher-level knowledge, and size of search.

Converging evidence indicates that perceptual, pattern-based cognition is critical in chess expertise. The most compelling data are that EYE MOVEMENTS during the first few seconds when examining a new chess position differ between experts and nonmasters (De Groot and Gobet 1996), and that masters still play at a high level in speed chess games where they have only five seconds per move on average, or in simultaneous games where their thinking time is reduced by the presence of several opponents (Gobet and Simon 1996).

Research on MEMORY has led to apparently contradictory conclusions. On the one hand, several experiments on the effect of interfering tasks (e.g., Charness 1976) have shown that two of Simon and Chase's (1973) assumptions—that storage into long-term memory is slow and that chunks are held in short-term memory—run into problems. This encouraged researchers such as Cooke et al. (1993) to emphasize the role of higher-level knowledge, already anticipated by De Groot (1946/1978). On the other hand, empirical evidence for chunks has also been mounting (e.g., Chi 1978; Gobet and Simon 1996; Saariluoma 1994).

Attempts to reconcile low-level and high-level types of encoding have recently been provided by the long-term WORKING MEMORY (LTWM) theory (Ericsson and Kintsch 1995) and by the template theory (Gobet and Simon 1996). LTWM proposes that experts build up both schema-based knowledge and domain-specific retrieval structures that rapidly encode the important elements of a problem. The template theory, based on the chunking theory and implemented as a computer program, proposes that chunks evolve into more complex data structures (templates), allowing some values to be encoded rapidly. Both theories also account for aspects of skilled perception and problem solving in chess.

Recent results indicate that stronger players search somewhat more broadly and deeply than weaker players (Charness 1981; Holding 1985), with an asymptote at high skill levels. In addition, the space searched remains small (thinking-aloud protocols indicate that grandmasters typically search no more than one hundred nodes in fifteen minutes). These results are compatible with a theory based on pattern recognition: chunks, which evoke moves or sequences of moves, make search more selective and allow better players to search more deeply.

While productive in its own terms, computer science research on chess (see GAME-PLAYING SYSTEMS) has had relatively little impact on the psychology of chess. The main advances have been the development of search techniques, which have culminated in the construction of DEEP BLUE, the first computer to have beaten a world champion in a match. More recently, chess has been a popular domain for testing MACHINE LEARNING techniques. Finally, attempts to use a production-system architecture (e.g., Wilkins 1980) have met with limited success in terms of the strength of the programs.

The key findings in chess research—selective search, pattern recognition, and memory for the domain material—have been shown to generalize to other domains of expertise. This augurs well for current interests in the field: integration of low- and high-level aspects of knowledge and unification of chess perception, memory, and problem-solving theories into a single theoretical framework.

Chinese Room Argument

The Chinese room argument is a refutation of strong artificial intelligence. "Strong AI" is defined as the view that an appropriately programmed digital computer with the right inputs and outputs, one that satisfies the Turing test, would necessarily have a mind. The idea of Strong AI is that the implemented program by itself is constitutive of having a mind. "Weak AI" is defined as the view that the computer plays the same role in studying cognition as it does in any other discipline. It is a useful device for simulating and therefore studying mental processes, but the programmed computer does not automatically guarantee the presence of mental states in the computer. Weak AI is not criticized by the Chinese room argument.

The argument proceeds by the following thought experiment. Imagine a native English speaker, let's say a man, who knows no Chinese locked in a room full of boxes of Chinese symbols (a data base) together with a book of instructions for manipulating the symbols (the program). Imagine that people outside the room send in other Chinese symbols which, unknown to the person in the room, are questions in Chinese (the input). And imagine that by following the instructions in the program the man in the room is able to pass out Chinese symbols that are correct answers to the questions (the output). The program enables the person in the room to pass the Turing test for understanding Chinese, but he does not understand a word of Chinese.

The point of the argument is this: if the man in the room does not understand Chinese on the basis of implementing the appropriate program for understanding Chinese, then neither does any other digital computer solely on that basis because no computer, qua computer, has anything the man does not have.

The larger structure of the argument can be stated as a derivation from three premises.

1. Implemented programs are by definition purely formal or syntactical. (An implemented program, as carried out by the man in the Chinese room, for example, is defined purely in terms of formal or syntactical symbol manipulations. The notion "same implemented program" specifies an equivalence class defined purely in terms of syntactical manipulations, independent of the physics of their implementation.)
2. Minds have mental or semantic contents. (For example, in order to think or understand a language you have to have more than just the syntax, you have to associate some meaning, some thought content, with the words or signs.)
3. Syntax is not by itself sufficient for, nor constitutive of, semantics. (The purely formal, syntactically defined symbol manipulations don't by themselves guarantee the presence of any thought content going along with them.)

Conclusion: Implemented programs are not constitutive of minds. Strong AI is false.

Why does the man in the Chinese room not understand Chinese even though he can pass the Turing test for understanding Chinese? The answer is that he has only the formal syntax of the program and not the actual mental content or semantic content that is associated with the words of a language when a speaker understands that language. You can see this by contrasting the man in the Chinese room with the same man answering questions put to him in his native English. In both cases he passes the Turing test, but from his point of view there is a big difference. He understands the English and not the Chinese. In the Chinese case he is acting as a digital computer. In the English case he is acting as a normal competent speaker of English. This shows that the Turing test fails to distinguish real mental capacities from simulations of those capacities. Simulation is not duplication, but the Turing test cannot detect the difference.

There have been a number of attempts to answer this argument, all of them, in the view of this author, unsuccessful. Perhaps the most common is the systems reply: "While the man in the Chinese room does not understand Chinese, he is not the whole system. He is but the central processing unit, a simple cog in the large mechanism that includes room, books, etc. It is the whole room, the whole system, that understands Chinese, not the man."

The answer to the systems reply is that the man has no way to get from the SYNTAX to the SEMANTICS, but neither

does the whole room. The whole room also has no way of attaching any thought content or mental content to the formal symbols. You can see this by imagining that the man internalizes the whole room. He memorizes the rulebook and the data base, he does all the calculations in his head, and he works outdoors. All the same, neither the man nor any subsystem in him has any way of attaching any meaning to the formal symbols.

The Chinese room has been widely misunderstood as attempting to show a lot of things it does not show.

1. The Chinese room does not show that "machines can't think." On the contrary, the brain is a machine and brains can think.
2. The Chinese room does not show that "computers can't think." On the contrary, something can be a computer and can think. If a computer is any machine capable of carrying out a computation, then all normal human beings are computers and they think. The Chinese room shows that COMPUTATION, as defined by Alan TURING and others as formal symbol manipulation, is not by itself constitutive of thinking.
3. The Chinese room does not show that only brains can think. We know that thinking is caused by neurobiological processes in the brain, but there is no logical obstacle to building a machine that could duplicate the causal powers of the brain to produce thought processes. The point, however, is that any such machine would have to be able to duplicate the specific causal powers of the brain to produce the biological process of thinking. The mere shuffling of formal symbols is not sufficient to guarantee these causal powers, as the Chinese room shows.

Church-Turing Thesis

Alonzo Church proposed at a meeting of the American Mathematical Society in April 1935, "that the notion of an effectively calculable function of positive integers should be identified with that of a recursive function." This proposal of identifying an informal notion, *effectively calculable function,* with a mathematically precise one, *recursive function,* has been called Church's thesis since Stephen Cole Kleene used that name in 1952. Alan TURING independently made a related proposal in 1936, Turing's thesis, suggesting the identification of effectively calculable functions with

functions whose values can be computed by a particular idealized computing device, a *Turing machine.* As the two mathematical notions are provably equivalent, the theses are "equivalent," and are jointly referred to as the Church-Turing thesis.

The reflective, partly philosophical and partly mathematical, work around and in support of the thesis concerns one of the fundamental notions of mathematical logic. Its proper understanding is crucial for making informed and reasoned judgments on the significance of limitative results—like GÖDEL'S THEOREMS or Church's theorem. The work is equally crucial for computer science, artificial intelligence, and cognitive psychology as it provides also for these subjects a basic theoretical notion. For example, the thesis is the cornerstone for Allen NEWELL's delimitation of the class of physical symbol systems, that is, universal machines with a particular architecture. Newell (1980) views this delimitation "as the most fundamental contribution of artificial intelligence and computer science to the joint enterprise of cognitive science." In a turn that had almost been taken by Turing (1948, 1950), Newell points to the basic role physical symbol systems have in the study of the human mind: "the hypothesis is that humans are instances of physical symbol systems, and, by virtue of this, mind enters into the physical universe . . . this hypothesis sets the terms on which we search for a scientific theory of mind." The restrictive "almost" in Turing's case is easily motivated: he viewed the precise mathematical notion as a crucial ingredient for the investigation of the mind (using computing machines to simulate aspects of the mind), but did not subscribe to a sweeping "mechanist" theory. It is precisely for an understanding of such—sometimes controversial—claims that the background for Church's and Turing's work has to be presented carefully. Detailed connections to investigations in cognitive science, programmatically indicated above, are at the heart of many contributions (cf. for example, COGNITIVE MODELING, COMPUTATIONAL LEARNING THEORY, and COMPUTATIONAL THEORY OF MIND).

The informal notion of an effectively calculable function, effective procedure, or algorithm had been used in nineteenth century mathematics and logic, when indicating that a class of problems is solvable in a "mechanical fashion" by following fixed elementary rules. Hilbert in 1904 already suggested taking formally presented theories as objects of mathematical study, and metamathematics has been pursued vigorously and systematically since the 1920s. In its pursuit concrete issues arose that required for their resolution a precise characterization of the class of effective procedures. Hilbert's *Entscheidungsproblem* (see Hilbert and Bernays 1939), the decision problem for first order logic, was one such issue. It was solved negatively—relative to the precise notion of recursiveness, respectively to Turing machine computability; though obtained independently by Church and Turing, this result is usually called Church's theorem. A second significant issue was the formulation of Gödel's Incompleteness theorems as applying to *all* formal theories (satisfying certain representability and derivability conditions). Gödel had established the theorems in his groundbreaking 1931 paper for specific formal systems like type theory of *Principia Mathematica* or Zermelo-Fraenkel set

theory. The general formulation required a convincing characterization of "formality" (see FORMAL SYSTEMS).

According to Kleene (1981) and Rosser (1984), Church proposed in late 1933 the identification of effective calculability with λ-definability. That proposal was not published at the time, but in 1934 Church mentioned it in conversation to Gödel, who judged it to be "thoroughly unsatisfactory." In his subsequent Princeton Lectures Gödel defined the concept of a (general) recursive function using an equational calculus, but he was not convinced that all effectively calculable functions would fall under it. The proof of the equivalence between λ-definability and recursiveness (found by Church and Kleene in early 1935) led to Church's first published formulation of the thesis as quoted above; it was reiterated in Church's 1936 paper. Turing also introduced in 1936 his notion of computability by machines. Post's 1936 paper contains a model of computation that is strikingly similar to Turing's, but he did not provide any analysis in support of the generality of his model. On the contrary, he suggested considering the identification of effective calculability with his concept as a working hypothesis that should be verified by investigating ever wider formulations and reducing them to his basic formulation. The classical papers of Gödel, Church, Turing, Post, and Kleene are all reprinted in Davis 1965, and good historical accounts can be found in Davis 1982, Gandy 1988, and Sieg 1994.

Church (1936) presented one central reason for the proposed identification, namely that other plausible explications of the informal notion lead to mathematical concepts weaker than or equivalent to recursiveness. Two paradigmatic explications, calculability of a function *via algorithms* and *in a logic,* were considered by Church. In either case, the steps taken in determining function values have to be effective; if the effectiveness of steps is taken to mean recursiveness, then the function can be *proved* to be recursive. This requirement on steps in Church's argument corresponds to one of the "recursiveness conditions" formulated by Hilbert and Bernays (1939). That condition is used in their characterization of functions that are evaluated according to rules in a deductive formalism: it requires the proof predicate for a deductive formalism to be primitive recursive. Hilbert and Bernays show that all such "reckonable" functions are recursive and actually can be evaluated in a very restricted number theoretic formalism. Thus, in any formalism that satisfies the recursiveness conditions and contains this minimal number theoretic system, one can compute exactly the recursive functions. Recursiveness or computability consequently has, as Gödel emphasized, an absoluteness property not shared by other metamathematical notions like provability or definability; the latter notions depend on the formalism considered.

All such indirect and ultimately unsatisfactory considerations were bypassed by Turing. He focused directly on the fact that *human mechanical* calculability on symbolic configurations was the intended notion. Analyzing the processes that underlie such calculations (by a *computer*), Turing was led to certain boundedness and locality conditions. To start with, he demanded the immediate recognizability of symbolic configurations so that basic computation steps need not be further subdivided. This demand and the evident limitation of the computor's sensory apparatus motivate the conditions. Turing also required that the computor proceed deterministically. The above conditions, somewhat hidden in Turing's 1936 paper, are here formulated following Sieg (1994); first the *boundedness conditions*:

(*B.1*) There is a fixed bound for the number of symbolic configurations a computor can immediately recognize.

(*B.2*) There is a fixed bound for the number of a computor's internal states that need to be taken into account.

Because the behavior of the computor is uniquely determined by the finitely many combinations of symbolic configurations and internal states, he can carry out only finitely many different operations. These operations are restricted by the *locality conditions:*

(*L.1*) Only elements of observed configurations can be changed.

(*L.2*) The computor can shift his attention from one symbolic configuration to another only if the second is within a bounded distance from the first.

Thus, on closer inspection, Turing's thesis is seen as the result of a two-part analysis. The first part yields the above conditions and Turing's *central thesis,* that any mechanical procedure can be carried out by a computor satisfying these conditions. The second part argues that any number theoretic function calculable by such a computor is computable by a Turing machine. Both Church and Gödel found Turing's analysis convincing; indeed, Church wrote (1937) that Turing's notion makes "the identification with effectiveness in the ordinary (not explicitly defined) sense evident immediately." From a strictly mathematical point, the analysis leaves out important steps, and the claim that is actually established is the more modest one that Turing machines operating on strings can be simulated by machines operating on single letters; a way of generalizing Turing's argument is presented in Sieg and Byrnes (1996).

Two final remarks are in order. First, all the arguments for the thesis take for granted that the effective procedures are being carried out by human beings. Gandy, by contrast, analyzed in his 1980 paper *machine* computability; that notion crucially involves parallelism. Gandy's mathematical model nevertheless computes only recursive functions. Second, the effective procedures are taken to be mechanical, not general cognitive ones—as claimed by Webb and many others. Also, Gödel was wrong when asserting in a brief note from 1972 that Turing intended to show in his 1936 paper that "mental procedures cannot go beyond mechanical procedures." Turing, quite explicitly, had no such intentions; even after having been engaged in the issues surrounding machine intelligence, he emphasized in his 1953 paper that the precise concepts (recursiveness, Turing computability) are to capture the mechanical processes that can be carried out by human beings.

Codeswitching

Codeswitching (CS) is commonly defined as the alternating use of two or more codes in the same conversational event. The term was first employed to refer to the coexistence of more than one structural system in the speech of one individual by JAKOBSON, Fant, and Halle (1952), who use "code" in the abstract information theoretical sense. In later writings, "code" has come to be synonymous with "language" or "speech variety." Recent research on CS falls within two distinct traditions: the syntactic, providing insights into the linguistic principles that underlie the form that CS takes; and the pragmatic that relates linguistic form to function in everyday discourse.

Contrary to common assumptions, CS is most frequent among proficient multilinguals. CS may be intersentential or intrasentential, the latter exemplified in the English-Spanish utterance, "Codeswitching among fluent bilinguals *ha sido la fuente de numerosas investigaciones*" ("has been the source of numerous studies"), and the English-Japanese, "That's how you say it *nihongo de*" ("in Japanese"). The status of such intrasentential CS had been much in dispute: some linguists view it as indicative of imperfect language acquisition or interference. However, later studies reveal that intrasentential CS requires advanced competence in the syntactic systems involved. Particularly significant is the fact that intrasentential CS demonstrates grammatical regularities, reflecting underlying, unconscious principles that speakers rely on in distinguishing between permissible and unacceptable switches.

The notion of grammatical equivalence has played an important role in the syntactic analysis of CS. One early formalization is Poplack's (1980) "Equivalence Constraint," according to which codes will be switched at points where the surface structures of the languages map onto each other. This premise has been challenged by studies on CS in typologically dissimilar languages (Romaine 1989). More recently, researchers have introduced CS data into the discussion of universal grammar, as advanced in Chomsky's principles and parameters framework (Chomsky 1981, 1986), maintaining that the relevant constraints on CS should exploit syntactic distinctions and relations already extant in the grammar. This line of inquiry was initiated by Woolford (1983), who developed a generative model of CS. Since that time, investigations into the properly syntactic principles underlying CS patterns have grown significantly in number and scope: Di Sciullo, Muysken, and Singh (1986) propose the Government Constraint, invoking this syntactic-theoretical hierarchical relation in disallowing CS between certain elements in the sentence; Belazi, Rubin, and Toribio (1994) propose the Functional Head Constraint, a specific application of the general X-bar theoretical process of feature checking that holds between a functional head and its complement (see X-BAR THEORY); and McSwan (1997) demonstrates the proper role of CS constraints within Chomsky's (1993) Minimalist Program. The validity of the aforementioned works relating CS to grammatical competence is further corroborated by investigations focusing on the development of CS ability in children acquiring multiple languages simultaneously. Especially noteworthy are writings by Jürgen Meisel (1990, 1994), whose findings on the syntactic regularities underlying early CS provide theoretical insights obscured in the investigation of monolingual acquisition. These developments make clear that the study of CS has reached a dimension of inquiry that can be informed by, and at once contribute to, the continued advancement of syntactic theory.

Pragmatic approaches to CS deal with the relation between structure and function in everyday speech exchanges, and cover a wider, often more loosely defined range of switching phenomena. Talk is treated as discourse level intentional action, where actors communicate in the context of social groupings, be they speech communities, social, ethnic, professional, or other interest groups (Hymes 1967; Clark 1996), acting in pursuit of context-specific communicative ends (Grice 1989). The verbal resources of such human populations are described in terms of inherently variable linguistic repertoires (Labov 1972) that, depending on local circumstances, consist of either grammatically distinct languages or dialects, or styles of the same language (Gumperz 1964; Hymes 1967). The use of one or another of the available coexisting codes (languages, dialects, styles, or speaking genres) serves a variety of rhetorical functions, for example to engage the listener, to shift footing, to mitigate or strengthen a speech act, to mark reported speech, and to repair or clarify. In this way, language switching can be said to be functionally equivalent to style shifting in monolingual speech (Zentella 1997).

A common claim is that syntactic and pragmatic approaches complement each other, one dealing with structure and the other with function. In one widely accepted view, for any one speech event, specific codes count as appropriate while others are marked (Myers-Scotton 1993). CS is said to convey information by virtue of the fact that the markedness directly reflects societal values and ideologies. For example, "standard" speech varieties are said to convey authority because they are associated with official situations. But linguistic anthropologists criticize this approach on the grounds that it rests on a dichotomized view of structure and function that cannot account for situated understanding (Bourdieu 1991; Hanks 1995; Auer 1998). It is assumed that the signaling processes underlying interpretation involve both symbolic (i.e., denotational) and indexical signs, which communicate via conventionalized associations between sign and context (Lucy 1993; Silverstein 1993). In discourse, indexical signs function metapragmatically to evoke the mostly unverbalized contextual presuppositions on which assessments of communicative intent rest. CS functions as one of a class of indexical signs or contextualization cues (Gumperz 1992, 1996). Along with others of the same class (e.g., PROSODY AND INTONATION and rhythm), such signs are not lexically meaningful; they work by constructing the ground for situated interpretation. By way of example, consider the following exchange. A third grader, D, is having difficulty with the adjectival use of "surprising" in a workbook question about a story discussed in class: What surprising discovery does Molly make? His partner G makes several unsuccessful attempts to explain, but D remains unconvinced until G finally comes up with the paraphrase: "A discovery *que era* ["that was"] surprising discovery." Whereupon D finally produces the expression "surprising discovery" on his own. The switch here counts as an indexical cue that reframes the issue, so as to relate the new expression to what D already knows (Gumperz, Cook-Gumperz, and Szymanski 1998).

When seen in the perspective of practice, then, CS does not convey propositional meaning nor does it directly convey societal attitudes: CS affects the situated interpretive process by enabling participants to project particular interpretations that are then confirmed or disconfirmed by what happens in subsequent speech. What distinguishes CS from other metapragmatic signs is that it is always highly ideologized, so that the sequential analysis of the interactive process by which interpretations are agreed upon can be a highly sensitive index, not solely of grammatical knowledge, but also of shared, culturally specific knowledge.

Cognitive Anthropology

Cognitive anthropology is a unified subfield of cultural anthropology whose principal aim is to understand and describe how people in societies conceive and experience their world (Casson 1994).

The definition of culture that guides research in cognitive anthropology holds that culture is an idealized cognitive system—a system of knowledge, beliefs, and values—that exists in the minds of members of society. Culture is the mental equipment that society members use in orienting, transacting, discussing, defining, categorizing, and interpreting actual social behavior in their society.

Among the many research topics in cognitive anthropology, three are central: cultural models, cultural universals, and CULTURAL CONSENSUS. The first of these will be the focus here.

Cultural models, often termed schemata, are abstractions that represent conceptual knowledge. They are cognitive structures in memory that represent stereotypical concepts. Schemata structure our knowledge of objects and situations, events and actions, and sequences of events and actions. General aspects of concepts are represented at higher levels in schematic structures, and variables associated with specific elements are represented at lower levels.

Items in the LEXICON—words—and grammatical categories and rules are associated in memory with cultural models. Linguistic forms and cognitive schemata "activate" each other: linguistic forms bring schemata to mind, and schemata are expressed in linguistic forms. Virtually all research strategies exploit this relationship between LANGUAGE AND THOUGHT in studying conceptual knowledge and cognitive systems.

The cognitive model underlying commercial events in our culture, a much discussed schema (e.g., Casson 1994), can serve as an example. The [Commercial Event] schema has the variables [buyer], [seller], [money], [goods], and [exchange] (brackets here distinguish conceptual units from words). In this way, [buyer] is a person who possesses [money], the medium of exchange, and [seller] is a person who possesses [goods], the merchandise for sale; [exchange] is an interaction in which [buyer] gives [money] and gets [goods], while [seller] gives [goods] and gets [money]. An event is understood as a commercial transaction when persons, objects, and

events in the environment are associated with appropriate schema variables.

A number of words—*buy, sell, pay, cost, worth, value, spend,* and *charge*—activate the [Commercial Event] schema. Each of these words selects particular aspects of the schema for highlighting or foregrounding, while leaving others in the background unexpressed. *Buy* focuses on the exchange from the buyer's perspective, and *sell* from the seller's perspective. *Cost* focuses on the money part of the money-goods relationship, and *value* and *worth* focus on the goods part of the relationship. *Pay* and *spend* focus on the buyer and the money part of the money-goods relationship, and *charge* focuses on the seller and the goods part of the money-goods relationship (Fillmore 1977).

Classification systems are complex cultural models structured by hierarchical embedding. Entities—objects, acts, and events—that are in fact different are grouped together in conceptual categories and regarded as equivalent. Semantic relationships among the categories define cognitive systems. Taxonomic hierarchies, or taxonomies, are classifications structured on the basis of the inclusion, or "kind of," relationship. Some categories included in the tree category, for example, are oak, pine, elm, spruce, poplar, walnut, and fir. Oak in turn includes white oak, post oak, pin oak, and many other kinds of oak.

Nontaxonomic classifications of various types are also hierarchically structured. Partonomic classifications are organized in terms of part-whole relationships. The family category, for example, has among its members (or parts) mother, son, and sister. Functional classifications are constructed on the basis of the instrumental, or "used for", relationship—a vehicle is any object that can be used for transportation, for example, car, bus, moped, or unicycle (Wierzbicka 1985).

Event scenarios are complex cultural models structured by horizontal linkages. Scenes in event schemata are linked in ordered sequences by way of causal relationships. The Yakan, a Philippine agricultural society living on Basilan Island in houses elevated on piles, have an event schemata specifying "how to enter a Yakan house." Social encounters are defined by the degree to which outsiders are able to negotiate penetration into households. An outsider progresses from "in the vicinity" of the house to "at" the house, from "below" the house to "on" the porch, from "outside" on the porch to "inside" the main room, and from the "foot zone" at the entrance door to the "head zone" opposite the door, which is the most private setting in the house (Frake 1975: 26–33).

Metaphorical cultural models are structured by conceptual METAPHORS. Abstract concepts that are not clearly delineated in experience, such as time, love, and ideas, are metaphorically structured, understood, and discussed in terms of other concepts that are more concrete in experience, such as money, travel, and foods (Lakoff and Johnson 1980). The metaphorical concept "embarrassment is exposure" is an example. The embarrassment schema is structured in terms of the exposure schema. The systematicity of the metaphor is reflected in everyday speech formulas, which are sources of insight into and evidence for the nature of the metaphor. Fixed-form expressions for "embarrass-

ment is exposure" are evident in these sentences: "You really exposed yourself," "He felt the weight of everyone's eyes," "I felt naked," "I was caught with my pants down," and "I wanted to crawl under a rock" (Holland and Kipnis 1994: 320–322).

Cultural universals are systems of conceptual knowledge that occur in all societies. In studying cognitive commonalities, anthropologists assume a "limited relativist," or universalist, position, adopting a relativist view in recognizing differences in cognitive and cultural systems and a universalist position in emphasizing fundamental concepts and uniformities in these systems (Lounsbury 1969: 10).

Comparative color category research, for instance, has shown that basic color categories are organized around best examples, and that these focal colors are the same across individuals and languages (Berlin and Kay 1969). It has also established that there are exactly eleven of these universal color categories—[black], [white], [red], [green], [yellow], [blue], [brown], [purple], [orange], [pink] and [gray]—that they are encoded in a strict evolutionary sequence, and that these universals are determined largely by neurophysiological processes in human color perception (Kay, Berlin, and Merrifield 1991; see COLOR CLASSIFICATION).

Cultural consensus is concerned with individual variability in cultural knowledge and how the diversity of individual conceptual systems are organized in cultural systems. Consensus theory examines the patterns of agreement among group members about particular domains of cultural knowledge in order to determine the organization of cognitive diversity. It establishes both a "correct" version of cultural knowledge and patterns of cognitive diversity (Romney, Weller, and Batchelder 1986: 316).

The Aguaruna Jivaro, a forest tribe in northern Peru, for example, derive the majority of their sustenance from manioc plants. A study of Aguaruna manioc gardens discovered that, although individual Aguaruna vary widely in their naming of manioc plants, they nonetheless maintain a consensus model of manioc classification. Patterns of agreement reveal that individuals learn a single set of manioc categories with varying degrees of success: some individuals have greater cultural competence in manioc identification than others (Boster 1985: 185).

Cognitive Archaeology

The term *cognitive archaeology* was introduced during the early 1980s to refer to studies of past societies in which explicit attention is paid to processes of human thought and symbolic behavior. As the archaeological record only consists of the material remains of past activities—artifacts, bones, pits, hearths, walls, buildings—there is no direct information about the types of belief systems or thought processes that existed within past minds. These must be inferred from those material remains. Cognitive archaeology attempts to do this, believing that appropriate interpretations of past material culture, the behavioral processes that created it, and long-term patterns of culture change evident from the archaeological record, such as the origin of agriculture and the development of state society, requires that those belief systems and processes of thought be reconstructed.

There is a diversity of approaches and studies that fall under the poorly defined umbrella of cognitive archaeology (see Renfrew et al. 1993). These can be grouped into three broad categories that we can term postprocessual archaeology, cognitive-processual archaeology, and evolutionary-cognitive archaeology. While these three categories differ in significant ways with regard to both form and content, they also share some overriding features. The first is that an understanding of human behavior and society, whether in the distant past or the present, requires explicit reference to human cognition—although there is limited agreement on quite what nature that reference should take. Second, that the study of past or present cognition cannot be divorced from the study of society in general—individuals are intimately woven together in shared frames of thought (Hodder, in Renfrew et al. 1993). Indeed, the study of past or present minds is hopelessly flawed unless it is integrated into a study of society, economy, technology, and environment. Third, that material culture is critical not only as an expression of human cognition, but also as a means to attain it.

Postprocessual studies, which began in the late 1970s, not only laid emphasis on the symbolic aspects of human behavior but also adopted a postmodernist agenda in which processes of hypothesis testing as a means of securing knowledge were replaced by hermeneutic interpretation (e.g., Hodder 1982, 1986). As such, these studies began as a reaction against what was perceived, largely correctly, as a crude functionalism that had come to dominate archaeological theory and attempted to provide a new academic agenda for the discipline, epitomized in a volume by Mike Shanks and Chris Tilley (1987) entitled *Re-constructing Archaeology.* While the critique of functionalism was warmly received and has had a long-lasting effect, it was soon recognized that the epistemology of relativism, the lack of explicit methodology, and the refusal to provide criteria to judge between competing interpretations constituted an appalling agenda for the discipline. Consequently, while such work was critical for the emergence of cognitive

archaeology, it now plays only a marginal role within the discipline.

A contrasting type of cognitive archaeology has attempted to provide an equal emphasis on symbolic thought and ideology, but sought to do this within a scientific frame of reference in which claims about past beliefs and ways of thought can be objectively evaluated. As such, this archaeology has been characterized as a "cognitive-processual" archaeology by Colin Renfrew (Renfrew and Bahn 1991). This covers an extremely broad range of studies in which attention has been paid to ideology, religious thought, and cosmology (e.g., Flannery and Marcus 1983; Renfrew 1985; Renfrew and Zubrow 1993). Such studies argue that these aspects of human behavior and thought are as amenable to study as are the traditional subjects of archaeology, such as technology and subsistence, which leave more direct archaeological traces. Of course, when written records are available to supplement the archaeological evidence, reconstruction of past beliefs can be substantially developed (Flannery and Marcus, in Renfrew et al. 1993). One branch of this cognitive-processual archaeology has attempted to focus on processes of human DECISION-MAKING, and argued that explicit reference to individuals is required for adequate explanations of long-term cultural change. Perles (1992), for instance, has attempted to infer the cognitive processes of prehistoric flint knappers, while Mithen (1990) used computer simulations of individual decision making to examine the hunting behavior of prehistoric foragers. Another important feature has been an explicit concern with the process of cultural transmission. In such studies attempts have been made to understand how the processes of social learning are influenced by different forms of social organization (e.g., Mithen 1994; Shennan 1996). More generally, it is argued that the long-term patterns of culture change in the archaeological record, such as the introduction, spread, and then demise of particular artifact types (e.g., forms of axe head) can only be explained by understanding both the conscious and unconscious processes of social learning (Shennan 1989, 1991).

A third category of studies in cognitive archaeology, although one that could be subsumed within cognitive-processual archaeology, consists of those that are concerned with the EVOLUTION of the human mind and that can be referred to as an evolutionary-cognitive archaeology. As the archaeological record begins 2.5 million years ago with the first stone tools, it covers the period of brain enlargement and the evolution of modern forms of language and intelligence. While the fossil record can provide data about brain size, anatomical adaptations for speech, and brain morphology (through the study of endocasts), the archaeological record is an essential means to reconstruct the past thought and behavior of our ancestors, and the selective pressures for cognitive evolution. Consequently, studies of human fossils and artifacts need to be pursued in a very integrated fashion if we are to reconstruct the evolution of the human mind.

The last decade has seen very substantial developments in this area, although significant contributions had already been made by Wynn (1979, 1981). He attempted to infer the levels of intelligence of human ancestors from the form of early prehistoric stone tools by adopting a recapitualist position and using the developmental stages proposed by PIAGET as models for stages of cognitive evolution. While there were other important attempts at inferring the mental characteristics of our extinct ancestors and relatives from their material culture, such as by Glynn Isaac (1986) and John Gowlett (1984), it was in fact a psychologist, Merlin Donald (1991), who was the first to propose a theory for cognitive evolution that made significant use of archaeological data in his book *Origins of the Modern Mind.*

His scenario, however, has been challenged by Mithen (1996a), who attempted to integrate current thought in EVOLUTIONARY PSYCHOLOGY with that in cognitive archaeology. As such, he argues that premodern humans (e.g., H. erectus, Neanderthals) had a domain-specific mentality and that this accounts for the particular character of their archaeological record. In his model, the origin of art, religious thought, and scientific thinking—all of which emerged rather dramatically about 30,000 years ago (70,000 years after anatomically modern humans appear in the fossil record)—arose from a new-found ability to integrate ways of thinking and types of knowledge that had been "trapped" in specific cognitive domains. It is evident that the remarkable development of culture in the past 30,000 years, and especially its cumulative character of knowledge (something that had been absent from all previous human cultures) is partly attributable to the disembodiment of mind into material culture. For example, the first art objects included those that extended memory from its biological basis in the brain to a material basis in terms of symbolic codes engraved on pieces of bone or in paintings on cave walls (e.g., Mithen 1988; Marshack 1991; D'Errico 1995). Depictions of imaginary beings are not simply reflections of mental representations, but are critical in allowing those representations to persist and to be transmitted to other individuals, perhaps across several generations (Mithen 1996b). In this regard, material culture plays an active role in formulating thought and transmitting ideas, and is not simply a passive reflection of these. Whether or not this particular scenario from evolutionary-cognitive archaeology has any merit remains to be seen. But it is one example of the major development of cognitive archaeology—in all of its guises—that has occurred during the last two decades. One must anticipate substantial future developments, especially if greater interdisciplinary research between archaeologists, biological anthropologists, and cognitive scientists can be achieved.

Cognitive Architecture

Cognitive architecture refers to the design and organization of the mind. Theories of cognitive architecture strive to provide an exhaustive survey of cognitive systems, a description of the functions and capacities of each, and a blueprint to integrate the systems. Such theories are designed around a small set of principles of operation. Theories of cognitive architecture can be contrasted with other kinds of cognitive theories in providing a set of principles for constructing cognitive models, rather than a set of hypotheses to be empirically tested.

Theories of cognitive architecture can be roughly divided according to two legacies: those motivated by the digital computer and those based on an associative architecture. The currency of the first kind of architecture is information in the form of symbols; the currency of the second kind is activation that flows through a network of associative links. The most common digital computer architecture is called the VON NEUMANN architecture in recognition of the contributions of the mathematician John von Neumann to its development. The key idea, the stored-program technique, allows program and data to be stored together. The von Neumann architecture consists of a central processing unit, a memory unit, and input and output units. Information is input, stored, and transformed algorithmically to derive an output. The critical role played by this framework in the development of modern technology helped make the COMPUTATIONAL THEORY OF MIND seem viable. The framework has spawned three classes of theories of cognitive architecture, each encompassing several generations. The three classes are not mutually exclusive; they should be understood as taking different perspectives on cognitive organization that result in different performance models.

The original architecture of this type was a PRODUCTION SYSTEM. In this view, the mind consists of a working memory, a large set of production rules, and a set of precedence rules determining the order of firing of production rules. A production rule is a condition-action pair specifying actions to perform if certain conditions are met. The first general theory of this type was proposed by NEWELL, Simon, and Shaw (1958) and was called the General Problem Solver (GPS). The idea was that a production system incorporating a few simple heuristics could solve difficult problems in the same way that humans did. A descendant of this approach, SOAR (Newell 1990), elaborates the production system architecture by adding mechanisms for making decisions, for recursive application of operators to a hierarchy of goals and subgoals, and for learning of productions. The architecture has been applied to help understand a range of human performance from simple stimulus-response tasks, to typing, syllogistic reasoning, and more.

A second class of von Neumann-inspired cognitive architecture is the information processing theory. Unlike production systems, which posit a particular language of symbolic transformation, information processing theories posit a sequence of processing stages from input through encoding, memory storage and retrieval, to output. All such theories assume the critical components of a von Neumann architecture: a central executive to control the flow of information, one or more memories to retain information, sensory devices to input information, and an output device. The critical issues for such theories concern the nature and time course of processing at each stage. An early example of such a theory is Broadbent's (1958) model of ATTENTION,

the imprint of which can be found on the "modal" information processing theory, whose central distinction is between short-term and long-term memory (e.g., Atkinson and Shiffrin 1968), and on later models of WORKING MEMORY.

The digital computer also inspired a class of cognitive architecture that emphasizes veridical representation of the structure of human knowledge. The computer model distinguishes program from data, and so the computer modeler has the option of putting most of the structure to be represented in the computer program or putting it in the data that the program operates on. Representational models do the latter; they use fairly sophisticated data structures to model organized knowledge. Theories of this type posit two memory stores: a working memory and a memory for structured data. Various kinds of structured data formats have been proposed, including frames (Minsky 1975), SCHEMATA (Rumelhart and Ortony 1977), and scripts (Schank and Abelson 1977), each specializing in the representation of different aspects of the world (objects, events, and action sequences, respectively). What the formats have in common is that they (i) represent "default" relations that normally hold, though not always; (ii) have variables, so that they can represent relations between abstract classes and not merely individuals; (iii) can embed one another (hierarchical organization); and (iv) are able to represent the world at multiple levels of abstraction.

The second type of cognitive architecture is associative. In contrast with models of the von Neumann type, which assume that processing involves serial, rule-governed operations on symbolic representations, associative models assume that processing is done by a large number of parallel operators and conforms to principles of similarity and contiguity. For example, an associative model of memory explains how remembering part of an event can cue retrieval of the rest of the event by claiming that an association between the two parts was constructed when the event was first encoded. Activation from the representation of the first part of the event flows to the representation of the second part through an associative connection. More generally, the first part of the event cues associative retrieval of the entire event (and thus the second part) by virtue of being similar to the entire event.

Associative models have a long history stretching back to Aristotle, who construed MEMORY and some reasoning processes in terms of associations between elementary sense images. More recent associative models are more promiscuous: different models assume associations between different entities, concepts themselves, or some more primitive set of elements out of which concepts are assumed to be constructed.

Such modern conceptions of associative cognitive architecture have two antecedents located in the history of cognitive science and two more immediate precursors. The first historical source is the foundational work on associative computation begun by MCCULLOCH and PITTS (1943) demonstrating the enormous computational power of populations of neurons and the ability of such systems to learn using simple algorithms. The second source is the application of associative models based on neurophysiology to psychology. An influential synthesis of these efforts was Hebb's

(1949) book, *The Organization of Behavior.* HEBB attempted to account for psychological phenomena using a theory of neural connections (cell assemblies) that could be neurophysiologically motivated, in part by appeal to large-scale cortical organization. Thus, brain architecture became a source of inspiration for cognitive architecture. Hebb's conception was especially successful as an account of perceptual learning. The two remaining antecedents involve technical achievements that led to a renewed focus on associative models in the 1980s. Earlier efforts to build associative devices resulted in machines that were severely limited in the kinds of distinctions they were able to make (they could only distinguish linearly separable patterns). This limitation was overcome by the introduction of a learning algorithm called "backpropagation of error" (Rumelhart, Hinton, and Williams 1986). The second critical technical achievement was a set of proofs, due in large part to Hopfield (e.g., 1982), that provided new ways of interpreting associative computation and brought new tools to bear on the study of associative networks. These proofs demonstrated that certain kinds of associative networks could be interpreted as optimizing mathematical functions. This insight gave theorists a tool to translate a problem that a person might face into an associative network. This greatly simplified the process of constructing associative models of cognitive tasks.

These achievements inspired renewed interest in associative architectures. In 1986, Rumelhart and McClelland published a pair of books on parallel, distributed processing that described a set of models of different cognitive systems (e.g., memory, perception, and language) based on common associative principles. The work lent credence to the claim that an integrated associative architecture could be developed.

Although a broad division between von Neumann and associative architectures helps to organize the various conceptions of mental organization that have been offered, it does an injustice to hybrid architectural proposals; that is, proposals that include von Neumann-style as well as associative components. Such alliances of processing systems seem necessary on both theoretical and empirical grounds (Sloman 1996). Only von Neumann components seem capable of manipulating variables in a way that matches human competence (*see* BINDING PROBLEM), yet associative components seem better able to capture the context-specificity of human judgment and performance as well as people's ability to deal with and integrate many pieces of information simultaneously. One important hybrid theory is ACT* (Anderson 1983). ACT* posits three memories: a production, a declarative, and a working memory, as well as processes that interrelate them. The architecture includes both a production system and an associative network. In this sense, ACT* is an early attempt to build an architecture that takes advantage of both von Neumann and associative principles. But integrating these very different attitudes in a principled and productive way is an ongoing challenge.

Cognitive Artifacts

Cognitive artifacts are physical objects made by humans for the purpose of aiding, enhancing, or improving cognition. Examples of cognitive artifacts include a string tied around the finger as a reminder, a calendar, a shopping list, and a computer. In the modern world, many cognitive artifacts rely on LITERACY and numeracy skills. Lists of various kinds support not only MEMORY, but also reasoning about classification and comparison. Goody (1977) argues that the advent of WRITING SYSTEMS fundamentally transformed human cognition. Nonlinguistic inscriptions such as maps, charts, graphs, and tables enable the superimposition of representations of otherwise incommensurable items (Latour 1986). Tabular formats for data are at least three thousand years old (Ifrah 1987), and support reasoning about the coordination of differing category structures, types, and quantities of goods, for example.

People often engage in activities characterized by the incremental creation and use of cognitive artifacts. Doing place-value arithmetic amounts to successively producing artifact structure, examining it, and then producing more structure (Rumelhart et al. 1986). Everyday tasks such as cooking involve a continuous process of creating and using cognitive artifacts. Kirsh (1995) refers to the systematic creation and use of spatial structure in the placement of cooking implements and ingredients as the *intelligent use of space.* Here, the arrangement of artifacts is itself a cognitive artifact.

Norman (1993) relaxes the definition of cognitive artifacts to include mental as well as material elements. Rules of thumb, proverbs, mnemonics, and memorized procedures are clearly artifactual and play a similar role to objects in some cognitive processes (Shore 1996). Of course, material cognitive artifacts are only useful when they are brought into coordination with a corresponding mental element—the knowledge of how to use them.

The behaviors of other actors in a social setting can serve as cognitive artifacts. The work of VYGOTSKY (Vygotsky 1978, 1986; Wertsch 1985) on activity theory emphasizes the role of others in creating a "zone of proximal development" in which the learning child is capable of cognitive activities that it could not do alone. Activity theory takes words and concepts to be powerful psychological tools that organize thought and make higher level cognitive processes possible. In this view, language becomes the ultimate cognitive artifact system, and cognitive artifacts are absolutely fundamental to human consciousness and what it means to be human.

One of the principal findings of studies of SITUATED COGNITION AND LEARNING is that people make opportunistic use of structure. The *method of loci* in which an orator who must remember a speech associates elements of the speech with architectural features of the place where the speech is delivered is a well-known example. Lave, Murtaugh, and de la Rocha (1984) examined the way that shoppers made use of the structure of supermarkets. The layout of the supermarket itself with the orderly arrangement of items on the shelf is the ultimate icon of the shopping list. Regular shoppers develop routine trajectories through this space, thus creating a sequence of reminders of items to buy. Scribner (1984) documented the ways that dairy workers take advantage of the layouts of standard diary product cases in filling orders. Beach (1988) went to bartender's school and learned how to use the shapes of drink glasses and their placement on the bar to encode the drinks in a multiple drink order. Hutchins (1995b) showed how airline pilots take advantage of an incidental feature of the airspeed indicator to identify +/–5 knot deviations from target speeds

by looking at the display in a particular way rather than by calculating. Frake (1985) showed how medieval sailors in northern Europe used the structure of the compass card to "see" the times of high and low tides at major ports. In each of these cases people use designed objects in ways that were not intended by the artifact's designers.

Sometimes even structures that are not made by humans play the same role as cognitive artifacts. Micronesian navigators can see the night sky as a 32-point compass that is used to express courses between islands (Gladwin 1970; Lewis 1972), and forms the foundation for a complex layered mental image that represents distance/rate/time problems in analog form (Hutchins and Hinton 1984; Hutchins 1995a). The Micronesian navigator uses the night sky in the same way that many manufactured navigational artifacts are used.

There is a continuum from the case in which a cognitive artifact is used as designed, to cases of cognitive uses of artifacts that were made for other purposes, to completely opportunistic uses of natural structure.

If one focuses on the products of cognitive activity, cognitive artifacts seem to amplify human abilities. A calculator seems to amplify my ability to do arithmetic, writing down something I want to remember seems to amplify my memory. Cole and Griffin (1980) point out that this is not quite correct. When I remember something by writing it down and reading it later, my memory has not been amplified. Rather, I am using a different set of functional skills to do the memory task. Cognitive artifacts are involved in a process of organizing functional skills into *functional systems.*

Computers are an especially interesting class of cognitive artifact. Their effects on cognition are in part produced via the reorganization of human cognitive functions, as is true of all other cognitive artifacts (Pea 1985). What sets computers apart is that they may also mimic certain aspects of human cognitive function. The complexity and power of the combination of these effects makes the study of HUMAN-COMPUTER INTERACTION both challenging and important.

While cognitive artifacts do not directly amplify or change cognitive abilities, there are side effects of artifact use. Functional skills that are frequently invoked in interaction with artifacts will tend to become highly developed, and those that are displaced by artifact use may atrophy.

Any particular cognitive artifact typically supports some tasks better than others. Some artifacts are tuned to very narrow contexts of use while others are quite general. The ones that are easy are easy because one can use very simple cognitive and perceptual routines in interaction with the technology in order to do the job (Norman 1987, 1993; Hutchins 1995a; Zhang 1992).

Cognitive artifacts are always embedded in larger sociocultural systems that organize the practices in which they are used. The utility of a cognitive artifact depends on other processes that create the conditions and exploit the consequences of its use. In culturally elaborated activities, partial solutions to frequently encountered problems are often crystallized in practices, in knowledge, in material artifacts, and in social arrangements.

Since artifacts require knowledge for use, the widespread presence of a technology affects what people know. Most members of Western society know how to read, use a telephone, drive a car, and so on. Conversely, the distribution of knowledge in a community constrains technology. If everyone already knows how to do something with a particular technology, an attempt to change or replace that technology may meet resistance because learning is expensive.

There is no widespread consensus on how to bound the category "cognitive artifacts." The prototypical cases seem clear, but the category is surrounded by gray areas consisting of mental and social artifacts, physical patterns that are not objects, and opportunistic practices. The cognitive artifact concept points not so much to a category of objects, as to a category of processes that produce cognitive effects by bringing functional skills into coordination with various kinds of structure.

Cognitive Development

Students of cognitive development ask how our young are able to acquire and use knowledge about the physical, social, cultural, and mental worlds. Questions of special interest include: what is known when; whether what is known facilitates or serves as a barrier to the accurate interpretation and learning of new knowledge; how knowledge development serves and interacts with problem-solving strategies; and the relationship between initial knowledge levels and ones achieved for everyday as opposed to expert use.

Several classes of theories share the premise that infants lack abstract representational abilities and therefore CONCEPTS. The infant mind to an associationist is a passive "blank slate"—upon which a wash of sensations emanating from the world is recorded as a result of the associative capacity. Stage theorists need not share the no innate knowledge assumption. Interestingly, however, PIAGET, Bruner, and VYGOTSKY do, although to them infants are able to participate actively in the construction of their own cognitive development. For Piaget, neonates spontaneously practice their reflexes, the effect being the differentiation of inborn reflexes into different sensory-motor schemes. Active use of these yields integrated action schemes, and thus novel ways to act on the environment (Piaget 1970). The information processing approach emphasizes the development of general processes like ATTENTION, short- and long-term memory, organization, and problem solving. The focus is on how learning and/or maturation overcome limits on information processing demands (Anderson 1995) and the development of successful PROBLEM SOLVING (Siegler 1997). Much attention is paid to how knowledge systems are acquired and circumvent these real-time limits on various processes. When it comes to the matter of what the newborn knows, the answer almost always is "nothing" (but see Mandler 1997). Thus, many cognitive development models are firmly grounded on associationist assumptions.

Reports of early conceptual competencies have encouraged the development of models that grant infants some knowledge to begin with. These include symbolic connectionist accounts that share much with associationist theories and modern instantiations of rationalism. In the latter case, humans are endowed with some innate ideas, modules, and/or domain-specific structures of mind. Possible candidates for innate endowments include implicit concepts about natural number, objects, and kinds of energy sources of animate and inanimate objects (Gelman and Williams 1997; Keil 1995; Pinker 1994). These kinds of models are learning models, ones built on the assumption that there is more than one learning mechanism. The idea is that there is a small set of domain-specific, computational learning devices—each with a unique structure and information processing system—that support and facilitate learning about the concepts of their domains. Gelman and Williams (1998) refer to these as skeletal-like, ready to assimilate and accommodate domain-relevant inputs, but very sketchy at first. Knowledge is not sitting in the head, ready to spring forth the moment the environment offers one bit of relevant data. But structures, no matter how nascent, function to support movement along a domain-relevant learning path by encouraging attention to and fostering storage of domain-relevant data.

For most associationist, stage, and information processing theorists, it takes a long time for newcomers to the world to develop concepts, because infants must first build up large memories of bits of sensory and response experiences; associate, connect, or integrate these in ways that represent things or events; associate, connect, or integrate the latter, and so on. The young mind's progress toward conceptual understandings is slow, from reliance on the sensory, on to use of perceptions, and eventually to developing the wherewithal to form abstract concepts and engage in intelligent problem solving. This common commitment to the traditional view that concepts develop from the concrete or perceptual to the abstract plays out differently depending on whether one is a stage theorist or not. For a non–stage theorist, the march to the abstract level of knowing is linear and cumulative. For a stage theorist, the progress usually involves movement through qualitatively different mental structures that can assimilate and use inputs in new ways. Many of the results of classification tasks used by Bruner, Piaget, and Vygotsky encourage the concrete-to-abstract characterization of cognitive development. Repeatedly, it is found that two- to six-year-olds do not use classification criteria in a consistent fashion. For example, when asked to put together objects that go together, one preschool child might make a train, another a long line of alternating colors, while another might focus on appearance as opposed to reality, and so on.

It is important to recognize that all theories of cognitive development grant infants some innate abilities. The abilities to receive punctate sensations of light, sound, or pressure, and so on, and form associations according to the laws of association (frequency and proximity) are foundational for associationists. Association between sensations and responses is the groundwork for knowledge of the world at a sensory and motor level. These in turn support knowledge acquisition at the perceptual level. Experiences at the perceptual level provide the opportunity for cross-modal associative learning

and the eventual induction of abstract concepts that are not grounded on particular perceptual information. Although there are important differences in the foundational assumptions of the association and traditional stage accounts, their characterizations of an infant's initial world are more similar than not. For example, associations are not Piaget's fundamental units of cognition; sensori-motor schemes are. But to him, an infant's initial knowledge is limited to innate reflexes and is combined with an inclination to actively use and adapt these as a result of repeated interactions with objects. This eventually leads to the development of intercoordinated schemes and movement to action-based representations that take the infant from an out-of-sight, out-of-mind stage to internalized representations, the mental building blocks of a world of three-dimensional objects in a three-dimensional space.

Piaget's basic assumptions about the nature of the data that feed early development apply to other stage theorists. In general, what initially count as relevant inputs are simple motoric, sensory, or perceptual features. His emphasis is more on children's active participation in their own cognitive development. Bruner and Vygotsky concentrate more on how others help the young child develop coherent knowledge about their social, cultural, and historical environments. Still, all concur that initial "concepts" are sensori-motor or perceptual in form and content; these are variously labeled as graphic collections, preconcepts, complexes, pseudoconcepts, and chain concepts. Thus, whether the account of the origins of knowledge is rooted in an associationist, information processing, or stage theory, the assumption is that first-order sense data, for example sensations of colored light, sound, pressure, etc., serve as the foundation upon which knowledge is developed. Principles or structures that organize the representations of concepts are a considerably advanced accomplishment, taking hold somewhere between five and seven years of age.

Those who embrace more rationalist accounts assume that the mind starts out with much more than the ability to sense and form associations or schemas about sensations and reflexes. Beginning learners have some skeletal structures with which to actively engage the environment; domain-relevant inputs are those that can be brought together and mapped to the existing mental structure. Put differently, skeletal mental structures are attuned to information in the environment at the level of structural universals, not the level of surface characteristics. Thus the nature of relevant data, even for beginning learners, can be rather abstract. It need not be bits of sensation or concrete. Young learners can have abstract concepts.

We now know that preschool-age children appeal to invisible entities to explain contamination, invoke internal or invisible causal forces to explain why objects move and stop, reason about the contrast between the insides and outsides of unfamiliar animals, choose strategies that are remarkably well suited to arithmetic problems, pretend that the same empty cup is first a full cup and then an empty cup, etc. Five-month-old infants respond in ways consistent with the beliefs that one solid object cannot pass through another solid object; an inanimate object cannot propel itself; and that mechanical and biomechanical motion are very different (see Wellman and S. Gelman 1997 for details and more examples).

With development, core knowledge systems can become extremely rich, whether or not formal schooling is available—so much so that the existing knowledge structure behaves like a barrier for learning new structures in the domain (Gelman 1993). For example, the intuitive belief that an inanimate object continues to move in a circle because it currently has such a trajectory is inconsistent with the theory of Newtonian mechanics. Yet the belief is held by many college students who have had physics courses. Similarly, our well-developed NAIVE MATHEMAT-ICS, sometimes called "street mathematics" (Nunes, Schliemann, and Carraher 1993), makes it hard to learn school mathematics. In these cases, school lessons do not suffice to foster new understandings and kinds of expertise. Be they nativist or nonnativist in spirit, efforts to account for the course of cognitive development will have to incorporate this fact about the effect, or lack of effect, of experience on learning and concept acquisition

Cognitive Dissonance

See DISSONANCE

Cognitive Ergonomics

Cognitive ergonomics is the study of cognition in the workplace with a view to design technologies, organizations, and learning environments. Cognitive ergonomics analyzes work in terms of cognitive representations and processes, and contributes to designing workplaces that elicit and support reliable, effective, and satisfactory cognitive processing. Cognitive ergonomics overlaps with related disciplines such as human factors, applied psychology, organizational studies, and HUMAN-COMPUTER INTERACTION.

The emergence of cognitive ergonomics as a unitary field of research and practice coincides with the rapid transformation of the workplace following the growth of complex technological environments and the widespread introduction of information technologies to automate work processes. The computerized workplace has generalized flexible and self-directed forms of work organization (Zuboff 1988; Winograd and Flores 1986). These transformations have raised a set of psychological, social, and technological issues: the development of competencies to master work processes through the new technology, the cognitive shift involved in the transition from controlling a process to monitoring automated systems (Bainbridge 1987; Sarter and Woods 1992), the acquisition of skills to use interactive tools, the transfer of knowledge and skills from the old to the new workplace. Technological innovation has also opened the possibility of improving human performance by aiding, expanding, and reorganizing human cognitive activities through the design of advanced tools, a challenge addressed by cognitive engineering and usability (Hollnagel and Woods 1983; Norman and Draper 1986; Nielsen 1993).

Cognitive ergonomics approaches these issues, on the one hand, by developing models of the knowledge structures and information-processing mechanisms that explain how individuals carry out their work tasks (doing PLAN-NING, PROBLEM SOLVING, DECISION-MAKING, using tools, and coordinating with other people); on the other, by developing methods for redefining the engineering process of workplace design. The two activities are tightly coupled because the integration of user needs and requirements in the design of systems and organizations is seen as the only possible answer for successful transformation of the workplace. User-centered design grounds the design process on general and domain-specific models of cognitive activity and is characterized by extensive investigation of user's goals, tasks, job characteristics, and by continual iterations of design and user testing of solutions. User-centered design encompasses a variety of methods to collect and analyze data about tasks and context of use, and of techniques to test and measure interactions between users and computer systems (Helander 1988).

General models of cognitive work-oriented activity have been developed to account for the complexity of human behaviors produced in work situations (Rasmussen 1986), to explain erroneous action (Norman 1981; Reason 1990), and to conceptualize human-computer interaction (Card, Moran, and Newell 1983; Norman and Draper 1986). Rasmussen's model of work activity distinguishes between automatic, automated, and deliberate behaviors, controlled respectively by skills, rules, and knowledge. Whereas skills and rules are activated in familiar situations, the elaboration of explicit understanding of the current situation and of a deliberate plan for action is necessary to deal with unfamiliar or unexpected situations. This framework has spurred several specific models of process control activities in, among others, fighter aircraft (Amalberti 1996), nuclear power plants (Woods, O'Brien, and Hanes 1987), steel plants (Hoc 1996), and surgical units (Cook and Woods 1994; De Keyser and Nyssen 1993).

The distinction between levels of cognitive control has also been the key to apprehend the reliability of the human component of the workplace. Reason's model (1990) of human error identifies slips and lapses caused respectively by ATTENTION and WORKING MEMORY failures at the skill-level of control; rule-based and knowledge-based mistakes caused by the selection/application of the wrong rule or by inadequate knowledge; and violations that account for intentional breaches of operational procedures.

Norman (1986) formulates a general model of human-computer interaction in terms of a cycle of execution and evaluation. The user translates goals into intentions and into action sequences compatible with physical variables, and evaluates the system state with respect to initial goals after perceiving and interpreting the system state. Bridging what Hutchins, Hollan, and Norman (1986) have named the *Gulf of Execution* and the *Gulf of Evaluation*, interaction can be facilitated by providing input and output functions for the user interface that match more closely the psychological needs of the user, building in AFFORDANCES that constrain the interpretation of the system state, and by providing coherent and clear design models that support users in building mental models of the system.

The bulk of the research in cognitive ergonomics has been carried out on domain-specific work processes. Viewed from an organizational perspective, work processes can be decomposed into sets of tasks, of which explicit

descriptions exist in the form of procedures. Task analysis methods combine operational procedure analysis and interviews with experts to describe the cognitive requirements, i.e., demands on MEMORY, attention, understanding, and coordination for realizing each step of the task (Diaper 1989). Leplat (1981) points out the gap that exists between normative accounts of work and actual practice, and argues for activity analysis of work to be carried out in the field, using techniques derived from ethnography. Viewed from an activity perspective, work processes involve problem setting, problem solving, troubleshooting, and collaborating. Roth and Woods (1988) see the work process as problem solving and combine a conceptual analysis of what is required to solve the problem, in terms of EXPERTISE, CAUSAL REASONING, DEDUCTIVE REASONING, decision making, and resource management, with empirical observation of how agents solve the problem in practice. Their study provides options for better meeting the cognitive demands of the task and gives rise to proposals for the design and development of new information displays that enhance agents' ability to anticipate process behavior.

A new perspective on work is emerging from Hutchins's research on distributed cognition. Hutchins (1995) takes the work process as problem solving that is dealt with by the workplace as a whole: a culturally organized setting, comprising individuals, organizational roles, procedures, tools, and practices. The cognitive processes necessary to carry out tasks are distributed between cognitive agents and COGNITIVE ARTIFACTS. Hutchins (1991) shows, for instance, that aircraft are flown by a cockpit system that includes pilots, procedures, manuals, and instruments. This view, while keeping within the information processing paradigm of cognition, recognizes fully the social and cultural dimensions of the workplace, counteracting a tendency to overestimate the cognitive processes at the expense of environmental, organizational, and contextual factors.

Cognitive Ethology

Cognitive ethology has been defined as the study of the mental experiences of animals, particularly in their natural environment, in the course of their daily lives. Data are derived from the observation of naturally occurring behavior as well as from experimental investigations conducted in the laboratory and in the field. By emphasizing naturally occurring behaviors, cognitive ethologists recognize that the problems faced in finding food and mates, rearing young, avoiding predators, creating shelters, and communicating and engaging in social interactions may require considerable cognitive skills, possibly more complex than and different from those usually examined in traditional psychological laboratory studies. The term "mental experiences" acknowledges that the mental capabilities of animals, in addition to unconscious mental processes, may also include conscious states. This affords the animals sensory experiences, pleasure and pain, the use of mental imagery, and involves at least simple intentional states such as wanting and believing.

Thus, broadly described, the subject of research in cognitive ethology includes any mental experiences and processes, including studies of habituation and sensitization, learning and memory, problem solving, perception, decision making, natural communication, and the artificial languages taught to apes, dolphins, and parrots (reviewed by Ristau and Robbins 1982; Ristau 1997). More narrowly defined, cognitive ethology emphasizes interest in possibly conscious animal mental experiences, particularly as occurring in communication and other social interactions and studies of intention. The field can also be construed as an ethological approach to cognition.

Although the field of cognitive ethology has roots in COMPARATIVE PSYCHOLOGY, ETHOLOGY, and studies of animal learning and memory, it traces its birth to the publication in 1976 of *The Question of Animal Awareness* by the biologist Donald Griffin (see also Griffin 1992).

What is the rationale for the field of cognitive ethology? As conceived by Griffin (1976), there are several reasons for considering that animals may think and be aware: (i) Argument from evolutionary continuity—animals share so many similarities in structure, process, and behavior with humans, why should we not expect them to share mental experience as well? (ii) Neurophysiological evidence—as far as can be determined, nonhuman animals share many neuroanatomical structures, including kinds of neurotransmitters, neurons, synaptic connections, and nerve impulses. We agree that humans are conscious, but, as yet, know of no special structure or process type that is responsible for consciousness or awareness, nor of any neurophysiological process that is uniquely human. (iii) Behavioral complexity and flexibility, particularly in the face of obstacles to the achievement of a goal, at least suggest that the organism may be thinking about alternative ways to behave. (iv) Communication as a window on animal minds—an animal's attention and response to the species' communicative signals—may suggest something of the mental experience and likely behaviors of the communicating organism.

Probably the most significant methodological characteristics of research in cognitive ethology is approximating important aspects of the natural conditions of the species under investigation and making very fine-grained analyses of behavior, usually necessitating videotaped data collection. Many experiments are conducted in the natural environment: (i) Ristau's (1991) studies of piping plovers' use of "injury feigning" in staged encounters with intruders. (ii) Observations of the social behavior of freely interacting organisms, for example Bekoff's (1995a) study of meta-communicative signals in play between two pet dogs. The dogs tended to use signals indicating "this is play" to initiate play bouts and after rough encounters possibly misinterpretable as aggressive (see SOCIAL PLAY BEHAVIOR). (iii) Structurally altered environmental space, for example Bekoff's (1995b) study of vigilance behavior as influenced by the geometry of birds' spatial arrangement at a feeder. Birds spent less time being vigilant for predators when perched in a circle and easily able to determine whether others were vigilant than when they were standing along a line so that such visibility was impossible. (iv) Acoustic playback of recorded species-typic communication signals, for example Seyfarth, Cheney, and Marler's (1980) playbacks to vervet monkeys. The vervets apparently can signal semantic information, not simply emotional states. The monkeys have distinct acoustic signals for a ground predator such as a leopard, a specific aerial predator, the martial eagle, and for snakes (see SOCIAL COGNITION IN ANIMALS).

Cognitive ethology studies differ in interpretation from more traditional approaches. Many ethologists and comparative psychologists have studied foraging behavior, but the cognitive ethologist is interested in different aspects of the data and draws different conclusions. The traditional ethologist might produce an ethogram of an individual animal's or species' behavior, namely a time budget of the various activities in which the animal(s) engage. A comparative psychologist might study the animals under laboratory conditions with strict stimulus control, striving to determine the stimuli apparently controlling the organism's behavior. In these various situations, the cognitive ethologists would be particularly interested in the cognitive capacities revealed, particularly as they might relate to problems encountered by the organism in its natural environment.

Cognitive ethological studies sometimes differ from other research in their scientific paradigm. A typical learn-

ing paradigm as used by experimental psychologists might test an animal's discriminative abilities and specificity, duration and stimulus control of memories, but the procedures rely on standard protocols with many trials. Learning over many trials is not the same capacity as intelligence, though it is necessary for intelligence. Intelligent behavior, of particular interest to cognitive ethologists, is most likely to be revealed when an organism encounters a novel problem, particularly one for which the organism is not specifically prepared by evolution. But one or few occurrences, at least in the past, have been pejoratively termed anecdotal and excluded from the scientific literature. Science can progress by including such observations, particularly from well-trained scientists who, with years of study, often have unique opportunities to observe animals in unusual circumstances. If possible, one attempts to design experiments that replicate the rare occurrence.

Since an organism's most interesting actions may not be predictable by the researcher, many investigations in cognitive ethology cannot proceed with predetermined checklists of behavior. Likewise the significance of given behaviors may not be apparent at the time of observation, but may later be understood in terms of a broader context, often extending over days, weeks, or years. These possibilities again require extensive use of video and careful notation of details. For example, a parent piping plover who hears an acoustic playback of a chick's screech and then searches unsuccessfully for the chick, sometimes next searches an area where a playback had been conducted days earlier (Ristau, pers. obs.).

A cognitive ethological approach is illustrated in experimental field studies of piping plovers' injury feigning or broken wing display (BWD), a behavior performed when an intruder/predator approaches the nest or young (Ristau 1991). The hypothesis to be evaluated was: The piping plover wants to lead the predator/intruder away from the nest/young. Alternatively, the use of BWDs might be viewed as the result of confusion or conflicting motivations or as a fixed action pattern with no voluntary control. Theories of how one might experimentally assess the plover's purpose drew inspiration from work such as that of the psychologist Tolman (1932), the philosopher Dennett (1983), and artificial intelligence researcher Boden (1983). Videotaped experiments were conducted on beaches where plovers nested. Human intruders approached the nest or young in directions unpredictable to the birds, so as to approximate the behavior of an actual predator. Questions asked were the following:

1. Is the bird's behavior appropriate to achieve the presumed goal? Specifically, does the plover move in a direction that would cause an intruder who was following to be further away from the nest/young? Answer: Yes. Furthermore, the plover displayed a behavior that might be expected if the bird were trying to attract the intruder's attention and thus was selective about where it displayed. The bird positioned itself before displaying, often even flying to a new location. Such new locations were closer to the intruder and usually closer to the center of the intruder's visual field/direction of movement as well.

2. Does a displaying bird monitor the intruder's behavior? Though difficult to determine exactly what the plover was monitoring, often in the midst of a display, the bird turned its head sharply back over its shoulder, eye toward the intruder.

3. Does the bird modify its behavior if its goal is not being achieved, specifically if the intruder does not follow the displaying bird? Again, yes. The plover reapproached the intruder or increased the intensity of its display if the intruder was not following, but did not do so if the intruder kept following the display.

Other experiments determined that the plover was sensitive to the direction of eye gaze of an intruder either toward or away from its nest. In others, the plover learned very rapidly to discriminate which intruders were dangerous, i.e., had approached closely to its nest, and which were not, those that had simply walked past the nest, rather far away.

The field of cognitive ethology has engendered considerable controversy (for example, see Mason 1976). Some experimental and comparative psychologists dissociate themselves from the endeavor and avoid use of mentalistic phrases such as "the organism wants to do X." However, in designing and interpreting the research, experimental psychologists have at least implicit assumptions about the needs and intentions of their animal subjects. The lab rat must *want* the food pellet and thus performs the experimenter's task to get it. In a test of CER (conditioned emotional responding), the rat inhibits bar pressing in the presence of a stimulus associated with shock. We are interested in the results only because we assume the rat is experiencing an emotional state related to human fear. Even the description of an organism's action contains implied attributions of intentions. Insofar as a rat is described as reaching *for* a pellet or walking *to* the water, a goal or motive is implied. To avoid the *for* or *to* makes the description a mere delineation of changes of position in space and loses the significance of the event. In similar vein, the experiments that studiously avoid mentalistic phrases, upon closer examination, entail assumptions about animal states and intentions.

One can only hope that the common concerns of the related disciplines will be recognized by researchers. It is probable that philosophers would find useful, directive constraints on their thinking from the data on animal cognition, and that the psychologists and biologists would better appreciate the contributions of philosophers that can help clarify concepts and reveal conceptual complexities in an experiment.

Cognitive Linguistics

Cognitive linguistics is not a single theory but is rather best characterized as a paradigm within linguistics, subsuming a number of distinct theories and research programs. It is characterized by an emphasis on explicating the intimate interrelationship between language and other cognitive faculties. Cognitive linguistics began in the 1970s, and since the mid-1980s has expanded to include research across the full range of subject areas within linguistics: syntax, semantics, phonology, discourse, etc. The International Cognitive Linguistics Association holds bi-annual meetings and publishes the journal *Cognitive Linguistics.*

The various theoretical frameworks within the cognitive paradigm are to a large degree mutually compatible, differing most obviously in the kinds of phenomena they are designed to address. Construction grammar advances the hypothesis that grammatical constructions are linguistic units in their own right, and that the constructional templates in which verbs are embedded contribute to determining argument structure and MEANING (Goldberg 1995). Mental spaces theory (Fauconnier 1985) focuses on the subtle relationships among elements in the various mental models that speakers construct, relationships that underlie a vast array of semantic phenomena such as scope ambiguities, negation, counterfactuals, and opacity effects.

A number of cognitive linguists are exploring the central role of METAPHOR in SEMANTICS and cognition (Lakoff and Johnson 1980), while others focus on the specific relationships between general cognitive faculties and language (Talmy 1988). Though not self-identified as a cognitive theory, Chafe's (1994) information flow theory is certainly compatible with the cognitive linguistic paradigm, as it explores the relationship between DISCOURSE units and information units in mental processing.

Arguably the most comprehensive theoretical framework within this area is cognitive grammar (Langacker 1987, 1991). The goal of cognitive grammar is to develop a theory of grammar and meaning that is cognitively plausible and that adheres to a kind of theoretical austerity summed up in the content requirement (Langacker 1987): the only structures permitted in the grammar of a language are (1) phonological, semantic, or symbolic structures that actually occur in linguistic expressions (where a symbolic structure is a phonological structure paired with a semantic structure, essentially a Saussurean "sign"); (2) schemas for such structures, where a schema is a kind of pattern or template that a speaker acquires through exposure to multiple exemplars of the pattern; and (3) categorizing relationships among the elements in (1) and (2) (for example, categorizing the syllable /pap/ as an instantiation of the schematic pattern /CVC/).

While not all cognitive linguists adopt the content requirement specifically, the principle of eschewing highly abstract theoretical constructs is endorsed by the cognitive linguistic movement as a whole.

The published work in cognitive grammar has focused on developing a fundamental vocabulary for linguistic analysis in which grammatical constructs are defined in terms of semantic notions, which are themselves characterized in terms of cognitive abilities that are well attested even outside of the linguistic domain. Basic grammatical categories (noun, verb, subject, etc.) and constructions are given cognitive semantic characterizations, obviating the need for abstract syntactic features and representations.

The possibility of defining grammatical notions in semantic terms depends upon taking into account *construal.* Construal refers to the way in which a speaker mentally shapes and structures the semantic content of an expression: the relative prominence of elements, their schematicity or specificity, and the point of view adopted. Many grammatical distinctions that had been traditionally considered to be "meaningless" (i.e., lacking in stable semantic content) are found instead to be markers of subtle distinctions in construal. The subject/object distinction, for example, is defined as a linguistic correlate of the more general ability to perceive figure versus ground. Active and passive versions of the "same sentence" therefore do not mean the same thing, even if they have identical truth conditions; they differ in fig-

ure/ground organization. The semantic definitions of grammatical categories similarly rely upon construal, although the details would require a great deal more discussion.

There are several key principles uniting the various theories and approaches within the cognitive linguistic paradigm.

1. Conceptual (subjectivist) semantics. Meaning is characterized as conceptualization: The meaning of an expression is the concepts that are activated in the speaker or hearer's mind. In this view, meaning is characterized as involving a relationship between words and the mind, not directly between words and the world (cf. INDIVIDUALISM).

2. Encyclopedic as opposed to dictionary semantics (Haiman 1980). Words and larger expressions are viewed as entry points for accessing open-ended knowledge networks. Fully explicating the meaning of an expression frequently requires taking into account imagery (both visual and nonvisual), metaphorical associations, mental models, and folk understandings of the world. Thus, the meaning of a word is generally not capturable by means of a discrete dictionary-like definition.

3. Structured categories. Categories are not defined in terms of criterial-attribute models or membership determined by necessary and sufficient features (Lakoff 1987; Taylor 1989). Rather categories are organized around prototypes, family resemblances, and subjective relationships between items in the category.

4. Gradient grammaticality judgments. Grammaticality judgments involve a kind of categorization, inasmuch as a speaker judges an utterance to be a more or less acceptable exemplar of an established linguistic pattern. Grammaticality judgments are therefore gradient rather than binary, and depend upon subtleties of context and meaning as well as conformity to grammatical conventions. Cognitive linguists in general do not endorse the goal of writing a grammar that will generate all and only the grammatical sentences of a language (see GENERATIVE GRAMMAR), as the gradience, variability, and context-dependence of grammaticality judgments render such a goal unrealizable.

5. Intimate interrelationship of language and other cognitive faculties. Cognitive linguists search for analogues for linguistic phenomena in general cognition (hence the name "cognitive" linguistics). Findings from psychology about the nature of human CATEGORIZATION, ATTENTION, MEMORY, etc., are taken to inform linguistic theory directly.

6. The nonautonomy of syntax. SYNTAX is understood to be the conventional patterns by which sounds (or signs) convey meanings. Syntax therefore does not require its own special primitives and theoretical constructs. Grammatical knowledge is captured by positing conventionalized or "entrenched" symbolic patterns that speakers acquire through exposure to actually occurring expressions.

Cognitive Maps

Edward Tolman is credited with the introduction of the term *cognitive map,* using it in the title of his classic paper (1948). He described experiments in which rats were trained to follow a complex path involving numbers of turns and changes of direction to get to a food box. Subsequently in a test situation the trained path was blocked off and a variety of alternative paths provided. A large majority of the rats chose a path that headed very close to the true direct direction of the food box, and not one that was close to the original direction of the path on which they had been trained. On the basis of such data Tolman argued that the rat had "acquired not merely a strip-map . . . but, rather, a wider comprehensive map to the effect that the food was located in such and such a direction in the room" (p. 204).

This concept of cognitive map has elicited considerable interest over the years since. Tolman's results seem to imply that animals or humans go beyond the information given when they go directly to a goal after having learned an indirect path. That conclusion is strongest when the spatial cues marking the goal location are not visible from the starting position. Rieser, Guth, and Hill (1986) reported a compelling experimental example of such behavior. Blindfolded observers learned the layout of objects in a room. They were trained specifically, and only, to walk without vision from a home base to each of three locations. Naturally they were also able to point from home base to the three locations quickly and accurately without vision. Furthermore, when they walked to any one of the locations, still without vision, they could point as rapidly and almost as accurately to the other two locations as they had from home base. As with Tolman's rats these observers seemed to have acquired knowledge of many of the spatial relations in a complex spatial layout from direct experience with only a small subset of those relations. In that sense they had acquired a cognitive map. More generally, two different criteria are often used to attribute to people maplike organization of spatial knowledge. One, as in the previous example, is when spatial inferences about the direction and distances among locations can be made without direct experience. The other is when it is possible to take mentally a different perspective on an entire spatial layout. This can be done by imagining

oneself in a different position with respect to a layout (Hintzman, Odell, and Arndt 1981).

From where do such cognitive maps arise? One answer involves the specific kinds of experience one has with the particular spatial layout in question. For example, Thorndyke and Hayes-Roth (1982) compared observers' organization of spatial knowledge after studying a map of a large building and after experience in actually navigating around the building. They found that map experience led to more accurate estimation of the straight line or Euclidean distances between locations and understandably to better map drawing, whereas actual locomotion around the building led to more accurate route distance estimation and to more accurate judgments of the actual direction of locations from station points within the building. A second answer involves the nature of one's experience with spatial layouts in general. Thus congenitally blind observers who have never had visual experience show less maplike organization of their spatial knowledge than do sighted ones (or at least take longer to develop such organization). Why might this be? One hypothesis (Rieser et al. 1995) is that sighted persons have prolonged experience with optical flow patterns as they move about during their lives. The information from this optical stimulation specifies how the distance and direction of locations with respect to the observer change as they move. Sighted persons use that knowledge to keep track of even out-of-sight locations as they move. Blind persons without the optical flow experience do not do this as well, and, of course, all their locomotion involves moving with respect to out-of-sight locations.

It seems clear that the absence of visual experience puts one at a disadvantage in developing cognitive maps of spatial layout. When is that visual experience important? The literature comparing early and late blinded observers in spatial perception and cognition tasks often reports better performance in the late blind (Warren 1984; Warren, Anooshian, and Bollinger 1973). However, the age boundaries are very fuzzy because the ages used vary from study to study and because the availability of blind participants of specific ages is rather limited. With sighted participants, maplike organization is evident at very early ages ranging from two years (Pick 1993) to six or seven years (Hazen, Lockman, and Pick 1978), depending on the situation.

Another kind of answer to the origin of maplike organization of spatial knowledge comes from the considerable research on underlying brain mechanisms. This research has been particularly concerned with where and how spatial information is represented in the brain and how, neurologically, orientation is maintained with respect to spatial layouts. Lesion studies and studies of single cell recording have been among the most informative. Many human brain damage studies have been concerned with VISUAL NEGLECT, a deficit in which part of a visual stimulus is ignored. Such deficits have often been associated with parietal lobe damage, and the neglect is of the visual space contralateral to the damage. This neglect apparently operates in memory as well as during perception. One example particularly relevant to cognitive mapping has been reported by Bisiach and Luzzatti (1978). Patients were asked to describe a familiar urban scene, when viewed from one end. They described it,

but ignored features on the left side. They were then asked to imagine viewing it from the other end. They now reported it including originally missing features that were now on the right side, omitting originally reported features now on the neglected left side.

A number of areas in the brain have been implicated in spatial information processing by SINGLE-NEURON RECORDING studies in animals. Besides the posterior parietal cortex, the HIPPOCAMPUS has been found to play a particularly important role. Indeed, O'keefe and Nadel (1978) authored a book entitled *The Hippocampus as Cognitive Map*. Early spatially relevant single cell recording research resulted in the exciting discovery of "place" cells. These cells fire selectively for particular locations in a spatial environment. However, place cells by themselves seem to reflect place recognition but not necessarily information about how to get from one place to another (especially if it is out of sight). An analysis by McNaughton, Knierim, and Wilson (1994) suggests a vector subtraction model that could solve the wayfinding problem. In their prototypic situation, a kind of detour behavior, an animal knows the distance and direction from its home to landmark A. On some occasion it finds itself at an unknown landmark C, from which A is visible but not its home. Their model suggests how hippocampus place cells in conjunction with distance and heading information are sufficient to generate a straight line path to its home. Heading information is potentially available from integration of vestibular stimulation, and there are a variety of visual sources for distance information.

Spatial analogies have frequently been attractive ways of describing nonspatial domains. Examples include kinship relations, bureaucratic organizations, statistical analyses, color perception, etc. An intriguing possibility is that our spatial thinking and the idea of cognitive maps can apply to other domains that are easily described in spatial terms. It is possible to think of cognitive maps of data bases—and indeed the term cognitive map is often being used more and more metaphorically. It is an empirical question with important practical and theoretical implications to know how well the underlying spatial cognition transfers to such nonspatial domains.

Cognitive Modeling, Connectionist

Connectionist cognitive modeling is an approach to understanding the mechanisms of human cognition through the use of simulated networks of simple, neuronlike processing units. Connectionist models are most often applied to what might be called natural cognitive tasks. These tasks include perceiving the world of objects and events and interpreting it for the purpose of organized behavior; retrieving contextually appropriate information from memory; perceiving and understanding language; and what might be called intuitive or implicit reasoning, in which an inference is derived or a solution to a problem is discovered without the explicit application of a predefined ALGORITHM. Because connectionist models capture cognition at a microstructural level, a more succinct characterization of a cognitive process—especially one that is temporally extended or involves explicit, verbal reasoning—can sometimes be given through the use of a more symbolic modeling framework. However, many connectionists hold that a connectionist microstructure underlies all aspects of human cognition, and a connectionist approach may well be necessary to capture the supreme achievements of human reasoning and problem solving, to the extent that such achievements arise from sudden insight, implicit reasoning, and/or imagining, as opposed to algorithmic derivation. See CONNECTIONISM, PHILOSOPHICAL ISSUES

Figure 1. A picture illustrating how a large number of very partial and ambiguous clues may lead to a perception of an object in a scene. Reprinted with permission from Figure 3-1 of Marr (1982).

for further discussion, and PROBLEM SOLVING and COGNITIVE MODELING, SYMBOLIC for other perspectives.

Connectionist models—often called parallel distributed processing models or NEURAL NETWORKS—begin with the assumption that natural cognition takes place through the interactions of large numbers of simple processing units. Inspiration for this approach comes from the fact that the brain appears to consist of vast numbers of such units—neurons. While connectionists often seek to capture putative principles of neural COMPUTATION in their models, the units in an actual connectionist simulation model should not generally be thought of as corresponding to individual neurons, because there are far fewer units in most simulations than neurons in the relevant brain regions, and because some of the properties of the units used may not be exactly neuron-like.

In connectionist systems, an active mental representation, such as a precept, is a pattern of activation over the set of processing units in the model. Processing takes place via the propagation of activation among the units, via weighted connections. The "knowledge" that governs processing consists of the values of the connection weights, and learning occurs through the gradual adaptation of the connection weights, which occur as a result of activity in the network, sometimes taken together with "error" signals, either in the form of a success or failure signal (cf. REINFORCEMENT LEARNING) or an explicit computation of the mismatch between obtained results and some "teaching" signal (cf., error correction learning, back propagation).

Perception

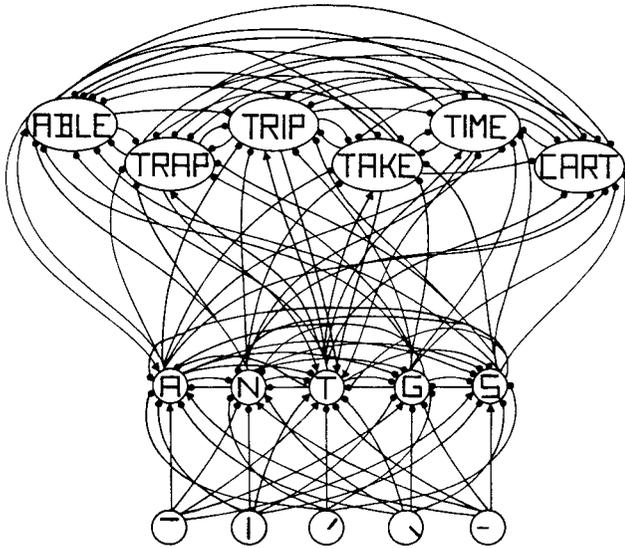
Perception is a highly context-dependent process. Individual stimulus elements may be highly ambiguous, but when considered in light of other elements present in the input, together with knowledge of patterns of co-occurrence of elements, there may be a single, best interpretation. Such is the case with the famous Dalmatian dog figure, shown in figure 1. An early connectionist model that captured the joint role of


Figure 2. A fraction of the units and connections from the interactive activation model of visual word perception. Reprinted with permission from figure 3 of McClelland and Rumelhart 1981.

stimulus and context information in perception was the interactive activation model (McClelland and Rumelhart 1981). This model contained units for familiar words, for letters in each position within the words, and for features of letters in each position (fig. 2). Mutually consistent units had mutually excitatory connections (e.g., T unit for T in the first position had a mutually excitatory connection with the units for words beginning with T, such as *TIME, TAPE,* etc.). Mutually inconsistent units had mutually inhibitory connections (e.g., there can only be one letter per position, so the units for all of the letters in a given position are mutually inhibitory). Simulations of perception as occurring through the excitatory and inhibitory interactions among these units have led to a detailed account of a large body of psychological evidence on the role of context in letter perception. The interactive activation model further addresses the fact that perceptual enhancement also occurs for novel, wordlike stimuli such as *MAVE*. The presentation of an item like *MAVE* produces partial activation of a number of word units (such as *SAVE, GAVE, MAKE, MOVE,* etc.). Each of these provides a small amount of feedback support to the units for the letters it contains, with the outcome that the letters in items like *MAVE* receive almost as much feedback as letters in actual words. Stochastic versions of the interactive activation model overcome empirical shortcomings of the original version (McClelland 1991).

Other connectionist models have investigated issues in the perception of spoken language (McClelland and Elman 1986), in VISUAL OBJECT RECOGNITION, AI (Hummel and Biederman 1992), and in the interaction of perceptual and attentional processes (Phaf, van der Heijden, and Hudson 1990; Mozer 1987; Mozer and Behrmann 1990).

Memory and Learning

A fundamental assumption of connectionist models of MEMORY is that memory is inherently a constructive process, tak-

ing place through the interactions of simple processing units, just as in the case of perception. One can think of recall as a process of constructing a pattern of activation that is taken by the recaller to reflect not the present input to the senses, but some pattern previously experienced. Central to this view is the idea that recall is prone to a variety of influences that often help us fill in missing details but which are not always bound to fill in correct information. An early model of memory retrieval (McClelland 1981) showed how multiple items in memory can become partially activated, thereby filling in missing information, when memory is probed. The partial activation is based on similarity of the item in memory to the probe and to the information initially retrieved in response to the probe. Similarity based generalization appears to be ubiquitous, and it can often lead to correct inference, but this is far from guaranteed, and indeed subsequent work by Nystrom and McClelland (1992) showed how connectionist networks can lead to blend errors in recall. Connectionist models have also been applied productively to aspects of concept learning (Gluck and Bower 1988), prototype formation (Knapp and Anderson 1984; McClelland and Rumelhart 1985) and the acquisition of conceptual representations of concepts (Rumelhart and Todd 1993). A crucial aspect of this latter work is the demonstration that connectionist models trained with back propagation can learn what basis to use for representations of concepts, so that similarity based generalization can be based on deep or structural rather than superficial aspects of similarity (Hinton 1989; see McClelland 1994 for discussion).

Connectionist models also address the distinction between explicit and implicit memory. Implicit memory refers to an aftereffect of experience with an item in a task that does not require explicit reference to the prior occurrence of the item. These effects often occur without any recollection of one having previously seen the item. Connectionist models account for such findings in terms of the adjustments of the strengths of the connections among the units in networks responsible for processing the stimuli (McClelland and Rumelhart 1985; Becker et al. 1997). Explicit memory for recent events and experiences may be profoundly impaired in individuals who show normal implicit learning (Squire 1992), suggesting a special brain system may be required for the formation of new explicit memories. A number of connectionist models have been proposed in an effort to explain how and why these effects occur (Murre 1997; Alvarez and Squire 1994; McClelland, McNaughton, and O'Reilly 1995).

Language and Reading

Connectionist models have suggested a clear alternative to the notion that knowledge of language must be represented as a system of explicit (though inaccessible) rules, and have presented mechanisms of morphological inflection, spelling-sound conversion, and sentence processing and comprehension that account for important aspects of the psychological phenomena of language that have been ignored by traditional accounts. Key among the phenomena not captured by traditional, rule-based approaches have been the existence of quasi-regular structure, and the sensitivity of language

behavior to varying degrees of frequency and consistency. While all approaches acknowledge the existence of exceptions, traditional approaches have failed to take account of the fact that the exceptions are far from a random list of completely arbitrary items. Exceptions to the regular past tense of English, for example, come in clusters that share phonological characteristics (e.g., weep-wept, sleep-slept, sweep-swept, creep-crept) and quite frequently have elements in common with the "regular" past tense (/d/ or /t/, like their "regular" counterparts). An early connectionist model of Rumelhart and McClelland (1986) showed that a network model that learned connection weights to generate the past tense of a word from its present tense could capture a number of aspects of the acquisition of the past tense. Critiques of aspects of this model (Pinker and Prince 1988; Lachter and Bever 1988) raised a number of objections, but subsequent modeling work (MacWhinney and Leinbach 1991; Plunkett and Marchman 1993) has addressed many of the criticisms. Debate still revolves around the need to assume that explicit, inaccessible rules arise at some point in the course of normal development (Pinker 1991). A similar debate has arisen in the domain of word reading (see Coltheart et al. 1993; Plaut et al. 1996).

Connectionist approaches have also been used to account for aspects of language comprehension and production. Connectionists suggest that language processing is a constraint-satisfaction process sensitive to semantic and contextual factors as well as syntactic constraints (Rumelhart 1977; McClelland 1987). Considerable evidence (Taraban and McClelland 1988; MacDonald, Pearlmutter, and Seidenberg 1994; Tanenhaus et al. 1995) now supports the constraint-satisfaction position, and a model that takes joint effects of content and sentence structure into account has been implemented (St. John and McClelland 1995). In production, evidence supporting a constraint-satisfaction approach to the generation of the sounds of a word has led to interactive connectionist models of word production (Dell 1986; Dell et al. forthcoming). Another, very important direction of connectionist work is the area of language centers on the learning of the grammatical structure of sentences in a class of connectionist networks known as the simple recurrent net (Elman 1990). Such networks could learn to become sensitive to long-distance dependencies characteristic of sentences with embedded clauses, suggesting that there may not be a need to posit explicit, inaccessible rules to account for human knowledge of syntax (Elman 1991; Servan-Schreiber, Cleeremans, and McClelland 1991; Rohde and Plaut forthcoming). However, existing models have been trained on very small "languages," and successes with larger language corpora, as well as demonstrations of sensitivity to additional aspects of syntax, are needed.

Reasoning and Problem Solving

While connectionist models have had considerable success in many areas of cognition, their full promise for addressing higher level aspects of cognition, such as reasoning and problem solving, remains to be fully realized. A number of papers point toward the prospect of connectionist models in these areas (Rumelhart et al. 1986; Rumelhart 1989) with-

out full implementations, perhaps in part because higher level cognition often has a temporally extended character, not easily captured in a single settling of a network to an attractor state. Though there have been promising developments in the use of RECURRENT NETWORKS to model temporally extended aspects of cognition, many researchers have opted for "hybrid" models. These models often rely on external, more traditional modeling frameworks to assign units and connections so that appropriate constraint-satisfaction processes can then be carried out in the connectionist component. This approach has been used in the domain of analogical reasoning (Holyoak and Thagard 1989). A slightly different approach, suggested by Rumelhart (1989), assumes that concepts are represented by distributed patterns of activity that capture both their superficial and their deeper conceptual and relational features. Discovering an analogy then consists of activating the conceptual and relational features of the source concept, which may then settle to an attractor state consisting of an analog in another domain that shares these same deep features but differs in superficial details.

Many researchers in this area view the "binding problem" (the assignment of arbitrary content to a slot in a structural description) as a fundamental problem to be solved in the implementation of connectionist models of reasoning, and several solutions have been proposed (Smolensky, Legendre, and Miyata forthcoming; Shastri and Ajjanagadde 1993; Hummel and Holyoak 1997). However, networks can learn to create their own slots so that they can carry out natural inferences in familiar content areas (St. John 1992). Whether learning mechanisms can yield a general enough implementation to capture people's ability to reason in unfamiliar domains remains to be determined.

Cognitive Modeling, Symbolic

Symbolic cognitive models are theories of human cognition that take the form of working computer programs. A cognitive model is intended to be an explanation of how some aspect of cognition is accomplished by a set of primitive computational processes. A model performs a specific cognitive task or class of tasks and produces behavior that constitutes a set of predictions that can be compared to data from human performance. Task domains that have received considerable attention include problem solving, language comprehension, memory tasks, and human-device interaction.

The scientific questions cognitive modeling seeks to answer belong to *cognitive psychology*, and the computational techniques are often drawn from *artificial intelligence.* Cognitive modeling differs from other forms of theorizing in psychology in its focus on functionality and computational completeness. Cognitive modeling produces both a theory of human behavior on a task and a computational artifact that performs the task.

The theoretical foundation of cognitive modeling is the idea that cognition is a kind of COMPUTATION (see also COMPUTATIONAL THEORY OF MIND). The claim is that what the mind does, in part, is perform cognitive tasks by computing. (This does not mean that the computer is a metaphor for the mind, or that the architectures of modern digital computers can give us insights into human mental architecture.) If this is the case, then it must be possible to explain cognition as a dynamic unfolding of computational processes. A cognitive model cast as a computer program is a precise description of what those processes are and how they develop over time to realize some task.

A cognitive model is considered to be a *symbolic* cognitive model if it has the properties of a symbolic system in the technical sense of Newell and Simon's (1976) physical symbol system hypothesis (PSSH). The PSSH provides a hypothesis about the necessary and sufficient conditions for a physical system to realize intelligence. It is a reformulation of Turing computation (see CHURCH-TURING THESIS) that identifies symbol processing as the key requirement for complex cognition. The requirement is that the system be capable of manipulating and composing symbols and symbol structures—physical patterns with associated processes that give the patterns the power to denote either external entities or other internal symbol structures (Newell 1980; Newell 1990; Pylyshyn 1989; Simon 1996). One of the distinguishing characteristics of symbols systems is that novel structures may be composed and interpreted, including structures that denote executable processes.

The extent to which symbolic processing is required for explaining cognition, and the extent to which *connectionist* models have symbolic properties, has been the topic of ongoing debates in cognitive science (Fodor and Pylyshyn 1988; Rumelhart 1989; Simon 1996; see COGNITIVE MODELING, CONNECTIONIST). Much of the debate has turned on the question of whether or not particular connectionist systems are able to compose and interpret novel structures. In particular, Fodor and Pylyshyn argue that any valid cognitive theory must have the properties of productivity and systematicity. Productivity refers to the ability to produce and entertain an unbounded set of novel propositions with finite means. Systematicity is most easily seen in linguistic processing, and refers to the intrinsic connection between our ability to produce and comprehend certain linguistic forms. For example, no speaker of English can understand the utterance "John loves the girl" without also being able to understand "the girl loves John," or any other utterance from the unbounded set of utterances of the form "X loves Y." Both productivity and systematicity point to the need to posit underlying abstract structures that can be freely composed, instantiated with novel items, and interpreted on the basis of their structure.

A variety of empirical constraints may be brought to bear on cognitive models. These include: basic *functionality* requirements (a model must actually perform the task to some approximation if it is to be veridical); data from *verbal protocols* of human subjects thinking aloud while PROBLEM SOLVING (these reveal intermediate cognitive steps that may be aligned with the model's behavior; Newell and Simon 1972; Ericsson and Simon 1984); *chronometric data* (such data can constrain a cognitive model once assumptions are made about the time course of the component computational processes; Newell 1990); *eye movement* data (eye fixation durations are a function of cognitive, as well as perceptual, complexity; Carpenter and Just 1987; Rayner 1977); *error patterns;* and data on *learning rates* and *transfer of cognitive skill* (such data constrain the increasing number of cognitive models that are able to change behavior over time; Singley and Anderson 1989).

Though the problem of under-constraining data is a universal issue in science, it is sometimes thought to be particularly acute in computational cognitive modeling, despite the variety of empirical constraints described above. There are two related sides to the problem. First, cognitive models are often seen as making many detailed commitments about aspects of processing for which no data distinguish among alternatives. Second, because of the universality of computational frameworks, an infinite number of programs can be created that mimic the desired behavior (Anderson 1978).

Theorists have responded to these problems in a variety of ways. One way is to adopt different levels of abstraction in the theoretical statements: in short, not all the details of the computer model are part of the theory. NEWELL (Newell 1990; Newell et al. 1991), MARR (1982), PYLYSHYN (1984) and others have developed frameworks for specifying systems at multiple levels of abstraction. The weakest possible correspondence between a model and human cognition is at

the level of input/output: if the model only responds to functionality constraints, it is intended only as a sufficiency demonstration and formal task definition (Pylyshyn 1984, 1989). The strongest kind of correspondence requires that the model execute the same algorithm (take the same intermediate computational steps) as human processing. (No theoretical interpretation of a cognitive model, not even the strongest, depends on the hardware details of the host machine.)

An important method for precisely specifying the intended level of abstraction is the use of programming languages designed for cognitive modeling, such as PRODUCTION SYSTEMS. Production systems were introduced by Newell (1973) as a flexible model of the control structure of human cognition. The flow of processing is not controlled by a fixed program or procedure laid out in advance, as is the case in standard procedural programming languages. Instead, production systems posit a set of independent production rules (condition-action pairs) that may fire any time their conditions are satisfied. The flow of control is therefore determined at run time, and is a function of the dynamically evolving contents of the working memory that triggers the productions. A cognitive model written in a production system makes theoretical commitments at the level of the production rules, and defines a computationally complete system at that level. The particular underlying implementation (e.g., LISP or Java) is theoretically irrelevant.

A complementary approach to reducing theoretical degrees of freedom is to apply the same model with minimal variation to a wide range of tasks. Each new task is not an unrelated pool of data to be arbitrarily fitted with a new model or with new parameters. For example, a computational model of short-term memory that accounts for immediate serial recall should also apply, with minimal strategy variations, to free recall tasks and recognition tasks as well (Anderson and Matessa 1997).

Recent cognitive modeling research combines these approaches by building and working with cognitive architectures. A COGNITIVE ARCHITECTURE posits a fixed set of computational mechanisms and resources that putatively underlie a wide range of human cognition. As these cognitive architectures never correspond to the architectures of modern computers (for example, they may demand a higher degree of parallelism), the architectures must first be *emulated* on computers before cognitive models can be built within them for specific tasks. Such architectures, together with the variety of empirical constraints outlined above, place considerable constraint on task models.

Examples of the architectural approach include ACT-R (Anderson 1993), CAPS (Just and Carpenter 1992), SOAR (Newell 1990), EPAM (Feigenbaum and Simon 1984), and Epic (Meyer and Kieras 1997). (All are production systems, with the exception of EPAM.) These architectures have collectively been applied to a broad set of phenomena in cognitive psychology. For example, Anderson and colleagues (Anderson 1993; Singley and Anderson 1989) have demonstrated that a production rule analysis of cognitive skill, along with the learning mechanisms posited in the ACT architecture, provide detailed and explanatory accounts of a range of regularities in cognitive skill acquisition in complex domains such as learning to program LISP. ACT also provides accounts of many phenomena surrounding the recognition and recall of verbal material (e.g., the fan effect), and regularities in problem-solving strategies (Anderson 1993; Anderson and Lebiere forthcoming). EPAM is one of the earliest computational models in psychology and accounts for a significant body of data in the learning and high-level perception of verbal material. It has been compared in some detail to related connectionist accounts (Richman and Simon 1989). SOAR is a learning architecture that has been applied to domains ranging from rapid, immediate tasks such as typing and video game interaction (John, Vera and Newell 1994) to long stretches of problem-solving behavior (Newell 1990), building on the earlier analyses by Newell and Simon (1972). SOAR has also served as the foundation for a detailed theory of sentence processing, which models both the rapid on-line effects of semantics and context, as well as subtle effects of syntactic structure on processing difficulty across several typologically distinct languages (Lewis 1996, forthcoming). EPIC is a recent architecture that combines a parallel production system with models of peripheral and motor components, and accounts for a substantial body of data in the performance of dual cognitive tasks (Meyer and Kieras 1997). CAPS is a good example of recent efforts in symbolic modeling to account for individual differences in cognitive behavior. CAPS explains differences in language comprehension performance by appeal to differences in working memory capacity (Just and Carpenter 1992). Polk and Newell (1995) developed a constrained parametric model of individual differences in syllogistic reasoning that provides close fits to particular individuals by making different assumptions about the way they interpret certain linguistic forms (see also Johnson-Laird and Byrne 1991).

In short, modern symbolic cognitive modeling is characterized by detailed accounts of chronometric data and error patterns; explorations of the explanatory role of the same basic architectural components across a range of cognitive tasks; attempts to clearly distinguish the contributions of relatively fixed architecture and more plastic task strategies and background knowledge; and attempts to explicitly deal with the problem of theoretical degrees of freedom. The underlying goal of all these approaches is to produce more unified accounts of cognition explicitly embodied in computational mechanisms.

Color Categorization

Lexical color categorization consists of the division of color sensations into classes corresponding to the significata of the color words of a particular language. Perceptual color categorization consists of the division of the color sensations into classes by the perceptual processes of an organism—human or nonhuman, adult or neonate, possessed of knowledge of a language or not so possessed. Conflict among views on the relationship of lexical to perceptual color categorization has prevailed for over a century. Nineteenth-century classicists, anthropologists, and opthalmologists were aware that all languages do not reflect identical lexical classifications of color. The classicist (and statesman) William Gladstone concluded that differences in color lexicons reflect differences in perceptual abilities, for example, "that the organ of color and its impressions were but partially developed among the Greeks of the heroic age" (see Berlin and Kay 1969:135). The opthalmologist Hugo Magnus recognized that failure to distinguish colors lexically need not indicate inability to distinguish them perceptually (see Berlin and Kay 1969: 144ff). These and other late nineteenth-century scholars strongly tended to view differences in color lexicons in evolutionary terms.

In the 1920s, 1930s, and 1940s, Edward SAPIR (e.g., 1921: 219) and B. L. Whorf (e.g., 1956 [1940]: 212ff) rejected evolutionism for the doctrine of radical linguistic and cultural relativity. The favorite field for the empirical establishment and rhetorical defense of the relativist view, which became established doctrine in the 1950s and 1960s, was the lexicon of color. With respect to color categorization, there have been two major traditions of research stemming from the relativity thesis: a within-language, correlational line of research and a cross-language, descriptive one.

Early work in the former tradition (e.g., Brown and Lenneberg 1954; Lenneberg and Roberts 1956) is primarily concerned with establishing a correlation between a linguistic variable distinguishing colors (for example, how easy different colors are to name or how easy they are to communicate about) and a nonlinguistic cognitive variable over colors: memorability. Discovery of such a correlation was interpreted as support for the Sapir-Whorf view that linguistic categorization can influence nonlinguistic perception/cognition. In the 1950s and 1960s, such correlations were reported within English and, to a limited extent, in other languages (Stefflre, Castillo Vales, and Morley 1966). Because it was assumed at the time that the linguistic variable (codability or communication accuracy) would vary across languages, correlation between a linguistic and nonlinguistic variable within a single language (almost always English) was taken to validate the doctrine that the coding systems of different languages induce differences in the nonlinguistic cognition of their speakers. Eleanor Rosch (e.g., Heider 1972) challenged this assumption on the basis of the apparent universal lexical salience of certain "focal" colors (identified by Berlin and Kay 1969). Rosch showed that universal perceptual salience determines both the nonlinguistic and the linguistic variables of the correlational approach, thus undercutting the logic of this line of research. Rosch's view was criticized by Lucy and Shweder (1979), who also challenged her experimental procedure; Lucy and Shweder's experimental procedure was in turn challenged by Kay and Kempton (1984), who supported Rosch's view of the matter.

(Kay and Kempton, using a noncorrelational, cross-linguistic experimental procedure, showed that certain nonlinguistic color classification judgments may be influenced by the lexical classification of color in a language, while others are not so influenced, thus re-establishing limited Whorfian effects in the color domain.)

In the tradition of cross-language description, the studies of the 1950s and 1960s likewise reflected the dominance of radical linguistic relativism (Ray 1952; Conklin 1955; Gleason 1961: 4). These studies sought to discover and celebrate the differences among color lexicons. In 1969, using the original stimulus set of Lenneberg and Roberts (1956), Berlin and Kay compared the denotation of basic color terms in twenty languages and, based on these findings, examined descriptions of seventy-eight additional languages from the literature. They reported that there are universals in the semantics of color: the major color terms of all languages are focused on one of eleven landmark colors. Further, they postulated an evolutionary sequence for the development of color lexicons according to which black and white precede red, red precedes green and yellow, green and yellow precede blue, blue precedes brown, and brown precedes purple, pink, orange and gray. These results were challenged on experimental grounds, mostly by anthropologists (e.g., Hickerson 1971; Durbin 1972; Collier 1973), and largely embraced by psychologists (e.g., Brown 1976; Miller and Johnson-Laird 1976; Ratliff 1976). A number of field studies stimulated by Berlin and Kay tended to confirm the main lines of the universal and evolutionary theory, while leading to reconceptualization of the encoding sequence (Berlin and Berlin 1975; Kay 1975). Based on earlier, unpublished work of Chad K. McDaniel, which established the identity of some of the universal semantic foci of Berlin and Kay with the psychophysically determined unique hues (see also in this connection Miller and Johnson-Laird 1976: 342–355; Ratliff 1976; Zollinger 1979), Kay and McDaniel (1978) again reconceptualized the encoding sequence, introducing the notion of fuzzy set into a formal model of color lexicons, and emphasized the role in early systems of categories representing fuzzy unions of Hering primaries. Kay and McDaniel also related the universal semantics of color to the psychophysical and neurophysiological results of Russel De Valois and his associates (e.g., De Valois, Abramov, and Jacobs 1966).

Since 1978, two important surveys of color lexicons have been conducted, both supporting the two broad Berlin and Kay hypotheses of semantic universals and evolutionary sequence in the lexical encoding of colors: the World Color Survey (Kay et al. 1997) and the Mesoamerican Color Survey (MacLaury 1997). Relativist objection to the Berlin and Kay paradigm of research on color categorization has continued, emphasis shifting away from criticism of the rigor with which the Berlin and Kay procedures of mapping words to colors were applied toward challenging the legitimacy of any such procedures (e.g., Lucy 1997; Saunders and van Brake l997)

Color, Neurophysiology of

Color vision is our ability to distinguish and classify lights of different spectral distributions. The first requirement of color vision is the presence in the RETINA of different photoreceptors with different spectral absorbances. The second requirement is the presence in the retina of postreceptoral neuronal mechanisms that process receptor outputs to produce suitable chromatic signals to be sent to the VISUAL CORTEX. The third requirement is a central mechanism that transforms the incoming chromatic signals into the color space within which the normal observer maps his sensations. A good deal is known of the neurophysiology and anatomy of the first two requirements, but very little is known of the third.

The visible range of light extends over a wavelength band from 400 to 700 nanometers (nm), from violet to red. Color vision has evolved in a number of species, including bees, fish, and birds, but among mammals only primates appear to use color as a major tool in their processing of visual scenes. Most natural colors, as opposed to those in the laboratory, are spectrally broad-band. There are many systems for specifying their spectral composition, ranging from simply the physical distribution across the spectrum, through industry standards based on descriptions of spectral mixtures as functions of three variables (for the three different photopigments in the human eye), to color spaces that attempt to reproduce the way in which we perceptually order colors (Wyszecki and Stiles 1982). For a cognitive psychologist, there are two different aspects of color vision: we are not only very good at distinguishing and classifying colors (under optimal conditions wavelength differences of just a few nanometers can be detected), but also color vision is very important in visual segmentation and OBJECT RECOGNITION.

Humans and Old World primates possess three different photoreceptor, or cone, types in the retina. A fourth type of photoreceptor, rods, is concerned with vision at low light levels and plays little role in color vision. The idea of three different cone types in human retina was derived from the empirical finding that any color can be matched by a mixture of three others. It was first proposed by Thomas Young in 1801, and taken up by Hermann von HELMHOLTZ later in the nineteenth century. The Young-Helmholtz theory came to be generally accepted, and the spectral absorbances of the three photopigments were determined through psychophysical measurements. However, it is only in recent years that it has become possible to directly demonstrate the presence of the three cones, either by measuring their spectral absorptions (Bowmaker 1991) or their electrical responses (Baylor, Nunn, and Schnapf 1987). The spectral absorbances peak close to 430, 535, and 565 nm, and preferred designations are short (S), middle (M), or long (L) wavelength cones, rather than color names such as blue, green, and red. It is important to realize that a single cone cannot deconfound intensity and wavelength; in order to distinguish colors, it is necessary to compare the outputs of two or more cone types.

There has been much recent interest in the molecular genetics of the photopigments in the cones, especially in the

reason why about 10 percent of the male population suffer from some degree of red-green color deficiency (Mollon 1997). The amino acids in the photopigment molecule that are responsible for pigment spectral tuning have been identified. A change in just a single amino acid can be detectable in an individual's color matches; it is rare for such a small molecular change to give rise to a measurable behavioral effect.

The spectral absorbances of the photopigments are broad, and this means that the signals from the different cones are highly correlated, especially with the broad-band spectra of the natural environment. This correlation gives rise to redundancy in the pattern of cone signals, and so postreceptoral mechanisms in the retina add or subtract cone outputs to code spectral distributions more efficiently, before signals are passed up the optic tract to the CEREBRAL CORTEX (Buchsbaum and Gottschalk 1983). Again, the first suggestion of such mechanisms came in the nineteenth century, from Oswald Hering. He proposed that there were black-white, red-green, and blue-yellow opponent processes in human vision, based on the impossibility of conceiving of reddish-green or bluish-yellow hues, whereas reddish-yellow is an acceptable color. Red, green, blue, and yellow are called the unique hues; it is possible to pick a wavelength that is uniquely yellow, without a reddish or greenish component.

Three main VISUAL PROCESSING STREAMS leave the primate retina to reach the cortex via the lateral geniculate nucleus. Each of them is associated with a very specific retinal circuitry, with signals being added or subtracted very soon after they have left the cones (Lee and Dacey 1997). One carries summed signals of the M- and L-cones; it is thought to form the basis of a luminance channel of PSYCHO-PHYSICS and is heavily involved in flicker and MOTION, PERCEPTION OF. It originates in a specific ganglion cell class, the parasol cells, and passes through the magnocellular layers of the lateral geniculate on the way to the cortex. A second channel carries the difference signal between the M- and L-cones, and forms the basis of a red-green detection channel of psychophysics. It begins in the midget ganglion cells of the retina and passes through the parvocellular layers of the lateral geniculate. The third channel carries the difference signal between the S-cones and a sum of the other two, and it is the basis of a blue-yellow detection mechanism. It begins in the small bistratified ganglion cells and passes through intercalated layers in the lateral geniculate. These red-green and blue-yellow mechanisms account well for our ability to detect small differences between colors. Neurophysiology and anatomy of these peripheral chromatic mechanisms have been established in some detail (Kaplan, Lee, and Shapley 1990; Lee 1996). It is thought that the S-cone and blue-yellow system is phylogenetically more ancient than the red-green one, and it is present in most mammals (Mollon 1991). Separate M- and L-cones and the red-green mechanism have evolved only in primates.

The lateral geniculate nucleus is not thought to substantially modify color signals from the retina, but what happens in the cerebral cortex is uncertain. It is possible to determine the spectral sensitivity of the opponent processes of Hering (Hurvich 1981), and it turns out that our perceptual color opponent space has different spectral properties compared to the cone difference signals that leave the retina, and that we use to distinguish small color differences. Put another way, the unique hues do not map directly onto the cone-opponent signals emanating from the retina. Transformation of retinal signals to produce our perceptual, opponent color space can be modeled (Valberg and Seim 1991; DeValois and DeValois 1993), but how this occurs neurophysiologically is unknown; it is even uncertain whether we should look for single cells in the cortex that code for Hering's opponent processes or unique hues, or whether these are an emergent property of the cortical cell network (Mollon and Jordan 1997).

It is generally thought that a high concentration of color-specific neurons are found in the cytochrome oxidase blobs in primary visual cortex (see Merigan and Maunsell 1993 for review). Some of these cells resemble retinal ganglion cells in their spectral properties; others do not (Lennie, Krauskopf, and Sclar 1990). These color-specific signals are then passed on to the temporal visual processing stream. Color signals do not seem to flow into the parietal visual processing stream, which has much to do with motion perception and is dominated by the magnocellular pathway.

Many cognitive aspects of COLOR VISION emerge at the cortical level. For example, so-called surface colors depend on the context in which they are seen; the color brown depends on a given spectral composition being set in a brighter surround. If the same spectral composition were viewed in a black surround, it would appear yellowish. The limited range of colors that can be seen in isolation, in a dark surround, are called aperture colors. Another important emergent feature is color constancy, our ability to correctly identify the color of objects despite wide changes in the spectral composition of illumination, which of course changes the spectral reflectance of light from a surface. Color constancy is not perfect, and is a complex function of the spectral and spatial characteristics of a scene (Pokorny, Shevell, and Smith 1991). It has been proposed that color constancy emerges in a secondary visual cortical area, V4 (Zeki 1980, 1983), but this remains controversial. Lastly, color also plays an important role in many higher order visual functions, such as SURFACE PERCEPTION or object identification. The neurophysiological correlates in the cortex of these higher order color vision functions are unknown, and are likely to be very difficult to ascertain. It seems probable that many of these functions are distributed through cortical neuronal networks, rather than existing as specific and well-defined chromatic channels, as in the retina.

Color Vision

Color vision is the ability to detect and analyze changes in the wavelength composition of light. As we admire a rainbow, we perceive different colors because the light varies in wavelength across the width of the bow.

An important goal of color science is to develop PSYCHOLOGICAL LAWS that allow prediction of color appearance from a physical description of stimuli. General laws have been elusive because the color appearance of a stimulus is strongly affected by the context in which it is seen. One well-known example is simultaneous color contrast. Color plates illustrating the color contrast can be found in most perception textbooks (e.g., Wandell 1995; Goldstein 1996; see also Evans 1948; Albers 1975; Wyszecki 1986).

In everyday use, we describe color appearance using simple color names, such as "red," "green," and "blue." There is good agreement across observers and cultures about the appropriate color name for most stimuli (see COLOR CATEGORIZATION). Technical and scientific use requires more precise terms. The purpose of a color order system is to connect physical descriptions of color stimuli with their appearance (see Derefeldt 1991; Wyszecki and Stiles 1982). Each color order system specifies a lexicon for color. Observers then scale (see PSYCHOPHYSICS) a large number of calibrated color stimuli using this lexicon, and from such data the relation between stimuli and names is determined. Examples of color order systems include the Munsell Book of Color and the Swedish Natural Color System (NCS). Note that color order systems do not address the problem of how context affects color appearance. Rather, each system specifies a particular configuration in which stimuli should be viewed if the system is to apply.

People are sensitive to wavelengths between 400 nanometers and 700 nanometers (nm); hence this region is called the visible spectrum. The chromatic properties of light are specified by how much energy the light contains at every wavelength in the visible spectrum. This specification is called the light's spectral power distribution. Color vision is mediated by three classes of cone photoreceptor. Each class of cones is characterized by its spectral sensitivity, which specifies how strongly that class responds to light energy at different wavelengths; the three classes of cones have their peak sensitivities in different regions of the visible spectrum, roughly at long (L), middle (M), and short (S) wavelengths. How the cones encode information about the spectral power distribution of light is discussed in RETINA and COLOR, NEUROPHYSIOLOGY OF (see also Wandell 1995).

Physically different lights can produce identical responses in all three classes of cones. Such lights, called metamers, are indistinguishable to the visual system (see Wyszecki and Stiles 1982; Brainard 1995). It is possible to construct metamers by choosing three primary lights and allowing an observer to mix them in various proportions. If the primaries are well chosen, essentially any other light can be matched through their mixture. This fact is known as the trichromacy of human color vision (see Wyszecki and Stiles 1982; Wandell 1995; Kaiser and Boynton 1996). Trichromacy facilitates most color reproduction technologies. Color television, for example, produces colors by mixing light emitted by just three phosphors, and color printers use only a small number of inks (see Hunt 1987).

Some people are color blind, usually because they lack one or more classes of cone. Individuals missing one class of cone are called dichromats. Consider a pair of lights which produce the same responses in the M- and S-cones but a different response in the L-cones. A normal trichromat will have no difficulty distinguishing the lights because of their different L-cone response. To a dichromat with no L-cones, however, the two lights will appear identical. Thus dichromats confuse lights that trichromats distinguish. In the most common forms of dichromacy, either the L- or M-cones are missing. This is often called red-green color blindness because of consequent confusions between reds and greens. Red-green dichromacy occurs more frequently in males

(about 2% of Caucasian males) than females (about 0.03% of Caucasian females). The rate in females is lower because the genes that code the L- and M-cone photopigments are on the X-chromosome. There are other forms of color blindness and anomalous color vision (see Pokorny et al. 1979).

Different species code color differently. Many mammals are dichromats with correspondingly less acute color vision than most humans. In addition, for two species with the same number of cones, color vision can differ because the cones of each species have different spectral sensitivities. Bees, for example, are trichromatic but have cones sensitive to ultraviolet light (Menzel and Backhaus 1991). Thus bees are sensitive to differences in spectral power distributions that humans cannot perceive, and vice versa. Note that the color categories perceived by humans are unlikely to match those of other species. Behavioral studies indicate that humans and pigeons group regions of the visible spectrum quite differently (see Jacobs 1981).

A key idea about postreceptoral color vision is the idea that signals from the separate cone classes are compared in color opponent channels, one signaling redness and greenness and a second signaling blueness and yellowness (Wandell 1995; Kaiser and Boynton 1996). An informal observation that supports the idea of opponency is that we rarely experience a single stimulus as being simultaneously red and green or simultaneously blue and yellow. Quantitative behavioral and physiological evidence also supports the idea of color opponency.

Why is color vision useful? With some notable exceptions (e.g. rainbows and signal lights), we rarely use color to describe the properties of lights per se. Rather, color vision informs us about objects in the environment. First, color helps us distinguish objects from clutter: ripe fruit is easy to find because of color contrast between the fruit and leaves. Second, color tells us about the properties of objects: we avoid eating green bananas because their color provides a cue to their ripeness. Finally, color helps us identify objects: we find our car in a crowded parking lot because we know its color (for more extended discussions, see Jacobs 1981; Mollon 1989).

The spectral power distribution of the color signal reflected from an object to an observer depends on two physical factors. The first factor is the spectral power distribution of the illuminant incident on the object. This varies considerably over the course of a day, with weather conditions, and between natural and artificial illumination. The second factor is the object's surface reflectance function, which specifies, at each wavelength, what fraction of the incident illuminant is reflected. For color to be a reliable indicator about object properties and identity, the visual system must separate the influence of the illuminant on the color signal from the influence of the surface reflectance. To the extent that the human visual system does so, we say that it is color constant.

The problem of color constancy is analogous to the problem of lightness constancy (see LIGHTNESS PERCEPTION). More generally, color constancy embodies an ambiguity that is at the core of many perceptual problems: multiple physical configurations can produce the same image (see COMPUTATIONAL VISION). Human vision has long been believed to exhibit approximate color constancy (e.g., Boring 1942; Evans 1948). Developing a quantitative account of human color constancy and understanding the computations that underlie it is an area of active current research (see Wandell 1995; Kaiser and Boynton 1996).

Columns and Modules

The CEREBRAL CORTEX sits atop the white matter of the brain, its 2 mm thickness subdivided into about six layers. Neurons with similar interests tend to cluster. Columns are usually subdivisions at the submillimeter scale, and modules are thought to occupy the intermediate millimeter scale, between maps and columns. Empirically, a column is simply a submillimeter region where many (but not all) neurons seem to have functional properties in common. They come in two sizes, with separate organizational principles. Minicolumns are about 23–65 μm across, and there are hundreds of them inside any given 0.4–1.0 mm macrocolumn.

Each cerebral hemisphere has about 52 "areas" distinguished on the basis of differences between the thickness of their layers; on average, a human cortical area is about half the size of a business card. Though area 17 seems to be a consistent functional unit, other areas prove to contain a half-dozen distinct physiological subdivisions ("maps") on the centimeter scale.

Both columns and modules may be regarded as the outcomes of a self-organizing tendency during development, patterns that emerge as surely as the hexagons of a honeycomb arise from the pounding of so many hemispherical bee's heads on the soft wax of tunnel walls. The hexagonal shape is an emergent property of such competition for territory; similar competition in the cortex may continue throughout adult life, maintaining a shifting mosaic of cortical columns.

A column functionally ties together all six layers. Layers *II* and *III* can usually be lumped together, as when one talks of the superficial pyramidal neurons. But layer *IV* has had to be repeatedly subdivided in the visual cortex (*IVa, IVb, IVc*α, *IVc*β). Layer *IV* neurons send most of their outputs up to *II* and *III*. Some superficial neurons send messages down to *V* and *VI*, though their most prominent connections (either laterally in the layers or via U-fibers in white matter) are within their own layers. Layer *VI* sends messages back down to the THALAMUS via the white matter, while *V* sends signals to other deep and distant neural structures, sometimes even the spinal cord.

For any column of cortex, the bottom layers are like a subcortical outgoing mailbox, the middle layer like an inbox, and the superficial layers somewhat like an interoffice mailbox spanning the columns and reaching out to other cortical areas (Calvin and Ojemann 1994). Indeed, Diamond (1979) argues that the "motor cortex" isn't restricted to the motor strip but is the fifth layer of the entire cerebral cortex. That's because *V*, whatever the area, contains neurons that at some stage of development send their outputs down to the spinal cord, with copies to the brain stem, BASAL GANGLIA, and hypothalamus. Likewise the fourth layer everywhere is the "sensory cortex," and the second and third layers everywhere are the true "association cortex" in this view.

Minicolumns appear to be formed from dendritic bundles. Ramón y CAJAL saw connect-the-dots clusters of cell bodies, running from white matter to the cortical surface; these hair-thin columns are about 30 µm apart in human cortex. It now appears that a column is like a stalk of celery, a vertical bundle containing axons and apical dendrites from about 100 neurons (Peters and Yilmaz 1993) and their internal microcircuitry.

Macrocolumns may, in contrast, reflect an organization of the input wiring, for example, corticocortical terminations from different areas often terminate in interdigitating zones about the width of a thin pencil lead. In 1957, Mountcastle and his coworkers discovered a tendency for somatosensory strip neurons responsive to skin stimulation (hair, light touch) to alternate with those specializing in joint and muscle receptors about every 0.5 mm. It now appears that there is a mosaic organization of similar dimensions, the neurons within each macrocolumn (or "segregate") having a receptive field optimized for the same patch of body surface (Favorov and Kelly 1994).

Hubel and Wiesel, recording in monkey visual cortex, saw curtainlike clusters ("ocular dominance columns") that specialized in the left eye, with an adjacent cluster about 0.4 mm away specializing in the right eye. As seems appropriate for an outcome of self-organization, average size varies among individuals over 0.4–0.7 mm; those with smaller ocular dominance columns have more of them (Horton and Hocking 1996).

Orientation columns are of minicolumn dimensions, within which the neurons prefer lines and edges that are tilted about the same angle from the vertical; there are many such minicolumns specializing in various angles within an ocular dominance macrocolumn (Hubel and Wiesel 1977). The relationships between minicolumns and macrocolumns are best seen in VISUAL CORTEX, though it may be hazardous to generalize from this because ocular dominance columns themselves are less than universal; for instance, they are not a typical feature of New World monkeys.

Color blobs are clusters of COLOR-sensitive neurons in the cortex at macrocolumnar spacing but involving only neurons of the superficial layers and not extending throughout all cortical layers, as in a proper column. Recently, recurrent excitation in the superficial layers has been identified as a coordinating (and perhaps self-organizing) principle among distant minicolumns (Calvin 1995). The superficial pyramids send myelinated axons out of the cortical layers into the white matter; their eventual targets are typically the superficial layers of other cortical areas when of the "feedback" type; when "feedforward" they terminate in *IV* and deep *III*.

But superficial pyramidal neurons also send unmyelinated collaterals sideways, with an unusual patterning that suggests a columnar organizing principle. Like an express train that skips intermediate stops, the collateral axon travels a characteristic lateral distance without giving off any terminal branches; then it produces a tight terminal cluster (see fig. 5 in Gilbert 1993). The axon may continue for many millimeters, repeating such clusters about every 0.43 mm in primary visual cortex, 0.65 mm in the secondary visual areas, 0.73 mm in sensory strip, and 0.85 mm in motor cortex of monkeys (Lund, Yoshioka, and Levitt 1993). Because of this local standard for axon length, mutual re-excitation becomes probable among some cell pairs. Macrocolumns of similar emphasis are seen to be connected by such synchronizing excitation. Calvin (1996) argues that these express connections could implement a Darwinian copying competition among Hebbian cell-assemblies on the time scale of thought and action, providing one aspect of CONSCIOUSNESS.

Though COMPUTATIONAL NEUROANATOMY has proved more complex, it has been widely expected that cerebral cortex will turn out to have circuits which, in different cortical patches, are merely repeats of a standard "modular" pattern, something like modular kitchen cabinets. Columns, barrels, blobs, and stripes have all been called modules, and the term is loosely applied to any segmentation

or repeated patchiness (Purves, Riddle, and LaMantia 1992) and to a wide range of functional or anatomical collectives. The best candidate for a true module was the "hypercolumn" (Hubel and Wiesel 1977): two adjacent ocular dominance columns, each containing a full set of orientation columns, suggested similar internal wiring, whatever the patch of visual field being represented. However, newer mapping techniques have shown that ocular dominance repeats are somewhat independent of orientation column repeats (Blasdel 1992), making adjacent hypercolumns internally nonidentical, that is, not iterated circuitry. Module remains a fuzzy term for anything larger than a macrocolumn but smaller than a map—though one increasingly sees it used as a trendy word denoting any cortical specialization, for example, modules as the foundation for "multiple intelligences."

Comparative Psychology

The comparative study of animal and human cognition should be an important part of cognitive science. The field of comparative psychology, however, emerged from the paradigm of BEHAVIORISM and so has not contributed greatly toward this end. The reasons for this are telling and help to explicate the main directions of modern evolutionary thinking about behavior and cognition.

The general program of comparative psychology began with Charles DARWIN's *Origin of Species* (1859). Darwin believed that the comparative study of animal behavior and cognition was crucial both for reconstructing the phylogenies of extant species (behavioral comparisons thus supplementing morphological comparisons) and for situating the behavior and cognition of particular species, including humans, in their appropriate evolutionary contexts. Toward these ends, Darwin (1871, 1872) reported some informal comparisons between the behavior of humans and nonhuman animals, as did his disciples Spencer (1894), Hobhouse (1901), and Romanes (1882, 1883). The goal was thus clear: to shed light on human cognition through a study of its evolutionary roots as embodied in extant animal species.

Arising as a reaction to some of the anthropomorphic excesses of this tradition was behaviorism. During the early and middle parts of the century, researchers such as Watson, Thorndike, and Tolman espoused the view that the psychology of nonhuman animals was best studied not informally or

anecdotally, but experimentally in the laboratory. Within this tradition, some psychologists became interested in comparing the learning skills of different animal species in a quantitative manner, and this procedure came to be known as comparative psychology. One especially well-known series of studies was summarized by Bitterman (1965), who compared several species of insect, fish, and mammal on such things as speed to learn a simple perceptual discrimination, speed to learn a reversal of contingencies, and other discrimination learning skills. An implicit assumption of much of this work was that just as morphology became ever more complex from insect to fish to mammals to humans, so behavior should show this same "progression" (see Rumbaugh 1970 and Roitblatt 1987 for more modern versions of this approach).

Comparative psychology came under attack from its inception by researchers who felt that studying animals outside of their natural ecologies, on experimental tasks for which they were not naturally adapted, was a futile, indeed a misguided, enterprise (e.g., Beach 1950; Hodos and Campbell 1969). They charged that studies such as Bitterman's smacked of a *scalae natura* in which some animals were "higher" or "more intelligent" than others, with, of course, humans atop the heap. That is, many of the comparative studies of learning implicitly assumed that nonhuman animals represented primitive steps on the way to humans as evolutionay *telos*. This contradicted the established Darwinian fact of treelike branching evolution in which no living species was a primitive version of any other living species, but rather each species was its own *telos*.

Another blow to comparative psychology came from experiments such as those of Garcia and Koelling (1966), which demonstrated that different species were evolutionarily prepared to learn qualitatively different things from their species-typical environments. More generally, many studies emanating from the traditions of ETHOLOGY and behavioral ecology at this same time demonstrated that different animal species were adapted to very different aspects of the environment and therefore that comparisons along any single behavioral dimension, such as learning or intelligence, were hopelessly simplistic and missed the essential richness of the behavioral ecology of organism-environment interactions (see Eibl-Eibesfeldt 1970 for a review). Ethologists and behavioral ecologists were much less interested in finding general processes or principles that spanned all animal species than were comparative psychologists, and they were much less inclined to treat human beings as any kind of special species in the evolutionary scheme of things.

Today, most scientists who study animal behavior have incorporated the insights of the ethologists and behavioral ecologists into their thinking so that it would currently be difficult to locate any individuals who call themselves comparative psychologists in the classic meaning of the term (see Dewsbury 1984a, 1984b for a slightly different perspective). However, there does exist a journal called the *Journal of Comparative Psychology*, and many important studies of animal behavior are published there—mostly experimental studies of captive animals (as opposed to ethological studies, which are more often naturalistic). In contrast to the classic, behavioristic form of comparative psychology, modern comparative studies pay much more attention to the particular cognitive skills of particular species and how these are adapted to particular aspects of specific ecological niches. This enterprise is sometimes called COGNITIVE ETHOLOGY.

For these same reasons, modern comparative studies typically compare only species that are fairly closely related to one another phylogenetically—thus assuring at least some commonalities of ecology and adaptation based on their relatively short times as distinct species. As one example, in the modern study of primate cognition there are currently debates over possible differences between Old World monkeys and apes, whose common ancestor lived about 20 to 30 million years ago. Some researchers claim that monkeys live in an exclusively sensori-motor world of the here-and-now and that only apes have cognitive representations of a humanlike nature (Byrne 1995). Other researchers claim that all nonhuman primates cognitively represent their worlds for purposes of foraging and social interaction, but that only humans employ the forms of symbolic representation that depend on culture, intersubjectivity, and language (Tomasello and Call 1997). These kinds of theoretical debates and the research they generate employ the comparative method, but they do so in much more ecologically and evolutionarily sensitive ways than most of the debates and research in classical comparative psychology.

Comparative studies, in the broad sense of the term, are important for cognitive science in general because: (1) they document something of the range of cognitive skills that have evolved in the natural world and how these work; (2) they help to identify the functions for which particular cognitive skills have evolved, thus specifying an important dimension of their nature; and (3) they situate the cognition of particular species, including humans, in their appropriate evolutionary contexts, which speaks directly to such crucial questions as the ontogenetic mechanisms by which cognitive skills develop in individuals.

Compositionality

Compositionality, a guiding principle in research on the SYNTAX-SEMANTICS INTERFACE of natural languages, is typically stated as follows: "The meaning of a complex expression is a function of the meanings of its immediate syntactic parts and the way in which they are combined." It says, for example, that the meaning of the sentence

$$_S [_{NP} \textit{Zuzana} [_{VP} [_V \textit{owns}] [_{NP} \textit{a schnauzer}]]],$$

where the commonly assumed syntactic structure is indicated by brackets, can be derived from the meanings of the NP *Zuzana* and the VP *owns a schnauzer,* and the fact that this NP and VP are combined to form a sentence. In turn, the meaning of *owns a schnauzer* can be derived from the meanings of *owns* and *a schnauzer* and the fact that they form a VP; hence, the principle of compositionality applies recursively. The principle is implicit in the work of Gottlob FREGE (1848–1920), and was explicitly assumed by Katz and Fodor (1963) and in the work of Richard Montague and his followers (cf. Dowty, Wall, and Peters 1981).

In some form, compositionality is a virtually necessary principle, given the fact that natural languages can express an infinity of meanings and can be learned by humans with finite resources. Essentially, humans have to learn the meanings of basic expressions, the words in the LEXICON (in the magnitude of 10^5), and the meaning effects of syntactic combinations (in the magnitude of 10^2; see SYNTAX). With that they are ready to understand an infinite number of syntactically well-formed expressions. Thus, compositionality is necessary if we see the language faculty, with Wilhelm von Humboldt, as making infinite use of finite means. But compositionality also embodies the claim that semantic interpretation is local, or modular. In order to find out what a (possibly complex) expression *A* means, we just have to look at *A,* and not at the context in which *A* occurs. In its strict version, this claim is clearly wrong, and defenders of compositionality have to account for the context sensitivity of intepretation in one way or other.

There are certain exceptions to compositionality in the form stated above. Idioms and compounds are syntactically complex but come with a meaning that cannot be derived from their parts, like *kick the bucket* or *blackbird.* They have to be learned just like basic words. But compositionality does allow for cases in which the resulting meaning is due to a syntactic construction, as in the comparative construction *The higher they rise, the deeper they fall.* Also, it allows for constructionally ambiguous expressions like *French teacher*: *French* can be combined with *teacher* as a modifier ("teacher from France"), or as an argument ("teacher of French"). Even though the constituents are arguably the same, the syntactic rules by which they are combined differ, a difference that incidentally shows up in stress (see STRESS, LINGUISTIC).

A hidden assumption in the formulation of the principle of compositionality is that the ways in which meanings are combined are, in some difficult-to-define sense, "natural." Even an idiom like *red herring* would be compositional if we allowed for unnatural interpretation rules like "The meaning of a complex noun consisting of an adjective and a noun is the set of objects that fall both under the meaning of the adjective and the meaning of the noun, except if the adjective is *red* and the noun is *herring,* in which case it may also denote something that distracts from the real issue." But often we need quite similar rules for apparently compositional expressions. For example, *red hair* seems to be compositional, but if we just work with the usual meaning of red (say, "of the color of blood"), then it would mean something like "hair of the color of blood." *Red hair* can mean that (think of a punk's hair dyed red), but typically is understood differently. Some researchers have questioned compositionality because of such context-dependent interpretations (cf. Langacker 1987). But a certain amount of context sensitivity can be built into the meaning of lexical items. For example, the context-sensitive interpretation of *red* can be given as: "When combined with a noun meaning N, it singles out those objects in N that appear closest to the color of blood for the human eye." This would identify ordinary red hair when combined with *hair.* Of course, prototypical red hair is not prototypically red; see Kamp and Partee (1995) for a discussion of compositionality and prototype theory.

Another type of context-sensitive expression that constitutes a potential problem for compositionality is pronouns. A sentence like *She owns a schnauzer* may mean different things in different contexts, depending on the antecedent of *she.* The common solution is to bring context into the formulation of the principle, usually by assuming that "meanings" are devices that change contexts by adding new information (as in models of DYNAMIC SEMANTICS, cf. Heim 1982; Groenendijk and Stokhof 1991). In general, compositionality has led to more refined ways of understanding MEANING (cf. e.g., FOCUS).

In the form stated above, compositionality imposes a homomorphism between syntactic structure and semantic interpretation: syntactic structure and semantic interpretation go hand in hand. This has led to a sophisticated analysis of the meaning of simple expressions. For example, while logic textbooks will give as a translation of *John and Mary came* a formula like C(j) ∧ C(m), it is obvious that the structures of these expressions are quite different—the syntactic constituent *John and Mary* does not correspond to any constituent in the formula. But we can analyze *John and Mary* as a QUANTIFIER, λX[X(j) ∧ X(m)], that is applied to *came,* C, and thus gain a structure that is similar to the English sentence. On the other hand, compositionality may impose certain restrictions on syntactic structure. For example, it favors the analysis of relative clauses as noun modifiers, [*every* [*girl who came*]], over the analysis as NP modifiers [[*every girl*] [*who came*]], as only the first allows for a straightforward compositional interpretation (cf. von Stechow 1980).

Compositionality arguments became important in deciding between theories of interpretation. In general, semantic theories that work with a representation language that allows for unconstrained symbolic manipulation (such as Discourse Representation Theory—Kamp 1981; Dynamic Semantics, or Conceptual Semantics—Jackendoff 1990) give up the ideal of compositional interpretation. But typically, compositional reformulations of such analyses are possible.

Computation

No idea in the history of studying mind has fueled such enthusiasm—or such criticism—as the idea that the mind is a computer. This idea, known as "cognitivism" (Haugeland 1981/1998) or the COMPUTATIONAL THEORY OF MIND, claims not merely that our minds, like the weather, can be modeled on a computer, but more strongly that, at an appropriate level of abstraction, we *are* computers.

Whether cognitivism is true—even what it means—depends on what computation is. One strategy for answering that question is to defer to practice: to take as computational whatever society *calls* computational. Cognitivism's central tenet, in such a view, would be the thesis that people share with computers whatever constitutive or essential property binds computers into a coherent class. From such a vantage point, a theory of computation would be *empirical,* subject to experimental evidence. That is, a theory of computation would succeed or fail to the extent that it was able to account for the machines that made Silicon Valley famous: the devices we design, build, sell, use, and maintain.

Within cognitive science, however, cognitivism is usually understood in a more specific, theory laden, way: as building in one or more substantive claims about the nature of computing. Of these, the most influential (especially in cognitive science and artificial intelligence) has been the claim that computers are *formal symbol manipulators* (i.e., actively embodied FORMAL SYSTEMS). In this three-part characterization, the term "symbol" is taken to refer to any causally efficacious internal token of a concept, name, word, idea, representation, image, data structure, or other ingredient that represents or carries information about something else (*see* INTENTIONALITY). The predicate "formal" is understood in two simultaneous ways: *positively,* as something like *shape, form,* or *syntax,* and *negatively,* as *independent of semantic properties,* such as reference or truth. *Manipulation* refers to the fact that computation is an active, embodied process—something that takes place in time. Together, they characterize computation as involving the active manipulation of semantic or intentional ingredients in a way that depends only on their formal properties. Given two data structures,

for example, one encoding the fact that Socrates is a man, the other that all men are mortal, a computer (in this view) could draw the conclusion that Socrates is mortal *formally* (i.e., would honor what Fodor 1975 calls the "formality condition") if and only if it could do so by reacting to the form or shape of the implicated data structures, without regard to their truth, reference, or MEANING.

In spite of its historical importance, however, it turns out that the formal symbol manipulation construal of computing is only one of half a dozen different ideas at play in present-day intellectual discourse.

Among alternatives, most significant is the body of work carried on in theoretical computer science under the label *theory of computation*. This largely automata-theoretic conception is based on Turing's famous construction of a "Turing machine": a finite state controller able to read, write, and move sequentially back and forth along an infinitely long tape that is inscribed with a finite but indefinite number of tokens or marks. It is this Turing-based theory that explains the notion of a *universal computer* on which the CHURCH-TURING THESIS rests (that anything that can be done algorithmically at all can be done by a computer). Although the architecture of Turing machines is specific, Turing's original paper (1936/1965) introduced the now ubiquitous idea of *implementing* one (virtual) architecture on top of another, and so the Church-Turing thesis is not considered to be architecturally bound. The formal theory of Turing machines is relatively abstract, and used primarily for theoretical purposes: to show what can and cannot be computed, to demonstrate complexity results (how much work is required to solve certain classes of problems), to assign formal semantics to programming languages, etc. Turing machines have also figured in cognitive science at a more imaginative level, for example in the classic formulation of the Turing test: a proposal that a computer can be counted as intelligent if it is able to mimic a person answering a series of typed questions sufficiently well to fool an observer.

Because of their prominence in theoretical computer science, Turing machines are often thought to capture the essential nature of computing—even though, interestingly, they are not explicitly characterized in terms of either SYNTAX or formality. Nor do these two models, formal systems and Turing machines, exhaust extant ideas about the fundamental nature of computing. One popular third alternative is that computation is *information processing*—a broad intuition that can be broken down into a variety of subreadings, including syntactic or quantitative variants (*à la* Shannon, Kolmogorov, Chaitin, etc.), semantic versions (*à la* Dretske, Barwise and Perry, Halpern, Rosenschein, etc.), and historical or socio-technical readings, such as the notion of information that undergirds public conceptions of the Internet. Yet another idea is that the essence of being a computer is to be a *digital state machine.* In spite of various proofs of broad behavioral equivalence among these proposals, for purposes of cognitive science it is essential to recognize that these accounts are conceptually distinct. The notion of formal symbol manipulation makes implicit reference to both syntax and semantics, for example, whereas the notion of a digital machine does neither; the theory of Turing computa-

bility is primarily concerned with input-output behavior, whereas formal symbol manipulation focuses on internal mechanisms and ways of working. The proposals are distinct in extension as well, as continuous Turing machines can solve problems unsolvable by digital (discrete) computers; not all digital machines (such as Lincoln Log houses) are symbol manipulators; and information, especially in its semantic reading as a counterfactual-supporting correlation, seems unrestricted by the causal locality that constrains the notion of effectiveness implicit in Turing machines.

It is not only at the level of basic theory or model that computation affects cognitive science. Whatever their underlying theoretical status, it is undeniable that computers have had an unprecedented effect on the human lives that cognitive science studies—both technological (e-mail, electronic commerce, virtual reality, on-line communities, etc.) and intellectual (in artificial intelligence projects, attempts to fuse computation and quantum mechanics, and the like). It is not yet clear, however, how these higher level developments relate to technical debates within cognitive science itself. By far the majority of real-world systems are written in such high-level programming languages as Fortran, C++, and Java, for example. The total variety of software architectures built in such languages is staggering—including data and control structures of seemingly unlimited variety (parallel and serial, local and distributed, declarative and procedural, sentential and imagistic, etc.). To date, however, this architectural profusion has not been fully recognized within cognitive science. Internal to cognitive science, the label "computational" is often associated with one rather specific class of architectures: serial systems based on relatively fixed, symbolic, explicit, discrete, high-level representations, exemplified by axiomatic inference systems, KNOWLEDGE REPRESENTATION systems, KNOWLEDGE-BASED SYSTEMS, etc. (van Gelder 1995).

This classic symbolic architecture is defended, for example by Fodor and Pylyshyn (1988), because of its claimed superiority in dealing with the systematicity, productivity, and compositionality of high-level thought. Its very specificity, however, especially in contrast with the wide variety of architectures increasingly deployed in computational practice, seems responsible for a variety of self-described "non-" or even "anti-" computational movements that have sprung up in cognitive science over the last two decades: connectionist or neurally inspired architectures (see COGNITIVE MODELING, CONNECTIONIST and CONNECTIONISM, PHILOSOPHICAL ISSUES); DYNAMIC APPROACHES TO COGNITION; shifts in emphasis from computational models to cognitive neuroscience; embodied and situated architectures that exploit various forms of environmental context dependence (see SITUATEDNESS/EMBEDDEDNESS); so-called complex adaptive systems and models of ARTIFICIAL LIFE, motivated in part by such biological phenomena as random mutation and evolutionary selection; interactive or even merely reactive robotics, in the style of Brooks (1997), Agre and Chapman (1987); and other movements. These alternatives differ from the classical model along a number of dimensions: (i) they are more likely to be parallel than serial; (ii) their ingredient structures, particularly at the

design stage, are unlikely to be assigned representational or semantic content; (iii) such content or interpretation as is ultimately assigned is typically based on use or experience rather than pure denotation or description, and to be "non-conceptual" in flavor, rather than "conceptualist" or "symbolic"; (iv) they are more likely to be used to model action, perception, navigation, motor control, bodily movement, and other forms of coupled engagement with the world, instead of the traditional emphasis on detached and even deductive ratiocination; (v) they are much more likely to be "real time," in the sense of requiring a close coupling between the temporality of the computational process and the temporality of the subject domain; and (vi) a higher priority is typically accorded to flexibility and the ability to cope with unexpected richness and environmental variation rather than to deep reasoning or purely deductive skills.

Taken collectively, these changes represent a sea change in theoretical orientation within cognitive science—often described in contrast with traditional "computational" approaches. Without a richer and more widely agreed upon theory of computation, however, able to account for the variety of real-world computing, it is unclear that these newly proposed systems should be counted as genuinely "noncomputational." No one would argue that these new proposals escape the COMPUTATIONAL COMPLEXITY limits established by computer science's core mathematical theory, for example. Nor can one deny that real-world computing systems are moving quickly in many of the same directions (toward parallelism, real-time interaction, etc.). Indeed, the evolutionary pace of real-world computing is so relentless that it seems a safe bet to suppose that, overall, society's understanding of "computation" will adapt, as necessary, to subsume all these recent developments within its ever-expanding scope.

Computation and the Brain

Two very different insights motivate characterizing the brain as a computer. The first and more fundamental assumes that the defining function of nervous systems is *representational*; that is, brain states represent states of some other system—the outside world or the body itself—where transitions between states can be explained as computational operations on representations. The second insight derives from a domain of mathematical theory that defines computability in a highly abstract sense.

The mathematical approach is based on the idea of a Turing machine. Not an actual machine, the Turing machine is a conceptual way of saying that any well-defined function could be executed, step by step, according to simple "if you are in state P and have input Q then do R" rules, given enough time (maybe infinite time; see COMPUTATION). Insofar as the brain is a device whose input and output can be characterized in terms of some mathematical function— however complicated—then in that very abstract sense, it can be mimicked by a Turing machine. Because neurobiological data indicate that brains are indeed cause-effect machines, brains are, in this formal sense, equivalent to a Turing machine (see CHURCH-TURING THESIS). Significant though this result is mathematically, it reveals nothing specific about the nature of mind-brain representation and computation. It does not even imply that the best explanation of brain function will actually be in computational/representational terms. For in this abstract sense, livers, stomachs, and brains—not to mention sieves and the solar system—*all* compute. What is believed to make brains unique, however, is their evolved capacity to represent the brain's body and its world, and by virtue of computation, to produce coherent, adaptive motor behavior in real time. Precisely what properties enable brains to do this requires empirical, not just mathematical, investigation.

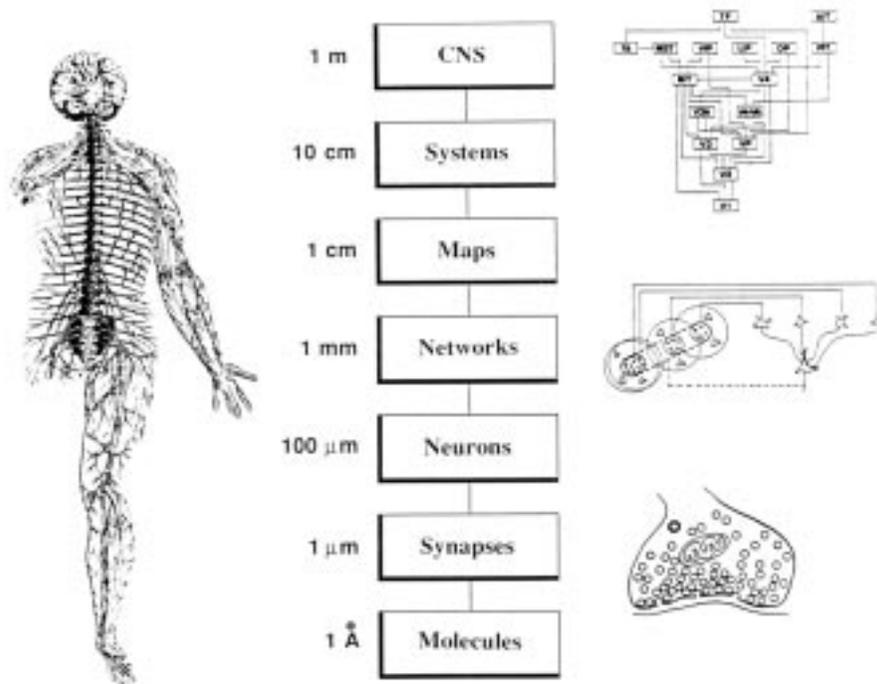
Broadly speaking, there are two main approaches to addressing the substantive question of how in fact brains represent and compute. One exploits the model of the familiar serial, digital computer, where representations are symbols, in somewhat the way sentences are symbols, and computations are formal rules (algorithms) that operate on symbols, rather like the way that "if-then" rules can be deployed in formal logic and circuit design. The second approach is rooted in neuroscience, drawing on data concerning how the cells of the brain (neurons) respond to outside signals such as light and sound, how they integrate signals to extract high-


Figure 1. Diagram showing the major levels of organization of the nervous system.

order information, and how later stage neurons interact to yield decisions and motor commands. Although both approaches ultimately seek to reproduce input-output behavior, the first is more "top-down," relying heavily on computer science principles, whereas the second tends to be more "bottom-up," aiming to reflect relevant neurobiological constraints. A variety of terms are commonly used in distinguishing the two: algorithmic computation versus signal processing; classical artificial intelligence (AI) versus connectionism; AI modeling versus neural net modeling.

For some problems the two approaches can complement each other. There are, however, major differences in basic assumptions that result in quite different models and theoretical foci. A crucial difference concerns the idea of levels. In 1982, David MARR characterized three levels in nervous systems. That analysis became influential for thinking about computation. Based on working assumptions in computer science, Marr's proposal delineated (1) the computational level of *abstract problem analysis* wherein the task is decomposed according to plausible engineering principles; (2) the level of the ALGORITHM, specifying a formal procedure to perform the task, so that for a given input, the correct output results; and (3) the level of physical *implementation,* which is relevant to constructing a working device using a particular technology. An important aspect of Marr's view was the claim that a higher level question was independent of levels below it, and hence that problems of levels 1 and 2 could be addressed independently of considering details of the implementation (the neuronal architecture). Consequently, many projects in AI were undertaken on the expectation that the known parallel, analog, continuously adapting, "messy" architecture of the brain could be ignored as irrelevant to modeling mind/brain function.

Those who attacked problems of cognition from the perspective of neurobiology argued that the neural architecture imposes powerful constraints on the *nature* and *range* of computations that can be performed in real time. They suggested that implementation and computation were much more *inter*dependent than Marr's analysis presumed. For example a visual pattern recognition task can be performed in about 300 milliseconds (msec), but it takes about 5–10 msec for a neuron to receive, integrate, and propagate a signal to another neuron. This means that there is time for no more than about 20–30 neuronal steps from signal input to motor output. Because a serial model of the task would require many thousands of steps, the time constraints imply that the parallel architecture of the brain is critical, not irrelevant.

Marr's tripartite division itself was challenged on grounds that nervous systems display not a single level of "implementation," but many levels of structured organization, from molecules to synapses, neurons, networks, and so forth (Churchland and Sejnowski 1992; fig. 1). Evidence indicates that various structural levels have important functional capacities, and that computation might be carried out not only at the level of the neuron, but also at a finer grain, namely the dendrite, as well as at a larger grain, namely the network. From the perspective of neuroscience, the hardware/software distinction did not fall gracefully onto brains.

What, in neural terms, are representations? Whereas the AI approach equates representations with symbols, a term well defined in the context of conventional computers, connectionists realized that "symbol" is essentially undefined in neurobiological contexts. They therefore aimed to develop a new theory of representation suitable to neurobiology. Thus they hypothesized that occurrent representations (those happening now) are patterns of *activation* across the units in a

neural net, characterized as a vector, $<x, y, z, . . .>$, where each element in the vector specifies the level of activity in a unit. Stored representations, by contrast, are believed to depend on the configuration of *weights* between units. In neural terms, these weights are the strength of synaptic connections between neurons.

Despite considerable progress, exactly how brains represent and compute remains an unsolved problem. This is mainly because many questions about how neurons code and decode information are still unresolved. New techniques in neuroscience have revealed that timing of neuronal spikes is important in coding, but exactly how this works or how temporally structured signals are decoded is not understood.

In exploring the properties of nervous systems, artificial NEURAL NETWORKS (ANNs) have generally been more useful to neuroscience than AI models. A useful strategy for investigating the functional role of an actual neural network is to train an ANN to perform a similar information processing task, then to analyze its properties, and then compare them to the real system. For example, consider certain neurons in the parietal cortex (area 7a) of the brain whose response properties are correlated with the position of the visual stimulus relative to head-centered coordinates. Since the receptor sheets (RETINA, eye muscles) cannot provide that information directly, it has to be computed from various input signals. Two sets of neurons project to these cells: some represent the position of the stimulus on the retina, some represent the position of the eyeball in the head. Modeling these relationships via an artificial neural net shows how the eyeball/retinal position can be used to compute the position of the stimulus relative to the head (see OCULOMOTOR CONTROL). Once trained, the network's structure can be analyzed to determine how the computation was achieved, and this may suggest neural experiments (Andersen 1995; see also COMPUTATIONAL NEUROSCIENCE).

How biologically realistic to make an ANN depends on the purposes at hand, and different models are useful for different purposes. At certain levels and for certain purposes, abstract, simplifying models are precisely what is needed. Such a model will be more useful than a model slavishly realistic with respect to every level, even the biochemical. Excessive realism may mean that the model is too complicated to analyze or understand or run on the available computers. For some projects such as modeling language comprehension, less neural detail is required than for other projects, such as investigating dendritic spine dynamics.

Although the assumption that nervous systems compute and represent seems reasonable, the assumption is not proved and has been challenged. Stressing the interactive and time-dependent nature of nervous systems, some researchers see the brain together with its body and environment as dynamical systems, best characterized by systems of differential equations describing the temporal evolution of states of the brain (*see* DYNAMIC APPROACHES TO COGNITION, and Port and van Gelder 1995). In this view both the brain and the liver can have their conduct adequately described by systems of differential equations. Especially in trying to explain the development of perceptual motor skills in neonates, a dynamical systems approach has shown considerable promise (Thelen and Smith 1994).

The main reason for adhering to a framework with computational resources derives from the observation that neurons represent various nonneural parameters, such as head velocity or muscle tension or visual motion, and that complex neuronal representations have to be constructed from simpler ones. Recall the example of neurons in area 7a. Their response profiles indicate that they represent the position of the visual stimulus in head-centered coordinates. Describing causal interactions between these cells and their input signals without specifying anything about representational role masks their function in the animal's visual capacity. It omits explaining how these cells come to represent what they do. Note that connectionist models can be dynamical when they include back projections, time constants for signal propagation, channel open times, as well as mechanisms for adding units and connections, and so forth.

In principle, dynamical models could be supplemented with representational resources in order to achieve more revealing explanations. For instance, it is possible to treat certain parameter settings as inputs, and the resultant attractor as an output, each carrying some representational content. Furthermore, dynamical systems theory easily handles cases where the "output" is not a single static state (the result of a computation), but is rather a trajectory or limit cycle. Another approach is to specify dynamical subsystems within the larger cognitive system that function as emulators of external domains, such as the task environment (see Grush 1997). This approach embraces both the representational characterization of the inner emulator (it represents the external domain), as well as a dynamical system's characterization of the brain's overall function.

Computational Complexity

How is it possible for a biological system to perform activities such as language comprehension, LEARNING, ANALOGY, PLANNING, or visual interpretation? The COMPUTATIONAL THEORY OF MIND suggests that it is possible the same way it is possible for an electronic computer to sort a list of numbers, simulate a weather system, or control an elevator: the brain, it is claimed, is an organ capable of certain forms of COMPUTATION, and mental activities such as those listed above are computational ones. But it is not enough to say that a mental activity is computational to account for its physical or biological realizability; it must also be the sort of task that can be performed by the brain in a plausible amount of time.

Computational complexity is the part of computer science that studies the resource requirements in time and memory of various computational tasks (Papadimitriou 1994). Typically, these requirements are formulated as functions of the size of the input to be processed. The central tenet of computability theory (one form of the CHURCH-TURING THESIS) is that any computational task that can be performed by a physical system of whatever form, can be performed by a very simple device called a Turing machine. The central tenet of (sequential) complexity theory, then, is that any computational task that can be performed by any physical system in $F(n)$ steps, where n is the size of the input, can be performed by a Turing machine in $G(n)$ steps, where F and G differ by at most a polynomial. A consequence of this is that any task requiring exponential time on a Turing machine would not be computable in polynomial time by anything physical whatsoever. Because exponentials grow so rapidly, such a task would be physically infeasible except for very small inputs.

How might this argument be relevant to cognitive science? Consider a simple form of visual interpretation, for example. Suppose it is hypothesized that part of how vision works is that the brain determines some property P of the scene, given a visual grid provided by the retina as input. Let us further suppose that the task is indeed computable, but an analysis shows that a Turing machine would require an exponential number of steps to do so. This means that to compute P quickly enough on all but very small grids, the brain would have to perform an unreasonably large number of elementary operations per second. The hypothesis, then, becomes untenable: it fails to explain how the brain could perform the visual task within reasonable time bounds.

Unfortunately, this putative example is highly idealized. For one thing, computational complexity is concerned with how the demand for resources scales as a function of the size of the input. If the required input does not get very large (as with individual sentences of English, say, with a few notable exceptions), complexity theory has little to contribute. For another, to say that the resource demands scale exponentially is to say that there will be inputs that require exponential effort. However, these could turn out to be extremely rare in real life, and the vast majority may very well be unproblematic from a resource standpoint. Thus the actual tractability of a task depends crucially on the range of inputs that need to be processed.

But these considerations do not undermine the importance of complexity. To return to the visual interpretation example, we clearly ought not to be satisfied with a theory that claims that the brain computes P, but that in certain extremely rare cases, it could be busy for hours doing so. Either such cases cannot occur at all for some reason, or the brain is able to deal with them: it gives up, it uses heuristics, it makes do. Either way, what the brain is actually doing is no longer computing P, but some close approximation to P that needs to be shown adequate for vision, and whose complexity in turn ought to be considered.

Another complication that should be noted is that it has turned out to be extremely difficult to establish that a computational task requires an exponential number of steps. Instead, what has emerged is the theory of NP-completeness (Garey and Johnson 1979). This starts with a specific computational task called SAT (Cook 1971), which involves determining whether an input formula of propositional logic can be made true. While SAT is not known to require exponential time, all currently known methods do require an exponential number of steps on some inputs. A computational task is NP-complete when it is as difficult as SAT: an efficient way of performing it would also lead to an efficient method for SAT, and vice versa. Thus, all NP-complete tasks, including SAT itself, and including a very large number seemingly related to assorted mental activities, are strongly believed (but are not known) to require exponential time.

The constraint of computational tractability has ended up being a powerful forcing function in much of the technical work in artificial intelligence. For example, research in KNOWLEDGE REPRESENTATION can be profitably understood as investigating reasoning tasks that are not only semantically motivated and broadly applicable, but are also computationally tractable (Levesque 1986). In many cases, this has involved looking for plausible approximations, restrictions, or deviations from the elegant but thoroughly intractable models of inference based on classical LOGIC (Levesque 1988). Indeed, practical KNOWLEDGE-BASED SYSTEMS have invariably been built around restricted forms of logical or probabilistic inference. Similar considerations have led researchers away from classical decision theory to models of BOUNDED RATIONALITY (Russell and Wefald 1991). In the area of COMPUTATIONAL VISION, it has been suggested that visual attention is the mechanism used by the brain to tame otherwise intractable tasks (Tsotsos 1995). Because the resource demands of a task are so dependent on the range of inputs, recent work has attempted to understand what it is about certain inputs that makes NP-complete tasks problematic (Hogg, Huberman, and Williams 1996). For a less technical discussion of this whole issue, see Cherniak 1986.

Computational Learning Theory

Computational learning theory is the study of a collection of mathematical models of machine learning, and has among its goals the development of new algorithms for learning from data, and the elucidation of computational and information-theoretic barriers to learning. As such, it is closely related to disciplines with similar aims, such as statistics and MACHINE LEARNING (see also NEURAL NETWORKS; PATTERN RECOGNITION AND FEEDFORWARD NETWORKS; and BAYESIAN LEARNING). However, it is perhaps coarsely distinguished from these other areas by an explicit and central concern for computational efficiency and the COMPUTATIONAL COMPLEXITY of learning problems.

Most of the problems receiving the greatest scrutiny to date can be traced back to the seminal paper of L. G. Valiant (1984), where a simple and appealing model is proposed that emphasizes three important notions. First, learning is probabilistic: a finite sample of data is generated randomly according to an unknown process, thus necessitating that we tolerate some error, hopefully quantifiable, in the hypothesis output by a learning algorithm. Second, learning algorithms must be computationally efficient, in the standard complexity-theoretic sense: given a sample of m observations from the unknown random process, the execution time of a successful learning algorithm will be bounded by a fixed polynomial in m. Third, learning algorithms should be appropriately general: they should process the finite sample to obtain a hypothesis with good generalization ability under a reasonably large set of circumstances.

In Valiant's original paper, the random process consisted of an unknown distribution or density P over an input space X, and an unknown Boolean (two-valued) target function f over X, chosen from a known class F of such functions. The finite sample given to the learning algorithm consists of pairs $\langle x, y \rangle$, where x is distributed according to P and $y = f(x)$. The demand that learning algorithms be general is cap-tured by the fact that the distribution P is arbitrary, and the function class F is typically too large to permit an exhaustive search for a good match to the observed data. A typical example sets F to be the class of all linear-threshold functions (perceptrons) over n-dimensional real inputs. In this case, the model would ask whether there is a learning algorithm that, for any input dimension n and any desired error $\varepsilon > 0$, requires a sample size and execution time bounded by fixed polynomials in n and $1/\varepsilon$, and produces (with high probability) a hypothesis function h such that the probability that $h(x) \neq f(x)$ is smaller than ε under P. Note that we demand that the hypothesis function h generalize to unseen data (as represented by the distribution P), and not simply fit the observed training data.

The last decade has yielded a wealth of results and analyses in the model sketched above and related variants. Many of the early papers demonstrated that simple and natural learning problems can be computationally difficult for a variety of interesting reasons. For instance, Pitt and Valiant (1988) showed learning problems for which the "natural" choice for the form of the hypothesis function h leads to an NP-hard problem, but for which a more general hypothesis representation leads to an efficient algorithm. Kearns and Valiant (1994) exhibited close connections between hard learning problems and cryptography by showing that several natural problems, including learning finite automata and boolean formula, are computationally difficult regardless of the method used to represent the hypothesis.

These results demonstrated that powerful learning algorithms were unlikely to be developed within Valiant's original framework without some modifications, and researchers turned to a number of reasonable relaxations. One fruitful variant has been to supplement the random sample given to the learning algorithm with a mechanism to answer *queries* —that is, rather than simply passively receiving $\langle x, y \rangle$ pairs drawn from some distribution, the algorithm may now actively request the classification of any desired x under the unknown target function f. With this additional mechanism, a number of influential and elegant algorithms have been discovered, including for finite automata by Angluin (1987, 1988; to be contrasted with the intractability without the query mechanism, mentioned above) and for decision trees by Kushelevitz and Mansour (1993).

One drawback to the query mechanism is the difficulty of simulating such a mechanism in real machine learning applications, where typically only passive observations of the kind posited in Valiant's original model are available. An alternative but perhaps more widely applicable relaxation of this model is known as the *weak learning* or *boosting* model. Here it is assumed that we already have possession of an algorithm that is efficient, but meets only very weak (but still nontrivial) generalization guarantees. This is formalized by asserting that the weak learning algorithm always outputs a hypothesis whose error with respect to the unknown target function is slightly better than "random guessing." The goal of a boosting algorithm is then to combine the many mediocre hypotheses' output by several executions of the weak learning algorithm into a single hypothesis that is much better than random guessing. This is made possible by assuming that the weak learning algorithm

will perform better than random guessing on many *different* distributions on the inputs. Initially proposed to settle some rather theoretical questions in Valiant's original model, the boosting framework has recently resulted in new learning algorithms enjoying widespread experimental success and influence (Freund and Schapire 1997), as well as new analyses of some classic machine learning heuristics, such as the CART and C4.5 decision tree programs (Kearns and Mansour 1996).

Although computational considerations are the primary distinguishing feature of computational learning theory, and have been the emphasis here, it should be noted that a significant fraction of the work and interest in the field is devoted to questions of a primarily statistical or information-theoretic nature. Thus, characterizations of the number of observations required by any algorithm (computationally efficient or otherwise) for good generalization have been the subject of intense and prolonged scrutiny, building on the foundational work of Vapnik (1982; see STATISTICAL LEARNING THEORY). Recent work has also sought similar characterizations without probabilistic assumptions on the generation of observations (Littlestone 1988), and has led to a series of related and experimentally successful algorithms.

A more extensive bibliography and an introduction to some of the central topics of computational learning theory is contained in Kearns and Vazirani 1994.

Computational Lexicons

A computational lexicon has traditionally been viewed as a repository of lexical information for specific tasks, such as parsing, generation, or translation. From this viewpoint, it must contain two types of knowledge: (1) knowledge needed for syntactic analysis and synthesis, and (2) knowledge needed for semantic interpretation. More recently, the definition of a computational lexicon has undergone major revision as the fields of COMPUTATIONAL LINGUISTICS and semantics have matured. In particular, two new trends have driven the design concerns of researchers:

- Attempts at closer integration of compositional semantic operations with the lexical information structures that bear them
- A serious concern with how lexical types reflect the underlying ontological categories of the systems being modeled

Two new approaches to modeling the structure of the LEXICON have recently emerged in computational linguistics: (1) theoretical studies of how computations take place in the mental lexicon; (2) developments of computational models of information as structured in lexical databases. The differences between the computational study of the lexicon and more traditional linguistic approaches can be summarized as follows:

Lexical representations must be explicit. The knowledge contained in them must be sufficiently detailed to support one or more processing applications.

The global structure of the lexicon must be modeled. Real lexicons are complex knowledge bases, and hence the structures relating entire words are as important as those relating components of words. Furthermore, lexical entries consisting of more than one orthographic word (collocations, idioms, and compounds) must also be represented.

The lexicon must provide sufficient coverage of its domain. Real lexicons can typically contain up to 400,000 entries. For example, a typical configuration might be: verbs (5K), nouns (30K), adjectives (5K), adverbs (<1K), logical terms (<1K), rhetorical terms (<1K), compounds (2K), proper names (300K), and various sublanguage terms.

Computational lexicons must be evaluable. Computational lexicons are typically evaluated in terms of: (i) coverage: both breadth of the lexicon and depth of lexical information; (ii) extensibility: how easily can information be added to the lexical entry? How readily is new information made consistent with the other lexical structures? (iii) utility: how useful are the lexical entries for specific tasks and applications?

Viewed independently of any specific application and evaluated in terms of its relevance to cognitive science, the

recent work on computational lexicons makes several important points. The first is that the lexical and interlexical structures employed in computational studies have provided some of the most complete descriptions of the lexical bases of natural languages. Besides the broad descriptive coverage of these lexicons, the architectural decisions involved in these systems have important linguistic and psychological consequences. For example, the legitimacy and usefulness of many theoretical constructions and abstract descriptions can be tested and verified by attempting to instantiate them in as complete and robust a lexicon as possible. Of course, completeness doesn't ensure correctness nor does it ensure a particularly interesting lexicon from a theoretical point of view, but explicit representations do reveal the limitations of a given analytical framework.

Content of a Single Lexical Entry

Although there are many competing views on the exact structure of lexical entries, there are some important common assumptions about the content of a lexical entry. It is generally agreed that there are three necessary components to the structure of a lexical item: *orthographic and morphological information*; i.e. how the word is spelled and what forms it appears in; *syntactic information*; for instance, what part of speech the word is; and *semantic information*; i.e., what representation the word translates to.

Syntactic information may be divided into the subtypes of *category* and *subcategory*. Category information includes traditional categories such as noun, verb, adjective, adverb, and preposition. While most systems agree on these "major" categories, there are often great differences in the ways they classify "minor" categories, such as conjunctions, quantifier elements, determiners, etc.

Subcategory information is information that divides syntactic categories into subclasses. This sort of information may be usefully separated into two types, *contextual features* and *inherent features*. The former are features that may be defined in terms of the contexts in which a given lexical entry may occur. *Subcategorization* information marks the local legitimate context for a word to appear in a syntactic structure. For example, the verb *devour* is never intransitive in English and requires a direct object; hence the lexicon tags the verb with a subcategorization requiring an NP object. Another type of context encoding is *collocational information,* where patterns that are not fully productive in the grammar can be tagged. For example, the adjective *heavy* as applied to *drinker* and *smoker* is collocational and not freely productive in nature.

Inherent features are features of lexical entries that cannot, or cannot easily, be reduced to a contextual definition. They include such features as count/mass (e.g., *pebble* vs. *water*), abstract, animate, human, and so on.

Semantic information can also be separated into two subcategories, *base semantic typing* and *selectional typing*. While the former identifies the broad semantic class that a lexical item belongs to (such as event, proposition, predicate), the latter class specifies the semantic features of arguments and adjuncts to the lexical item.

Global Structure of the Lexicon

From the discussion above, the entries in a lexicon would appear to encode only concepts such as category information, selectional restrictions, number, type and case roles of arguments, and so forth. While the utility of this kind of information is beyond doubt, the emphasis on the individual entry misses out on the issue of global lexical organization. This is not to dismiss ongoing work that does focus precisely on this issue; for instance, attempts to relate grammatical alternations with semantic classes (e.g., Levin 1993).

One obvious way to organize lexical knowledge is by means of lexical inheritance mechanisms. In fact, much recent work has focused on how to provide shared data structures for syntactic and morphological knowledge (Flickinger, Pollard, and Wasow 1985). Evans and Gazdar (1990) provide a formal characterization of how to perform inferences in a language for multiple and default inheritance of linguistic knowledge. The language developed for that purpose, DATR, uses value-terminated attribute trees to encode lexical information. Taking a different approach, Briscoe, dePaiva, and Copestake (1993) describe a rich system of types for allowing default mechanisms into lexical type descriptions.

Along a similar line, Pustejovsky and Boguraev (1993) describe a theory of shared semantic information based on orthogonal typed inheritance principles, where there are several distinct levels of semantic description for a lexical item. In particular, a set of semantic roles called *qualia structure* is relevant to just this issue. These roles specify the purpose (telic), origin (agentive), basic form (formal), and constitution (const) of the lexical item. In this view, a lexical item inherits information according to the qualia structure it carries. In this view, multiple inheritance can be largely avoided because the qualia constrain the types of concepts that can be put together. For example, the predicates *cat* and *pet* refer to formal and telic qualia, respectively.

The Computational Lexicon as Knowledge Base

The interplay of the lexical needs of current language processing frameworks and contemporary lexical semantic theories very much influences the direction of computational dictionary analysis research for lexical acquisition. Given the increasingly prominent place the lexicon is assigned—in linguistic theories, in language processing technology, and in domain descriptions—it is no accident, nor is it mere rhetoric, that the term "lexical knowledge base" has become a widely accepted one. Researchers use it to refer to a large-scale repository of lexical information, which incorporates more than just "static" descriptions of words, for example, clusters of properties and associated values. A lexical knowledge base should state constraints on word behavior, dependence of word interpretation on context, and distribution of linguistic generalizations.

A lexicon is essentially a dynamic object, as it incorporates, in addition to its information types, the ability to perform inference over them and thus induce word meaning in context. This is what a computational lexicon is: a theoretically sound and computationally useful resource for real

application tasks and for gaining insights into human cognitive abilities.

Computational Linguistics

Computational linguistics (CL; also called natural language processing, or NLP) is concerned with (1) the study of computational models of the structure and function of language, its use, and its acquisition; and (2) the design, development, and implementation of a wide range of systems such as SPEECH RECOGNITION, language understanding and NATURAL LANGUAGE GENERATION. CL applications include interfaces to databases, text processing, and message understanding, multilingual interfaces as aids for foreign language correspondences, web pages, and speech-to-speech translation in limited domains. On the theoretical side, CL uses computational modeling to investigate syntax, semantics, pragmatics (that is, certain aspects of the relationship of the speaker and the hearer, or of the user and the system in the case of a CL system), and discourse aspects of language. These investigations are interdisciplinary and involve concepts from artificial intelligence (AI), linguistics, logic, and psychology. By connecting the closely interrelated fields of computer science and linguistics, CL plays a key role in cognitive science.

Because it is impossible to cover the whole range of theoretical and practical issues in CL in the limited space available, only a few related topics are discussed here in some detail, to give the reader a sense of important issues. Fortunately, there exists a comprehensive source, documenting all the major aspects of CL (*Survey of the State of Art in Human Language Technology* forthcoming).

Grammars and Parsers

Almost every NLP system has a grammar and an associated parser. A *grammar* is a finite specification of a potentially infinite number of sentences, and a *parser* for the grammar is

an ALGORITHM that analyzes a sentence and, if possible, assigns one or more grammar-based structural descriptions to the sentence. The structural descriptions are necessary for further processing—for example, for semantic interpretation.

Many CL systems are based on context-free grammars (CFGs). One such grammar, *G,* consists of a finite set of nonterminals (for example, S: sentence; NP: noun phrase; VP: verb phrase; V: verb; ADV: adverb), a finite set of terminals, or lexical items, and a finite set of rewrite rules of the form $A \rightarrow W$, where A is a nonterminal and W is a string of nonterminals and terminals. S is a special nonterminal called the "start symbol."

CFGs are inadequate and need to be augmented for a variety of reasons. For one, the information associated with a phrase (a string of terminals) is not just the atomic symbols used as nonterminals, but a complex bundle of information (sets of attribute-value pairs, called "feature structures") that needs to be associated with strings. Moreover, appropriate structures and operations for combining them are needed, together with a CFG skeleton. For another, the string-combining operation in a CFG is concatenation, (for example, if u and v are strings, v concatenated with u gives the string $w = uv$, that is, u followed by v), and more complex string-combining as well as tree-combining operations are needed to describe various linguistic phenomena. Finally, the categories in a grammar need to be augmented by associating them with feature structures, a set of attribute-value pairs that are then combined in an operation called "unification." A variety of grammars such as generalized phrase structure grammar (GPSG), HEAD-DRIVEN PHRASE STRUCTURE GRAMMAR (HPSG), and LEXICAL FUNCTIONAL GRAMMAR (LFG) are essentially CFG-based unification grammars (Bresnan and Kaplan 1983; Gazdar et al. 1985; Pollard and Sag 1994).

Computational grammars need to describe a wide range of dependencies among the different elements in the grammar. Some of these dependencies involve agreement features, such as person, number, and gender. For example, in English, the verb agrees with the subject in person and number. Others involve verb subcategorization, in which each verb specifies one (or more) subcategorization frames for its complements. For instance, *sleep* (as in *Harry sleeps*) does not require any complement, while *like* (as in *Harry likes peanuts*) requires one complement; *give* (as in *Harry gives Susan a flower*) requires two complements; and so forth. Sometimes the dependent elements do not appear in their normal positions. In *Who$_i$ did John invite e$_i$*, where e_i is a stand-in for *who$_i$*, *who$_i$* is the filler for the gap e_i (see WH-MOVEMENT). The filler and the gap need not be at a fixed distance. Thus in *Who$_i$ did Bill ask John to invite e$_i$*, the filler and the gap are more distant than in the previous sentence. Sometimes the dependencies are nested. In German, for example, one could have *Hans$_i$ Peter$_j$ Marie$_k$ schwimmen$_k$ lassen$_j$ sah$_i$* (Hans saw Peter make Marie swim), where the nouns (arguments) and verbs are in nested order, as the subscripts indicate. And sometimes they are crossed. In Dutch, for example, one could have *Jan$_i$ Piet$_j$ Marie$_k$ zag$_i$ laten$_j$ zwemmen$_k$* (Jan saw Piet make Marie swim). There are, of course, situations where the dependencies have

more complex patterns. Precise statements of such dependencies and the domains over which they operate constitute the major activity in the specification of a grammar. Computational modeling of these dependencies is one of the key areas in CL. Many (for example, the crossed dependencies discussed above) cannot be described by context-free grammars and require grammars with larger domains of locality. One such class is constituted by the so-called mildly context-sensitive grammars (Joshi and Schabes 1997). Two grammar formalisms in this class are tree-adjoining grammars (TAGs) and combinatory categorial grammars (CCGs; Joshi and Schabes 1997; Steedman 1997; see also CATEGORIAL GRAMMAR). TAGs are also unification-based grammars.

Parsing sentences according to different grammars is another important research area in CL. Indeed, parsing algorithms are known for almost all context-free grammars used in CL. The time required to parse a sentence of length n is at most Kn^3, where K depends on the size of the grammar and can become very large in the worst case. Most parsers perform much better than the worst case on typical sentences, however, even though there are no computational results, as yet, to characterize their behavior on typical sentences. Grammars that are more powerful than CFGs are, of course, harder to parse, as far as the worst case is concerned. Like CFGs, mildly context-sensitive grammars can all be parsed in polynomial time, although the exponent for n is 6 instead of 3. A crucial problem in parsing is not just to get all possible parses for a sentence but to rank the parses according to some criteria. A grammar can be combined with statistical information to provide this ranking.

Thus far, we have assumed that the parser only handles complete sentences and either succeeds or fails to find the parses. In practice, we want the parser to be flexible. It should be able to handle fragments of sentences, or if it fails, it should fail gracefully, providing as much analysis as possible for as many fragments of the sentence as possible, even if it cannot glue all the pieces together.

Finally, even though the actual grammars in major CL systems are large, their coverage is not adequate. Building a grammar by hand soon reaches its limit in coping with free text (say, text from a newspaper). Increasing attention is being paid both to automatically acquiring grammars from a large corpus and to statistical parsers that produce parses directly based on the training data of the parsed annotated corpora.

Statistical Approaches

Although the idea of somehow combining structural and statistical information was already suggested in the late 1950s, it is only now, when we have formal frameworks suitable for combining structural and statistical information in a principled manner and can use very large corpora to reliably estimate the statistics needed to deduce linguistic structure, that this idea has blossomed in CL.

STATISTICAL TECHNIQUES IN NATURAL LANGUAGE PROCESSING in conjunction with large corpora (raw texts or texts annotated in various ways) have also been used to automatically acquire linguistic information about MORPHOLOGY

(prefixes, suffixes, inflected forms), subcategorization, semantic classes (classification of nouns based on what predicates they go with; compound nouns such as *jet engines, stock market prices;* classification of verbs, for example, *to know*, or events, for example, *to look;* and so on), and, of course, grammatical structure itself. Such results have opened up a new direction of research in CL, often described as "corpus-based CL."

It should be clear from the previous discussion that, for the development of corpus-based CL, very large quantities of data are required (the Brown corpus from the 1960s is about 1 million words). Researchers estimate that about 100 million words will be required for some tasks. The technologies that will benefit from corpus-based NLP include speech recognition, SPEECH SYNTHESIS, MACHINE TRANSLATION, full-text information retrieval, and message understanding, among others. The need for establishing very large text and speech databases, annotated in various ways, is now well understood. One such database is the Linguistic Data Consortium (LDC), a national and international resource supported by federal and industrial grants, and useful also for psycholinguistic research (especially in experimental design for controlling lexical and grammatical frequency biases; see http://www.ldc.upenn.edu).

Computational Neuroanatomy

The term *computational anatomy* was introduced in Schwartz 1980, which suggested that the observables of functional anatomy, such as columnar and topographic structure, be made the basis of the state variables for perceptual computations (rather than, as is universally assumed, some combination of single neuronal response properties). The goal of computational neuroanatomy is to construct a supraneuronal continuum, or "field theory," approach to neural structure and function, to the "particulate" approach associated with the properties of single neurons. In particular, the details of spatial neuroanatomy of the nervous system are viewed as computational, rather than as mere "packaging" (see Schwartz 1994 for a comprehensive review of the structural and functional correlates of neuroanatomy).

Global Map Structure

It is widely accepted that the cortical magnification factor in primates is approximately inverse linear, at least for the central twenty degrees of field (e.g., Tootell et al. 1985; van Essen, Newsome, and Maunsell 1984; Dow, Vautin, and Bauer 1985), and preliminary results from functional MAGNETIC RESONANCE IMAGING (fMRI) suggest roughly the same for humans. The simple mathematical argument showing there is only one complex analytic two-dimensional map function that has this property, namely, the complex logarithm (Schwartz 1977, 1994), suggested an experiment. Determine the point correspondence data from a 2DG (2-deoxyglucose) experiment, accurately measure the flattened cortical surface, and check the validity of the Reimann mapping theorem prediction of primary visual cortex (V1) topography, or, equivalently, of the hypothesis that global topography in V1 is a generalized conformal map. The results of this experiment (Schwartz, Munsif, and Albright 1989; Schwartz 1994) confirmed that cortical topography is in strong agreement with the conformal mapping hypothesis, up to an error estimated to be roughly 20 percent.

Local Map Structure

A large number of NEURAL NETWORK models have been constructed to address the generation of ocular dominance and orientation columns in cat and monkey VISUAL CORTEX. Surprisingly, the common element in all these models, often not explicitly stated, is the use of a spatial filter applied to spatial white noise (Rojer and Schwartz 1990a). Thus ocular dominance columns are the result of band-pass filtering a scalar white noise variable (ocularity). Orientation columns, as originally pointed out by Rojer and Schwartz (1990a), could be understood as the result of applying a band-pass filter to vector noise, that is, to a vector quantity whose magnitude represented strength of tuning, and whose argument represented orientation. One recent result of this analysis is that the zero-crossings of the cortical orientation map were predicted, on topological grounds, to provide a coordinate system in which left- and right-handed orientation vortices should alternate in handedness (i.e., clockwise or counterclockwise orientation change). This prediction was tested with optical recording data on primate visual cortex orientation maps and found to be in perfect agreement with the data (Tal and Schwartz 1997).

Unified Global and Local Map Structure

A joint map structure to express the global conformal topographic structure, and, at the same time, the local orientation

column and ocular dominance column structure of primate V1, was introduced by Landau and Schwartz (1994), making use of a new construct in computational geometry called the "protocolumn."

Global Map Function

One obvious functional advantage of using strongly space-variant (e.g., foveal) architecture in vision is data compression. It has been estimated that a constant-resolution version of visual cortex, were it to retain the full human visual field and maximum human visual resolution, would require roughly 10^4 as many cells as our actual cortex (and would weigh, by inference, roughly 15,000 pounds; Rojer and Schwartz 1990b). The problem of viewing a wide-angle work space at high resolution would seem to be best performed with space-variant visual architectures, an important theme in MACHINE VISION (Schwartz, Greve, and Bonmassar 1995). The complex logarithmic mapping has special properties with respect to size and rotation invariance. For a given fixation point, changing the size or rotating a stimulus causes its cortical representation to shift, but to otherwise remain invariant (Schwartz 1977). This symmetry property provides an excellent example of computational neuroanatomy: simply by virtue of the spatial properties of cortical topography, size and rotation symmetries may be converted into the simpler symmetry of shift. One obvious problem with this idea is that it only works for a given fixation direction. As the eye scans an image, translation invariance is badly broken. Recently, a computational solution to this problem has been found, by generalizing the Fourier transform to complex logarithmic coordinate systems, resulting in a new form of spatial transform, called the "exponential chirp transform" (Bonmassar and Schwartz forthcoming.) The exponential chirp transform, unlike earlier attempts to incorporate Fourier analysis in the context of human vision (e.g., Cavanagh 1978), provides size, rotation, and shift invariance properties, while retaining the fundamental space-variant structure of the visual field.

Local Map Function

The ocular dominance column presents a binocular view of the visual world in the form of thin "stripes," alternating between left- and right-eye representations. One question that immediately arises is how this aspect of cortical anatomy functionally relates to binocular stereopsis. Yeshurun and Schwartz (1989) constructed a computational stereo algorithm based on the assumption that the ocular dominance column structure is a direct representation, as an anatomical pattern, of the stereo percept. It was shown that the power spectrum of the log power spectrum (also known as the "cepstrum") of the interlaced cortical "image" provided a simple and direct measure of stereo disparity of objects in the visual scene. This idea has been subsequently used in a successful machine vision algorithm for stereo vision (Ballard, Becker, and Brown 1988), and provides another excellent illustration of computational neuroanatomy.

The regular local spatial map of orientation response in cat and monkey, originally described by Hubel and Wiesel (1974), suggested the hypothesis that a local analysis of shape, in terms of periodic changes in orientation of a stimulus outline, might provide a basis for shape analysis (Schwartz 1984). A parametric set of shape descriptors, based on shapes whose boundary curvature varied sinusoidally, was used as a probe for the response properties of neurons in infero-temporal cortex, which is one of the final targets for V1, and which is widely believed to be an important site for shape recognition. This work found that a subset of the infero-temporal neurons examined were tuned to stimuli with sinusoidal curvature variation (so-called Fourier descriptors), and that these responses showed a significant amount of size, rotation, and shift invariance (Schwartz et al. 1983).

Computational Neuroscience

The goal of computational neuroscience is to explain in computational terms how brains generate behaviors. Computational models of the brain explore how populations of highly interconnected neurons are formed during development and how they come to represent, process, store, act on, and be altered by information present in the environment (Churchland and Sejnowski 1992). Techniques from computer science and mathematics are used to simulate and analyze these computational models to provide links between the widely ranging levels of investigation, from the molecular to the systems levels. Only a few key aspects of computational neuroscience are covered here (see Arbib 1995 for a comprehensive handbook of brain theory and neural networks).

The term *computational* refers both to the techniques used in computational neuroscience and to the way brains process information. Many different types of physical systems can solve computational problems, including slide rules and optical analog analyzers as well as digital computers, which are analog at the level of transistors and must settle into a stable state on each clock cycle. What these have in common is an underlying correspondence between an abstract computational description of a problem, an algorithm that can solve it, and the states of the physical system that implement it (figure 1). This is a broader approach to COMPUTATION than one based purely on symbol processing.

There is an important distinction between general-purpose computers, which can be programmed to solve many different types of algorithms, and special-purpose computers, which are designed to solve only a limited range of problems. Most neural systems are specialized for particular tasks, such as the RETINA, which is dedicated to visual transduction and image processing. As a consequence of the close coupling between structure and function in a brain area, anatomy and physiology can provide important clues to the algorithms implemented, and the computational function of that area (figure 1), which might not be apparent in a general-purpose computer whose function depends on software.

Another major difference between the brain and a general-purpose digital computer is that the connectivity between neurons and their properties are shaped by the environment during development and remain plastic even in adulthood. Thus, as the brain processes information, it changes its own structure in response to the information being processed. Adaptation and learning are important mechanisms that allow brains to respond flexibly as the world changes on a wide range of time scales, from seconds to years. The flexibility of the brain has survival advantages when the environment is nonstationary and the evolution of cognitive skills may deeply depend on genetic processes that have extended the time scales for brain plasticity.

Brains are complex, dynamic systems, and brain models provide intuition about the possible behaviors of such systems, especially when they are nonlinear and have feedback loops. The predictions of a model make explicit the consequences of the underlying assumptions, and comparison with experimental results can lead to new insights and discoveries. Emergent properties of neural systems, such as oscillatory behaviors, depend on both the intrinsic properties of the neurons and the pattern of connectivity between them.

Perhaps the most successful model at the level of the NEURON has been the classic Hodgkin-Huxley (1952) model of the action potential in the giant axon of the squid (Koch and Segev 1998). Data were collected under a variety of conditions, and a model later constructed to integrate the data into a unified framework. Because most of the variables in the model are measured experimentally, only a few unknown parameters need to be fit to the experimental data. Detailed models can be used to choose among experiments that could be used to distinguish between different explanations of the data.

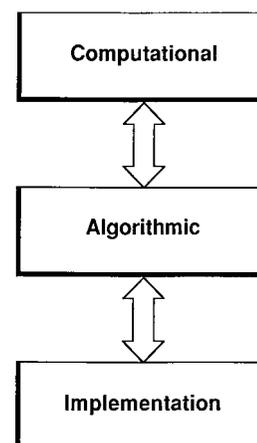
The classic model of a neuron, in which information flows from the dendrites, where synaptic signals are integrated, to the soma of the neuron, where action potentials


Figure 1. Levels of analysis (Marr 1982). The two-way arrows indicate that constraints between levels can be used to gain insights in both directions.

are initiated and carried to other neurons through long axons, views dendrites as passive cables. Recently, however, voltage-dependent sodium, calcium, and potassium channels have been observed in the dendrites of cortical neurons, which greatly increases the complexity of synaptic integration. Experiments and models have shown that these active currents can carry information in a retrograde direction from the cell body back to the distal synapse tree (see also COMPUTING IN SINGLE NEURONS). Thus it is possible for spikes in the soma to affect synaptic plasticity through mechanisms that were suggested by Donald HEBB in 1949.

Realistic models with several thousand cortical neurons can be explored on the current generation of workstation. The first model for the orientation specificity of neurons in the VISUAL CORTEX was the feedforward model proposed by Hubel and Wiesel (1962), which assumed that the orientation preference of cortical cells was determined primarily by converging inputs from thalamic relay neurons. Although solid experimental evidence supports this model, local cortical circuits have been shown to be important in amplifying weak signals and suppressing noise as well as performing gain control to extend the dynamic range. These models are governed by the type of attractor dynamics analyzed by John Hopfield (1982), who provided a conceptual framework for the dynamics of feedback networks (Churchland and Sejnowski 1992).

Although the spike train of cortical neurons is highly irregular, and is typically treated statistically, information may be contained in the timing of the spikes in addition to the average firing rate. This has already been established for a variety of sensory systems in invertebrates and for peripheral sensory systems in mammals (Rieke et al. 1996). Whether spike timing carries information in cortical neurons remains, however, an open research issue (Ritz and Sejnowski 1997). In addition to representing information, spike timing could also be used to control synaptic plasticity through Hebbian mechanisms for synaptic plasticity.

Other models have been used to analyze experimental data in order to determine whether they are consistent with a particular computational assumption. For example, Apostolos Georgopoulos has used a "vector-averaging" technique to compute the direction of arm motion from the responses of cortical neurons, and William Newsome and his colleagues (Newsome, Britten, and Movshon 1989) have used SIGNAL DETECTION THEORY to analyze the information from cortical neurons responding to visual motion stimuli (Churchland and Sejnowski 1992). In these examples, the computational model was used to explore the information in the data but was not meant to be a model for the actual cortical mechanisms. Nonetheless, these models have been highly influential and have provided new ideas for how the cortex may represent sensory information and motor commands.

A NEURAL NETWORK model that simplifies the intrinsic properties of neurons can help us understand the information contained in populations of neurons and the computational consequences. An example of this approach is a recent model of parietal cortex (Pouget and Sejnowski 1997) based on the response properties of cortical neurons, which are involved in representing spatial location of objects in the environment. Examining which reference frames are used in the cortex for performing sensorimotor transformations, the model makes predictions for experiments performed on patients with lesions of the parietal cortex who display spatial neglect.

Conceptual models can be helpful in organizing experimental facts. Although thalamic neurons that project to the cortex are called "relay cells," they almost surely have additional functions because the visual cortex makes massive feedback projections back to them. Francis Crick (1994) has proposed that the relay cells in the THALAMUS may be involved in ATTENTION, and has provided an explanation for how this could be accomplished based on the anatomy of the thalamus. His searchlight model of attention and other hypotheses for the function of the thalamus are being explored with computational models and new experimental techniques. Detailed models of thalamocortical networks can already reproduce the low-frequency oscillations observed during SLEEP states, when feedback connections to the thalamus affect the spatial organization of the rhythms. These sleep rhythms may be important for memory consolidation (Sejnowski 1995).

Finally, small neural systems have been analyzed with dynamic systems theory. This approach is feasible when the numbers of parameters and variables are small. Most models of neural networks involve a large number of variables, such as membrane potentials, firing rates, and concentrations of ions, with an even greater number of unknown parameters, such as synaptic strengths, rate constants, and ionic conductances. In the limit that the number of neurons and parameters is very large, techniques from statistical physics can be applied to predict the average behavior of large systems. There is a midrange of systems where neither type of limiting analysis is possible, but where simulations can be performed. One danger of relying solely on computer simulations is that they may be as complex and difficult to interpret as the biological systems themselves.

To better understand the higher cognitive functions, we will need to scale up simulations from thousands to millions of neurons. While parallel computers are available that permit massively parallel simulations, the difficulty of programming these computers has limited their usefulness. A new approach to massively parallel models has been introduced by Carver Mead (1989), who builds subthreshold complementary metal-oxide semiconductor Very-Large-Scale Integrated (CMOS VLSI) circuits with components that directly mimic the analog computational operations in neurons. Several large silicon chips have been built that mimic the visual processing found in retinas. Analog VLSI cochleas have also been built that can analyze sound in real time. These chips use analog voltages and currents to represent the signals, and are extremely efficient in their use of power compared to digital VLSI chips. A new branch of engineering called "neuromorphic engineering" has arisen to exploit this technology.

Recently, analog VLSI chips have been designed and built that mimic the detailed biophysical properties of neurons, including dendritic processing and synaptic conductances (Douglas, Mahowald, and Mead 1995), which has opened the possibility of building a "silicon cortex." Protocols are being designed for long-distance communication between

analog VLSI chips using the equivalent of all-or-none spikes, to mimic long-distance communication between neurons.

Many of the design issues that govern the evolution of biological systems also arise in neuromorphic systems, such as the trade-off in cost between short-range connections and expensive long-range communication. Computational models that quantify this trade-off and apply a minimization procedure can predict the overall organization of topographical maps and columnar organization of the CEREBRAL CORTEX.

Although brain models are now routinely used as tools for interpreting data and generating hypotheses, we are still a long way from having explanatory theories of brain function. For example, despite the relatively stereotyped anatomical structure of the CEREBELLUM, we still do not understand its computational functions. Recent evidence from functional imaging of the cerebellum suggests that it is involved in higher cognitive functions, and not just a motor controller. Modeling studies may help to sort out competing hypotheses. This has already occurred in the oculomotor system, which has a long tradition of using control theory models to guide experimental studies.

Computational neuroscience is a relatively young, rapidly growing discipline. Although we can now simulate only small parts of neural systems, as digital computers continue to increase in speed, it should become possible to approach more complex problems. Most of the models developed thus far have been aimed at interpreting experimental data and providing a conceptual framework for the dynamic properties of neural systems. A more comprehensive theory of brain function should arise as we gain a broader understanding of the computational resources of nervous systems at all levels of organization.

Computational Psycholinguistics

In PSYCHOLINGUISTICS, computational models are becoming increasingly important both for helping us understand and develop our theories and for deriving empirical predictions from those theories. How a theory of language processing behaves usually depends not just on the mechanics of the model itself, but also on the properties of the linguistic input. Even when the theory is conceptually simple, the interaction between theory and language is often too complex to be explored without the benefit of computer simulations. It is no surprise then that computational models have been at the center of some of the most significant recent developments in psycholinguistics.

The main area of contact with empirical data has been made by models operating roughly at the level of the word. Although there are active and productive efforts underway to develop models of higher-level processes such as syntactic parsing (Kempen and Vosse 1989; McRoy and Hirst 1990; Marcus 1980) and discourse (Kintsch and van Dijk 1978; Kintsch 1988; Sharkey 1990), the complexity of these processes makes it harder to derive detailed experimental predictions.

The neighborhood activation model (Luce, Pisoni, and Goldinger 1990) gives a computational account of isolated word recognition, but only TRACE (McClelland and Elman 1986) and Shortlist (Norris 1994a) have been applied to the more difficult problem of how words can be recognized in continuous speech, where the input may contain no reliable cues to indicate where one word ends and another begins. Both of these models are descendants of McClelland and Rumelhart's (1981) connectionist interactive activation model (IAM) of VISUAL WORD RECOGNITION. The central principle of both models is that the input can activate multiple word candidates, represented by nodes in a network, and that these candidates then compete with each other by means of inhibitory links between overlapping candidates. Thus the spoken input "get in" might activate "tin" as well as "get" and "in," but "tin" would be inhibited by the other two overlapping words. TRACE and Shortlist represent opposite positions in the debate over whether SPOKEN WORD RECOGNITION is an interactive process. In TRACE there is continuous interaction between the lexical and phonemic levels of representation, whereas Shortlist has a completely bottom-up, modular architecture. They also differ in their solution to

the problem of how to recognize words beginning at different points in time. TRACE uses a permanent set of complete lexical networks beginning at each point where a word might begin. In Shortlist the network performing the lexical competition is created dynamically and contains only those candidates identified by a bottom-up analysis of the input. On a purely practical level, at least, this has the advantage of enabling Shortlist to perform simulations with realistically sized lexicons of twenty or thirty thousand words. Shortlist has also been extended (Norris, McQueen and Cutler 1995) to incorporate the metrical segmentation strategy of Cutler and Norris (1988), which enables the model to make use of metrical cues to word boundaries.

The most significant nonconnectionist model of spoken word recognition has been Oden and Massaro's (1978) fuzzy logical model of perception (FLMP). FLMP differs from TRACE and Shortlist in that it can be seen as a generic account of how decisions are made on the basis of information from different sources. FLMP itself has nothing to say, for example, about the competition process vital for the recognition of words in continuous speech in both TRACE and Shortlist. Comparisons between FLMP and TRACE in terms of their treatment of the relationship between lexical and phonemic information led to a major revision of the IAM framework and the development of the stochastic interactive activation model (Massaro 1989; McClelland 1991).

IAMs and spreading activation models have also been predominant in the area of LANGUAGE PRODUCTION (Dell 1986, 1988; Harley 1993; Roelofs 1992; see also Houghton 1990). Dell's model is designed to account for the nature and distribution of speech errors. It takes as its input an ordered set of word units (lemmas), representing the speaker's intended production, and produces as its output a string of phonemes that may be corrupted or misordered. In Dell (1988) the model consists of a lexical network in which word nodes are connected to their constituent phonemes by reciprocal links and by a word shape network that reads out successive phonemes in the appropriate syllable structure. The main effect of the reciprocal links from phonemes to words is to give the model a tendency for its errors to form real rather than nonsense words. Whether the production system really does contain these feedback links has been the topic of extensive debate between Dell and Levelt. Levelt, Roelofs, and Meyer (forthcoming) describe the latest computational implementation of the WEAVER++ model, which is a noninteractive spreading activation model designed to account for an extensive body of response time (RT) data on production as well as speech error data.

The most controversial connectionist model of language has been the Rumelhart and McClelland (1986) model for acquisition of the past tense of verbs. Conventional linguistic accounts of quasi-regular systems such as the past tense assume that the proper explanation is in terms of rules and a list of exceptions. Rumelhart and McClelland modeled the acquisition of the past tense using a simple pattern associator that mapped the phonology of verb roots (e.g., *kill*, *run*) onto their past tense forms (*killed*, *ran*). They claimed that their model not only explained important facts about the acquisition of verbs, but that it did so without using linguistic rules.

The model was fiercely criticized by Pinker and Prince (1988). Later models by MacWhinney and Leinbach (1991) and Plunkett and Marchman (1991, 1993), using backpropagation with hidden units, rectified some of the technical deficiencies of the original model, and claimed to give a more accurate account of the developmental data, but the debate between the connectionist and symbolic camps continues. Recently reported neuropsychological and neuroimaging data suggest a neuroanatomical distinction between mechanisms underlying the rule-based and non-rule-based processes (e.g., Marslen-Wilson and Tyler forthcoming).

A parallel set of arguments has surrounded models of reading aloud. The relationship between spelling and sound is another example of a quasi-regular system where backpropagation networks have been used to give a unitary account of the READING process rather than incorporating spelling-to-sound rules and a list of exception words (e.g., *yacht*, *choir*) not pronounced according to the rules (Seidenberg and McClelland 1989; Plaut et al. 1996). The more traditional two-process view is represented by Coltheart et al. (1993), while an interactive activation model by Norris (1994b) takes an intermediate stance.

Computational Theory of Mind

The computational theory of mind (CTM) holds that the mind is a digital computer: a discrete-state device that stores symbolic representations and manipulates them according to syntactic rules; that thoughts are mental representations—more specifically, symbolic representations in a LANGUAGE OF THOUGHT; and that mental processes are causal sequences driven by the syntactic, but not the semantic, properties of the symbols. Putnam (1975) was perhaps the first to articulate CTM, but it has found many proponents, the most influential being Fodor (1975, 1981, 1987, 1990, 1993) and Pylyshyn (1980, 1984).

CTM's proponents view the theory as an extension of the much older idea that thought is MENTAL REPRESENTATION—an extension that shows us how a commitment to mental states can be compatible with a causal account of mental processes and with a commitment to materialism and the generality of physics. Older breeds of representationalism were unable to explain how mental processes could be semantically coherent—how thoughts could follow one another in a fashion appropriate to their meanings, while also being bona fide causal processes that did not depend on an inner homunculus who understood the meanings of the representations. Using formalization and digital computers, however, we can explain how this occurs. Formalization shows us how to link semantics to syntax. For any formalizable symbol system, it is possible to develop a set of formal derivation rules, based wholly on syntactic properties, that license all and only the inferences permissible on semantic grounds. Computers show us how to link syntax to causation. For any finite formal system, it is possible to construct a digital computer that automates the derivations of that system. Thus, together, formalization and computation show us how to link semantics to causation in a material system like a digital computer: design a set of syntactic rules that "track" the semantic properties of the symbols (i.e., formalize the system), and then implement those rules in a computer. Because digital computers are purely physical systems, this shows us it is possible for a purely physical system to carry out symbolic inferences that respect the semantics of the symbols without recourse to a homunculus or to any other nonphysical agency. Syntactic properties are the causal determinants of reasoning, syntax tracks semantics, and syntactic properties can be implemented in a physical system.

CTM has been touted both for its connections to successful empirical research in cognitive science and for its promise in resolving philosophical problems. The main argument in favor of the language of thought hypothesis and CTM has been the "only game in town" argument: cognitive theories of language, learning, and other psychological phenomena are the only viable theories we possess, and these theories presuppose an inner representational system. Therefore we have a prima facie commitment to the existence of such a representational system (Fodor 1975). Some have claimed that CTM also explains the INTENTIONALITY of mental states and that it reconciles mentalism with materialism. The meanings and intentionality of mental states are "inher-

ited from" the meanings and intentionality of the "mentalese" symbols (Fodor 1981). And because symbols, the ultimate bearers of semantic properties and intentionality, can both have meaning and be physical objects, there is not even a prima facie conflict between a commitment to semantics and intentionality and a commitment to materialism. Finally, CTM has been held to explain the generative and creative powers of thought that result from the COMPOSITIONALITY of the language of thought. Chomskian linguistics shows us how an infinite number of possible sentences can be generated out of a finite number of atomic lexical units, syntactic structures, and transformation rules. If the basis of thought is a symbolic language, these same resources can be applied directly to explain the compositionality of thought.

Although CTM gained a great deal of currency in the late 1970s and 1980s, it has since been criticized on a number of fronts. First, with philosophers' rediscovery in the late 1980s of alternative approaches to psychological modeling, represented in NEURAL NETWORKS and dynamic adaptive systems, the empirical premise of the "only game in town" argument has been brought into question. Indeed, the main thrust of philosophical debate about neural networks and connectionism has been over whether their models of psychological phenomena are viable alternatives to rule-and-representation models.

Second, writers such as Dreyfus (1972, 1992) and Winograd and Flores (1986) have claimed that much human thought and behavior cannot be reduced to explicit rules, and hence cannot be formalized or reduced to a computer program. Thus, even if CTM does say something significant about the parts of human cognition that can be formalized, there are large portions of human mental life about which it can say nothing. Dreyfus and others have attempted to argue that this includes all expert knowledge and such simple skills as knowing how to drive a car or order in a restaurant.

A third line of criticism has been directed at CTM's use of symbolic meaning to explain the semantics of thought, on the grounds that symbolic meaning is derivative from the intentionality of thought, either causally (Searle 1980; Haugeland 1978; Sayre 1986) or conceptually (Horst 1996). Thus the attempt to explain intentionality by appeal to symbols is circular and regressive. Searle (1990) and Horst (1996) have taken this line of argument even further, claiming that the "representations" in computers are not even symbolic or syntactic in their own right, but possess these properties by virtue of the intentions and conventions of computer users: a digital machine not connected to our interpretive practices has a "syntax" only in a metaphorical sense of that word. Horst's version of these criticisms also yields an argument against the claim to reconcile mentalism with materialism: what digital computers show us how to do is to link convention-laden symbolic meaning with CAUSATION by way of convention-laden syntax, not to link the sense of "meaning" attributed to mental states with causation.

A fourth line of criticism has come from advocates of externalist theories of meaning. For many years, advocates of CTM tended also to be advocates of a "methodological solipsism" (Fodor 1980) or INDIVIDUALISM who held that the typing of mental states needed to be insensitive to features outside of the cognizer because the computational processes that determined thought have access only to mental representations. At the same time, CTM required that the typing of mental states reflect their semantic properties. These two commitments together seemed to be incompatible with externalist theories of content, which hold that the meanings of many terms are at least partially determined by factors that lie outside of the cognizer, such as its physical (Putnam 1975) and linguistic (Burge 1979, 1986) environment. This was used by some externalists (e.g., Baker 1987) as an argument against computationalism, and was used at least at one time by Fodor (1980) as a reason to reject externalism. Nevertheless, at least some computationalists, including Fodor (1993), have now embraced strategies for reconciling computational theories of mental processes with externalist theories of meaning for mental representations.

Computational Vision

The analysis of a visual image yields a rich understanding of what is in the world, where objects are located, and how they are changing with time, allowing a biological or machine system to recognize and manipulate objects and to interact physically with its environment. The computational approach to the study of vision explores the information-processing mechanisms needed to extract this important information. The integration of a computational perspective with experimental studies of biological vision systems from psychology and neuroscience can ultimately yield a more complete functional understanding of the neural mechanisms underlying visual processing.

Vision begins with a large array of measurements of the light reflected from object surfaces onto the eye. Analysis then proceeds in multiple stages, with each producing increasingly more useful representations of information in the scene. Computational studies suggest three primary representational stages. *Early representations* may capture information such as the location, contrast, and sharpness of significant intensity changes or edges in the image. Such changes correspond to physical features such as object boundaries, texture contours, and markings on object surfaces, shadow boundaries, and highlights. In the case of a dynamically changing scene, the early representations may also describe the direction and speed of movement of image intensity changes. *Intermediate representations* describe information about the three-dimensional (3-D) shape of object surfaces from the perspective of the viewer, such as the orientation of small surface regions or the distance to surface points from the eye. Such representations may also describe the motion of surface features in three dimensions. Visual processing may then proceed to higher-level representations of objects that describe their 3-D shape, form, and orientation relative to a coordinate frame based on the objects or on a fixed location in the world. Tasks such as object recognition, object manipulation, and navigation may operate from the intermediate or higher-level representations of the 3-D layout of objects in the world. (See also MACHINE VISION for a discussion of representations for visual processing.)

Models for computing the early representations of intensity edges typically begin by filtering the image with filters that smooth and differentiate the image intensities. Smoothing at multiple spatial scales allows the simultaneous representation of the gross structure of image contours, while preserving the fine detail of surface markings and TEXTURE. The differentiation operation transforms the image into a representation that facilitates the localization of edge contours and computation of properties such as their sharpness and contrast. Significant intensity changes may correspond to maxima, or peaks, in the first derivative, or to zero-crossings in the second derivative, of the image intensities. Subsequent image analysis may operate on a representation of image contours. Alternative models suggest that later processes operate directly on the result of the filtering stage.

Several sources of information are used to compute the 3-D shape of object surfaces. Binocular stereo uses the relative location of corresponding features in the images seen by the left and right eyes to infer the distance to object surfaces. Abrupt changes in motion between adjacent image regions indicate object boundaries, while smooth variations in the direction and speed of motion within image regions can be used to recover surface shape. Other cues include systematic variations in the geometric structure of image textures, such as changes in the orientation, size, or density of texture elements; image shading, which refers to smooth variations of intensity that occur as surfaces bend toward or away from a light source; and perspective, which refers to the distortion of object contours that results from the perspective projection of the 3-D scene onto the two-dimensional (2-D) image. (See STRUCTURE FROM VISUAL INFORMATION SOURCES and STEREO AND MOTION PERCEPTION for further discussion of visual cues to structure and form.)

The computation of 3-D structure cannot proceed unambiguously from the 2-D image alone. Models also incorpo-

rate physical constraints that capture the typical behavior of objects in the world. For the early and intermediate stages of processing, these constraints are as general as possible. Existing models use constraints based on the following typical behaviors: object surfaces are coherent and typically vary smoothly and continuously from one image location to the next; objects usually move rigidly, at least within small image regions; illumination usually shines from above the observer; changes in the reflectance properties of a surface (such as its color) usually occur abruptly while illumination may vary slowly across the image. Models also incorporate the known physics of how the image is formed from the perspective projection of light reflected from surfaces onto the eyes. Computational studies of vision identify appropriate physical constraints and show how they can be built into a specific algorithm for computing the image representations.

Among cues for recovering 3-D structure from 2-D images, the two most extensively studied by computational and biological researchers are binocular stereo and motion. For both stereo and motion measurement, the most challenging computational problem is the correspondence problem. Given a representation of features in the left and right images, or two images displaced in time, a matching process must identify pairs of features in the two images that are projections of the same physical structure in space. Many models attempt to match edge features in the two images. Some models, such as an early model of human stereo vision proposed by MARR and Poggio (Marr 1982), simultaneously match image edge representations at multiple spatial scales. The correspondence of features at a coarse scale can provide a rough 3-D layout of a scene that can guide the correspondence of features at finer scales. Information such as the orientation or contrast of edge features can help identify pairs of similar features likely to correspond to one another. Stereo and motion models also typically use physical constraints such as uniqueness (i.e., features in one image have a unique corresponding feature in the other) and continuity or smoothness (i.e., nearby features in the image lie at similar depths or have a similar direction and speed of motion). Many models incorporate some form of optimization: a solution is found that best satisfies a complex set of criteria based on all of the physical constraints taken together. In the case of motion processing, the analysis of the movement of features in the changing 2-D image is followed by a process that infers the 3-D structure of the moving features. Most computational models of this inference use the rigidity constraint: they attempt to find a rigidly moving 3-D structure consistent with the computed 2-D image motion. (For specific models of stereo and motion processing, see Faugeras 1993; Hildreth and Ullman 1989; Kasturi and Jain 1991; Landy and Movshon 1991; Marr 1982; Martin and Aggarwal 1988; and Wandell 1995.)

Much attention has been devoted to the higher-level problem of object recognition, which requires that a representation derived from a viewed object in the image be matched with internal representations of a similar object stored in memory. Most computational models consider the recognition of objects on the basis of their 2-D or 3-D shape. Recognition is difficult because a given 3-D object can have many appearances in the 2-D image. Most recognition models can be classified into three main approaches. The first assumes that objects have certain invariant properties that are common to all of their views. Recognition typically proceeds in this case by first computing a set of simple geometric properties of a viewed object from image information, and then selecting an object model that offers the closest fit to the set of observed property values. The second approach focuses on the decomposition of objects into primitive, salient parts. In this case, models first find primitive parts in an image, and then identify objects on the basis of the detected parts and their spatial arrangement. The best-known model of this type was proposed by Biederman (1985; see Ullman 1996). The third major approach to object recognition uses a process that explicitly compensates for the transformation between a viewed object and its stored model. One example of this approach proposed by Ullman (1996) first computes the geometric transformations that best explain the mapping between a viewed object and each object model in a database. A second stage then recognizes the object by finding which combination of object model and transformation best matches the viewed object. (Some specific models of recognition are described in Faugeras 1993 and Ullman 1996.)

Computer-Human Interaction

See HUMAN-COMPUTER INTERACTION

Computing in Single Neurons

Over the past few decades, NEURAL NETWORKS have provided the dominant framework for understanding how the brain implements the computations necessary for its survival. At the heart of these networks are very dynamic and complex processing nodes, individual neurons. A typical NEURON in the CEREBRAL CORTEX receives input from a few thousand fellow neurons and, in turn, passes on messages to a few thousand other neurons. One hundred thousand such cells are packed into a cubic millimeter of cortical tissue, which amounts to 4 kilometers of axonal wiring, 500 meters of dendrites, and close to one billion synapses (Braitenberg and Schüz 1991).

Synapses, the specialized connections between two neurons, come in two basic flavors, excitatory and inhibitory. An excitatory synapse will reduce the electrical potential across the membrane of its target cell (that is, it will depolarize the cell), while an inhibitory synapse will hyperpolarize the cell. If the membrane potential at the cell body exceeds a particular threshold value, the neuron generates a short, millisecond-long pulse, called an "action potential" or "spike" (figure 1). Otherwise, it remains silent. The amount of synaptic input determines how fast the cell generates spikes, and these are in turn conveyed to the next target cells through the output axon. Information processing in an average human cortex then relies on the proper interconnection of about 4×10^{10} such neurons in a network of stupendous size.

In 1943, MCCULLOCH and PITTS showed that this view is at least plausible. They described each synapse by a single scalar weight, ranging from positive to negative depending on whether the synapse was excitatory or inhibitory. The contributions from all synapses, multiplied by their synaptic weights, add linearly at the cell body. If this sum exceeds a threshold, a spike is generated. McCulloch and Pitts argued that, with the addition of memory, a sufficiently large number of these logical "neurons," wired together in an appropriate manner, can compute anything that can be computed on any digital computer.

LEARNING entered this picture in the form of HEBB's (1949) rule, postulating that the synapse between neuron A and neuron B increases its "weight" if activity in A occurs at the same time as activity in B. Half a century later, we have solid evidence that such changes do take place in a well-studied phenomenon termed LONG-TERM POTENTIATION (LTP). Here, the synaptic weight increases for days or even weeks. It can be induced by simultaneous activity at the pre- and postsynaptic termini, in agreement with Hebb's rule (Nicoll and Malenka 1995). Of more recent vintage is the discovery of a complementary process, a decrease in synaptic weight called "long-term depression" (Stevens 1996).

Over the last few years, it has become abundantly clear that dendrites do much more than simply convey synaptic inputs to the cell body for linear summation. Dendrites have traditionally been treated as passive cables, surrounded by a membrane that can be modeled by a conductance in parallel with a capacitance (Segev, Rinzel, and Shepherd 1995). When synaptic input is applied, such an arrangement acts as a low-pass filter, removing the high frequencies but performing no other significant information processing. Dendrites with such a passive membrane would not really disturb our view of neurons as linear threshold units.

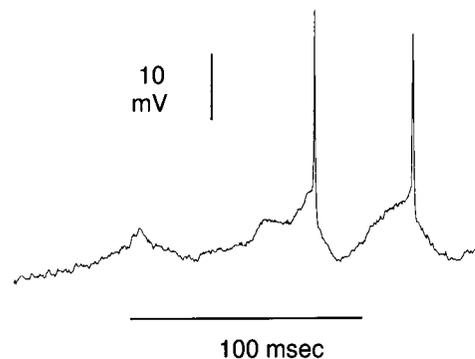
As long ago as the 1950s, Hodgkin and Huxley (1952) showed how the transient changes in such active voltage-dependent membrane conductances generate and shape the action potential. But it was assumed that they are limited to the axon and the adjacent cell body. We now know that many dendrites of pyramidal cells are endowed with a relatively homogeneous distribution of sodium conductances as


Figure 1. Action potentials recorded in a single neuron in the visual cortex, shown as a plot of membrane potential against time. (*a*) A visual stimulus causes a sustained barrage of synaptic input, which triggers three cycles of depolarization. The first cycle does not reach the threshold for generating a spike, but the second and third do. Each spike lasts for about 1 msec. (Data provided by B. Ahmed, N. Berman, and K. Martin.)

well as a diversity of calcium membrane conductances (Johnston et al. 1996).

What is the function of these active conductances? One likely explanation (supported by computer models) is that calcium and potassium membrane conductances in the distant dendrites can selectively linearize and amplify this input. Voltage-dependent conductances can also subserve a specific nonlinear operation, multiplication, one of the most common operations carried out in the nervous system (Koch and Poggio 1992). If the dendritic tree contains sodium or calcium conductances, or if the synapses use a particular type of receptor (the so-called NMDA receptor), the inputs can interact synergistically, with the strongest response occurring when inputs from different neurons are located close to each other on a patch of dendritic membrane. Simulations (Mel 1994) show that the firing rate of such a neuron is proportional to the *product,* rather than the *sum,* of its inputs.

Ramòn y CAJAL postulated the law of "dynamic polarization," stipulating that dendrites and cell bodies are the receptive areas for the synaptic input, and that the resulting output pulses are transmitted unidirectionally along the axon to its targets. From work on brain slices, however, it seems that this is by no means the whole story. Single action potentials can propagate not only forward from their initiation site along the axon, but also backward into the dendritic tree, a phenomenon known as antidromic spike invasion (Stuart and Sakmann 1994). It remains unclear whether dendrites themselves can initiate action potentials. If spikes can be generated locally under physiological conditions, they could implement powerful logical operations far away from the cell body (Softky 1994).

What of the role of time in neuronal processing? There are two main aspects to this issue: (1) the relationship between the timing of an event in the external world and the timing of the representation of that event at the single-neuron level; (2) the accuracy and importance of the relative timing of spikes between two or more neurons.

Regarding the first aspect, some animals can discriminate intervals of the order of a microsecond (for instance, to localize sounds), implying that the timing of sensory stimuli must be represented with similar precision in the brain, and is probably based on the average timing of spikes in a population of cells. It is also possible to measure the precision with which individual cells track the timing of external events. For instance, certain cells in the monkey VISUAL CORTEX are preferentially stimulated by moving stimuli, and these cells can modulate their firing rate with a precision of less than 10 msec (Bair and Koch 1996).

The second aspect of the timing issue is the extent to which the exact temporal arrangements of spikes—both within a single neuron and across several neurons—matters for information processing. It is usually assumed that, to cope with the apparent lack of reliability of single cells, the brain makes use of a "firing rate" code. Only the average number of spikes within some suitable time window, say a fraction of a second, matters. The detailed pattern of spikes (figure 2) is thought by many to be largely irrelevant, a hypothesis supported by the existence of a quantitative relationship between the firing rates of single cortical neurons and psychophysical judgments made by monkeys. That is,

the behavior of a monkey in a visual discrimination task can be statistically predicted by counting spikes in a single neuron in the visual cortex (Newsome, Britten, and Movshon 1989). Robustness of this encoding is further ensured by averaging the response over a large number of similar cells (a process known as population coding).

Recent years have witnessed a resurgence in *information-theoretic* approaches to the nervous system (Rieke et al. 1996). We know that individual neurons, such as motion-selective cells in the fly or single auditory inputs in the bullfrog, can encode between 1 and 3 bits of sensory information per output spike, amounting to rates of up to 300 bits per second. This information is encoded using changes in the instantaneous interspike interval between a handful of spikes. Such a temporal encoding mechanism is within 10 to 40 percent of the theoretical maximum allowed by the spike train variability. This implies that individual spikes can carry significant amounts of information, at odds with the idea that neurons are unreliable and can only signal in the aggregate. At these rates, the optic nerve would convey between one and ten million bits per second. (This compares to a ten-speed CD-ROM drive, which transfers information at 1.5 million bits per second.)

Timing precision of spiking across populations of simultaneously firing neurons is believed to be a key element in neuronal strategies for encoding perceptual information in the sensory pathways (Abeles 1990; Singer and Gray 1995). Yet if information is indeed embodied in a temporal code, how, if at all, is it decoded by the target neurons? Do neurons act as *coincidence detectors,* able to detect the arrival time of incoming spikes at a millisecond or better resolution? Or do they integrate more than a hundred or so relatively small inputs over many tens of milliseconds until the threshold for spike initiation is reached (Softky 1995; see figure 1)?

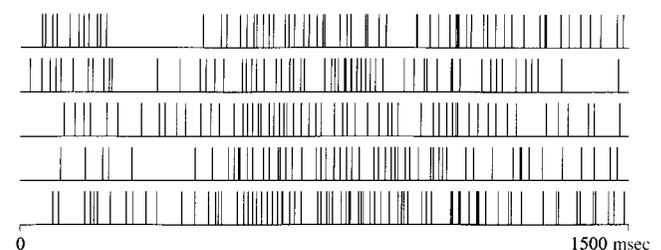
Current thinking about computation has the brain as a hybrid computer. Individual nerve cells convert the incoming streams of binary pulses into analog, spatially distributed variables: the postsynaptic membrane potential and calcium distribution throughout the dendritic tree. This transformation involves highly dynamic synapses that adapt to their input. Information is then processed in the analog domain, using a number of linear and nonlinear operations (multiplication, saturation, amplification, thresholding) implemented


Figure 2. Variability in neuronal responses (each line in the trace corresponds to a spike of the type shown in figure 1). If the same stimulus is presented twice in succession, it induces the same average firing rate on both trials (about 50 Hz), although the exact timing of individual spikes shows random variation. (Data provided by W. Newsome and K. Britten.)

in the dendritic cable structure and augmented by voltage-dependent membrane and synaptic conductances. The result is converted into asynchronous binary pulses and conveyed to the following neurons. The functional resolution of these pulses is in the millisecond range, with temporal synchrony across neurons likely to contribute to coding. Reliability could be achieved by pooling the responses of a small number (20–200) of neurons.

And what of MEMORY? It is everywhere (but cannot be randomly accessed). It resides in the concentration of free calcium in dendrites and cell body; in the presynaptic terminal; in the density and exact voltage dependency of the various ionic conductances; in the density and configuration of specific proteins in the postsynaptic terminals; and, ultimately, in the gene in the cell's nucleus for lifetime memories.

Concepts

The elements from which propositional thought is constructed, thus providing a means of understanding the world, concepts are used to interpret our current experience by classifying it as being of a particular kind, and hence relating it to prior knowledge. The concept of "concept" is central to many of the cognitive sciences. In cognitive psychology, conceptual or semantic encoding effects occur in a wide range of phenomena in perception, ATTENTION, language comprehension, and MEMORY. Concepts are also fundamental to reasoning in both machine systems and people. In AI, concepts are the symbolic elements from which KNOWLEDGE REPRESENTATION systems are built in order to provide machine-based expertise. Concepts are also often assumed to form the basis for the MEANING of nouns, verbs and adjectives (see COGNITIVE LINGUISTICS and SEMANTICS). In behaviorist psychology, a concept is the propensity of an organism to respond differentially to a class of stimuli (for example a pigeon may peck a red key for food, ignoring other colors). In cultural anthropology, concepts play a central role in constituting the individuality of each social group. In comparing philosophy and psychology, it is necessary to distinguish philosophical concepts understood as abstractions, independent of individual minds, and psychological concepts understood as component parts of MENTAL REPRESENTATIONS of the world (see INDIVIDUALISM).

Philosophy distinguishes NARROW CONTENT, which is the meaning of a concept in an individual's mental representation of the world, from *broad content*, in which the meaning of a concept is also partly determined by factors in the external world. There has been much debate on the question of how to *individuate* the contents of different concepts, and whether this is possible purely in terms of narrow content (Fodor 1983; Kripke 1972), and how concepts as purely internal symbols in the mind relate to classes of entities in the external world.

Concepts are considered to play an "intensional" and an "extensional" role (FREGE 1952). There are different technical ways to approach this distinction. One philosophical definition is that the *extension* is the set of all objects in the "actual" world which fall under the concept, whereas the *intension* is the set of objects that fall under the concept in "all possible worlds." In cognitive science a less strict notion of intension has been operationalized as the set of propositional truths associated with a proper understanding of the concept—for example that chairs are for sitting on. It resembles a dictionary definition, in that each concept is defined by its relation to others. Intensions permit inferences to be drawn, as in "This is a chair, therefore it can be sat upon," although, as the example illustrates, these inferences may be fallible. The extension of a concept is the class of objects, actions or situations in the actual external world which the concept represents and to which the concept term therefore refers (Frege's "reference"). Frege argued that intension determines extension; thus the extension is the class of things in the world for which the intension is a true description. This notion of concepts leads to a research program for the analysis of relevant concepts (such as "moral" or "lie") in which proposed intensional analyses of concepts are tested against intuitions of the extension of the concept, either real or hypothetical. Fodor (1994) has advanced arguments against this program. To avoid the circularity found in dictionaries, the intension of a concept must be expressed in terms of more basic concepts (the "symbol grounding problem" in cognitive science). The problems involved in grounding concepts have led Fodor to propose a strongly innatist account of concept acquisition, according to which all simple concepts form unanalyzable units, inherited as part of the structure of the brain. Others have explored ways to ground concepts in more basic perceptual symbolic elements (Barsalou 1993).

In the psychology of concepts, there are three main research traditions. First, the "cognitive developmental" tradition, pioneered by PIAGET (1967), seeks to describe the ages and stages in the growing conceptual understanding of children. Concepts are schemas. Through self-directed action and experience the *assimilation* of novel experiences or situations to a schema leads to corresponding *accommodation* of the schema to the experience, and hence to CONCEPTUAL CHANGE and development. Piaget's theory of adult intelligence has been widely criticized for overestimating the cognitive capacities of most adults. His claims about the lack of conceptual understanding in young children have also been challenged in the literature on conceptual development (Carey 1985; Keil 1989). Research in this tradition has also had a major influence on theories of adult concepts developed within the lexical semantics tradition.

The second research tradition derives from behaviorist psychology, for which concepts involve the ability to classify the world into categories (see also CATEGORIZATION and MACHINE LEARNING). Animal discrimination learning paradigms have been used to explore how people learn and represent new concepts. A typical experiment involves a controlled stimulus set, usually composed of arbitrary and meaningless elements, such as line segments, geometric symbols, or letters, which has to be classified into two or more classes. The stimuli in the set are created by manipulating values on a number of stimulus dimensions (for example, shape or color). A particular value on a particular dimension constitutes a stimulus feature. The distribution of stimuli across the classes to be learned constitutes the structure of the concept. Training in these experiments typically involves using trial-and-error learning with feedback. In a subsequent transfer or generalization phase, novel stimuli are presented for classification without feedback, to test what has been learned. Three types of model have been explored in this paradigm. "Rule-based" learning models propose that participants try to form hypotheses consistent with the feedback in the learning trials (see for example Bruner, Goodnow, and Austin 1956). "Prototype" learning models propose that participants form representations of the average or prototypical stimulus for each class, and classify these by judging how similar the new stimulus is to each prototype. "Exemplar" models propose that participants store individual exemplars and their classification in memory, and base the classification on the relative average similarity of a stimulus to the stored exemplars in each class, with a generally assumed exponential decay of similarity as distance along stimulus dimensions increases (Nosofsky 1988). Exemplar models typically provide the best fits to experimental data, although rules and prototypes may also be used when the experimental conditions are favorable to their formation. NEURAL NETWORK models of category learning capture the properties of both prototype and exemplar models because they abstract away from individual exemplar representations, but at the same time are sensitive to patterns of co-occurrence of particular stimulus features.

The study of categorization learning in the behaviorist tradition has generated powerful models of fundamental learning processes with an increasing range of application, although the connection to other traditions in the psychology of concepts (for example, cognitive development or lexical semantics) is still quite weak. As in much behaviorist-inspired experimental research, the desire to have full control over the stimulus structure has led to the use of stimulus domains with low meaningfulness and hence poor ECOLOGICAL VALIDITY.

The third research tradition derives from the application of psychological methods to lexical semantics, the representation of word meaning, where concepts are studied through their expression in commonly used words. Within the Fregean branch of this tradition, interest has focused on how the intensions of concepts are related to their extensions. Tasks have been devised to examine each of these two aspects of people's everyday concepts. Intensions are typically studied through feature-listing tasks, where people are asked to list relevant aspects or attributes of a concept which might be involved in categorization, and then to judge their importance to the definition of the concept. Extensions are studied by asking people either to generate or to categorize lists of category members. The use of superordinate concepts (for example, birds or tools) allows instances to be named with single words. Extensions may also be studied through the classification of hypothetical or counterfactual examples, or through using pictured objects.

Five broad classes of model have been proposed within the lexical semantics tradition. The "classical" model assumes that concepts are clearly defined by a conjunction of singly necessary and jointly sufficient attributes (Armstrong, Gleitman, and Gleitman 1983; Osherson and Smith 1981). The first problem for this model is that the attributes people list as true or relevant to a concept's definition frequently include nonnecessary information that is not true of all category members (such as that birds can fly), and often fail to provide the basis of a necessary and sufficient classical definition. Second, there are category instances which show varying degrees of disagreement about their classification both between individuals and for the same individuals on different occasions (McCloskey and Glucksberg 1978). Third, clear category members differ in how "typical" they are judged to be of the category (Rosch 1975). The classical view was therefore extended by proposing two kinds of attribute in concept representations—*defining features,* which form the core definition of the class, and *characteristic features,* which are true of typical category members only and which may form the basis of a *recognition procedure* for quick categorization. Keil and Batterman (1984) reported a development with age from the use of characteristic to defining features. Nevertheless, the extended classical model is still incompatible with the lack of clearly expressible definitions for most everyday concept terms.

In the second or "prototype" model, concepts are represented by a prototype with all the most common attributes of the category, which includes all instances sufficiently similar to this prototype (Rosch and Mervis 1975). The typicality of an instance in a category depends on the number of attributes which an instance shares with other category members. Prototype representations lead naturally to non-defining attributes and to the possibility of unstable categorization at the category borderline. Such effects have been demonstrated in a range of conceptual domains. A corollary of the prototype view is that the use of everyday concepts may show nonlogical effects such as intransitivity of categorization hierarchies, and nonintersective conjunctions (Hampton 1982, 1988). Associated with prototype theory is the theory of *basic levels* in concept hierarchies. Rosch, Simpson, and Miller (1976) proposed that the SIMILARITY structure of the world is such that we readily form a basic level of categorization—typically, that level corresponding to high-frequency nouns such as chair, apple, or car—and presented evidence that both adults and children find thinking to be easier at this level of generality (as opposed to superordinate levels such as furniture or fruit, or subordinate levels such as armchair or McIntosh). This intuitive notion has, however, proved hard to formalize in a rigorous way, and the evidence for basic levels outside the well-studied biological and artifact domains remains weak. Attempts to model the combination of prototype concept classes with FUZZY LOGIC (Zadeh 1965) has also proved to be ill founded (Osherson and Smith 1981), although they have led to the development of more general research in conceptual combination (Hampton 1988).

In the third or "exemplar" model, which is only weakly represented in the lexical semantic research tradition, lexical concepts are based not on a prototype but on a number of different exemplar representations. For example, small

metal spoons and large wooden spoons are considered more typical than small wooden spoons and large metal spoons (Medin and Shoben 1988). This fact could be evidence for representation through stored exemplars, although it could also be explained by a disjunctive prototype representation. Formally, explicit exemplar models are generally underpowered for representing lexical concepts, having no means to represent intensional information for stimulus domains that do not have a simple dimensional structure. As a result, they have no way to derive logical entailments based on conceptual meaning (for example, that all robins are birds).

The fourth model is the "theory-based" model (Murphy and Medin 1985), which has strong connections with the COGNITIVE DEVELOPMENT tradition. Concepts are embedded in theoretical understanding of the world. While a prototype representation of the concept bird would consist of a list of unconnected attributes, the theory-based representation would also represent theoretical knowledge about the relation of each attribute to others in a complex network of causal and explanatory links, represented in a structured frame or schema. Birds have wings in order to fly, which allows them to nest in trees, which they do to escape predation, and so forth. According to this view, objects are categorized in the class which best explains the pattern of attributes they possess (Rips 1989).

The fifth and final model, psychological ESSENTIALISM (Medin and Ortony 1989), is a development of the classical and theory-based models, and attempts to align psychological models with the philosophical intuitions of Putnam and others. The model argues for a classical "core" definition of concepts, but one which may frequently contain an empty "place holder." People believe that there is a real definition of what constitutes a bird (an *essence* of the category), but they do not know what it is. They are therefore forced to use available information to categorize the world, but remain willing to yield to more expert opinion. Psychological essentialism captures Putnam's intuition (1975) that people defer to experts when it comes to classifying biological or other technical kinds (for example, gold). However, it has not been shown that the model applies well to concepts beyond the range of biological and scientific terms (Kalish 1995) or even to people's use of natural kind terms such as *water* (Malt 1994).

The proliferation of different models for concept representation reflects the diversity of research traditions, the many different kinds of concepts we possess, and the different uses we make of them.

Conceptual Change

Discussion of conceptual change is commonplace throughout cognitive science and is very much a part of understanding what CONCEPTS themselves are. There are examples in the history and philosophy of science (Kuhn 1970, 1977), in the study of SCIENTIFIC THINKING AND ITS DEVELOPMENT, in discussions of COGNITIVE DEVELOPMENT at least as far back as PIAGET (1930) and VYGOTSKY (1934), in linguistic analysis both of language change over history and of LANGUAGE ACQUISITION, and in computer science and artificial intelligence (AI) (Ram, Nersessian, and Keil 1997). But no one sense of conceptual change prevails, making it difficult to define conceptual change in uncontroversial terms. We can consider four types of conceptual change (see also Keil 1998) as being arrayed along a continuum from the simple accretion of bits of knowledge to complete reorganizations of large conceptual structures, with a fifth type that can involve little or no restructuring of concepts but radical changes in how they are used. Common to all accounts is the idea that either conceptual structure itself or the way that structure is used changes over time. The most discussed account focuses on structural change seen as a dramatic and qualitative restructuring of whole systems of concepts (type 4). All five types are critical to consider, however, because very often the phenomena under discussion have not been studied in sufficient detail to say which type best explains the change.

1. *Feature or property changes and value changes on dimensions.* With increasing knowledge, different clusters of features may come to be weighted more heavily in a

concept, perhaps because they occur more frequently in a set of experiences. A young child might weight shape somewhat more heavily in her concept of a bath towel than texture, while an older child might do the opposite. In its simplest form, such a developmental change may not connect to any other relations or beliefs, such as why texture is now more important. An older child might disagree with a younger one on identifying some marginal feature of bath towels, and while we might thereby attribute this difference to conceptual change, we might not see the concepts as really being very different.

Changes in feature weightings and dimensional value shifts are ubiquitous in cognitive science studies of concepts. They are seen at all ages ranging from studies of infant categorization to adult novice-to-expert shifts (see INFANT COGNITION and EXPERTISE). Any time that some bit of information is incrementally added to a knowledge base and results in a different feature weighting, such a change occurs. When such changes have no other obvious consequences for how knowledge in a domain is represented, they constitute the most minimal sense of conceptual change, and for many who contrast "learning" with true conceptual change, not a real case at all (Carey 1991).

2. *Shifting use of different sorts of properties and relations.* Conceptual change could occur because of changes in the kinds of feature used in representations. Infants and young children have been said to use perceptual and not conceptual features to represent classes of things, or perceptual and not functional ones, or concrete and not abstract ones (e.g., Werner and Kaplan 1963). More recently, young children are said to use one-place predicates and not higher-order relational ones (Gentner and Toupin 1988), or to rely heavily on shape-based features early on in some contexts (Smith, Jones, and Landau 1996). Similar arguments have been made about novice to expert shifts in adults (Chi, Feltovich, and Glaser 1981) and even about the evolution of concepts from those in "primitive" cultures to those in more "advanced" ones (cf. Horton 1967; see also LURIA).

Several forms of conceptual change can be captured by shifts in what feature types are used in concepts. Despite a wide range of proposals in this area, however, it is striking how many have always been controversial, especially in claims of cross-cultural differences (Cole and Means 1981). There is no consensus on changes in the sorts of properties, relations, or both available at different points in development, expertise, or historical change, nor on the very real possibility of no true changes in the availability of property types.

Part of the problem is the need for better theories of property types. It is difficult to make claims about perceptual to conceptual shifts, or perceptual to functional shifts, if the contrast between perceptual and conceptual features is murky. Claims of changes in feature types therefore need to attend closely to philosophical analyses of properties and relations, which in turn need to attend more to the empirical facts.

3. *Changes in computations performed on features.* Conceptual change can also arise from new kinds of computations performed on a constant set of features, such as from tabulations of features based on frequency and correlational information, to more rulelike organizations of the same features (Sloman 1996). In other cases, there have been claims of changes from prelogical to quasi-logical computations over features (Inhelder and Piaget 1958), or changes from integral to separable operations on features and dimensions (Kemler and Smith 1978); or changes from feature frequency tabulations to feature correlation tabulations.

Although most models tend to propose changes in computations that apply across all areas of cognition, such transitions can also occur in circumscribed domains of thought even as there are no global changes in computational ability (Chi 1992). Second, these models do not require that concepts be interrelated in a larger structure. They are neutral in that respect and thus allow each concept to change on its own. In practice, this is highly implausible and may in the end render such models inadequate because they fail to make stronger claims about links among concepts.

There are also cases where there is no absolute change in feature or computational types, but rather a strong change in the ratio of types. Thus a younger child may have true conceptual or functional features but may have ten times as many perceptual ones in her concepts, whereas an older child may have the opposite ratio. Similarly, a younger child may perform logical computations on feature sets, but may do so much more rarely and may more frequently resort to simpler probabilistic tabulations. This variant is important because it offers a very different characterization of the younger child in terms of basic competencies. Younger children are not incapable of representing certain feature types or engaging in certain computations; rather, they do so much less often, perhaps as a function of being much more inexperienced in so many domains (Keil 1989).

4. *Theoretic changes, where theories spawn others and thereby create new sets of concepts.* The most dramatic kinds of conceptual change, and those occupying most discussions in cognitive science at large, are those that view concepts as embedded in larger explanatory structures, usually known as "theories," and whose changes honor DOMAIN SPECIFICITY. Sweeping structural changes are said to occur among whole sets of related concepts in a domain. For example, a change in one concept in biology will naturally lead to simultaneous changes in other biological concepts because they as a cluster tend to complement each other symbiotically. Within this type, three kinds of change are normally described: (a) birth of new theories and concepts through the death of older ones (Gopnik and Wellman 1994); (b) gradual evolution of new theories and concepts out of old ones in a manner that eventually leaves no traces of the earlier ones (Wiser and Carey 1983); and (c) birth of new theories and attendant concepts in a manner that leaves the old ones intact (Carey 1985).

One key issue in choosing among these kinds of theoretic change is the extent to which concepts of one type are incommensurable or contradictory with those of another type (Kuhn 1970, 1982). Kuhn suggested that conceptual changes in domains could lead to "paradigm shifts" in which concepts in a prior system of beliefs might not even be understandable in terms of the new set of beliefs, just as concepts in that newer system might not be understandable in terms of the older one. The ideas of paradigm shifts and

ensuing incommensurability have been highly influential in many areas of cognitive science, most notably in the study of conceptual change in childhood (Carey 1985). A related issue asks how contradictions and anomalies in an older theory precipitate change (Chinn and Brewer 1993; Rusnock and Thagard 1995).

Although most discussion of theoretic conceptual change has focused on these three kinds of restructuring, unambiguous empirical evidence for these systemic restructurings as opposed to the other four types of conceptual change (1, 2, 3, 5) is often difficult to come by. For example, when a child undergoes a dramatic developmental shift in how she thinks about the actions of levers, although that change might reflect a restructuring of an interconnected set of concepts in a belief system about physical mechanics, it might also reflect a change in the kinds of features that are most emphasized in mechanical systems, or how the child performs computations on correlations that she notices among elements in mechanical systems.

5. *Shifting relevances.* Children and adults often come to dramatic new insights not because of an underlying conceptual revolution or birth of a new way of thinking, but rather because they realize the relevance or preferred status of an already present explanatory system to a new set of phenomena. Because the realization can be sudden and the extension to new phenomena quite sweeping, it can have all the hallmarks of profound conceptual change. It is, however, markedly different from traditional restructuring notions. Children, for example, can often have several distinct theories available to them throughout an extensive developmental period but might differ dramatically from adults in where they think those theories are most relevant (e.g., Gutheil, Vera, and Keil 1998). Children might not differ across ages in their possession of the theories but rather in their application of them. These kinds of relevance shifts, combined with theory elaboration in each domain, may be far more common than cases of new theories arising de novo out of old ones.

An increasing appreciation of these different types of conceptual change is greatly fostered by a cognitive science perspective on knowledge; for as questions cross the disciplines, they become treated in different ways and different kinds of conceptual change stand out as most prominent. In addition, these types of conceptual change need not be mutually exclusive. For example, changes in the kinds of features that are emphasized and in the kinds of computations performed on those features can occur on a domain-specific basis and might result in a set of concepts having different structural relations among each other.

Conceptual Role Semantics

See FUNCTIONAL ROLE SEMANTICS

Conditioning

When Ivan Pavlov observed that hungry dogs salivated profusely not only at the taste or sight of food, but also at the sight or sound of the laboratory attendant who regularly fed them, he described this salivation as a "psychical reflex" and later as a "conditional reflex." Salivation was an inborn, reflexive response, unconditionally elicited by food in the mouth, but which could be elicited by other stimuli conditionally on their having signaled the delivery of food. The term *conditional* was translated as "conditioned," whence by back-formation the verb "to condition," which has been used ever since.

In Pavlov's experimental studies of conditioning (1927), the unconditional stimulus (US), food or dilute acid injected into the dog's mouth, was delivered immediately after the presentation of the conditional stimulus (CS), a bell, metronome, or flashing light, regardless of the animal's behavior. The US served to strengthen or reinforce the conditional reflex of salivating to the CS, which would extinguish if the US was no longer presented. Hence the US is often referred to as a "reinforcer." Pavlovian or classical conditioning is contrasted with instrumental or operant conditioning, where the delivery of the reinforcer is dependent on the animal performing a particular response or action. This was first studied in the laboratory by Thorndike (1911), at much the same time as, but quite independently of, Pavlov's experiments. Thorndike talked of "trial-and-error learning," but the "conditioning" terminology was popularized by Skinner (1938), who devised the first successful fully automated apparatus for studying instrumental conditioning.

In Pavlovian conditioning, the delivery of the reinforcer is contingent on the occurrence of a stimulus (the CS), whereas in instrumental conditioning, it is contingent on the occurrence of a designated response. This operational distinction was first clearly articulated by Skinner, but Miller and Konorski (1928) in Poland and Grindley (1932) in England had already argued, on experimental and theoretical grounds, for the importance of this distinction. According to the simplest, and still widely accepted, interpretation of Pavlovian conditioning, the US serves to elicit a response (e.g., salivation), and pairing a CS with this US results in the formation of an association between the two, such that the presentation of the CS can activate a representation of the US, which then elicits the same (or a related) response. This account cannot explain the occurrence of instrumental conditioning. If the delivery of a food reinforcer is contingent on the execution of a particular response, this may well lead to the formation of an association between response and reinforcer. The Pavlovian principle can then predict that the dog performing the required response will salivate when doing so (a prediction that has been confirmed), but what needs to be explained is why the dog learns to perform the response in the first place.

Another way of stating the distinction between Pavlovian and instrumental conditioning is to note that instrumentally conditioned responses are being modified by their consequences, much as Thorndike's law of effect, or Skinner's talk of "controlling contingencies of reinforcement,"

implied. The hungry rat that presses a lever to obtain food, will desist from pressing the lever if punished for doing so. But Pavlovian conditioned responses are not modified by their consequences; they are simply elicited by a CS associated with a US, as experiments employing omission schedules demonstrate. If, in a Pavlovian experiment, the delivery of food to a hungry pigeon is signaled by the illumination of a small light some distance away from the food hopper, the pigeon will soon learn to approach and peck at this light, even though this pattern of behavior takes it farther away from the food, to the point of reducing the amount of food it obtains. Indeed, it will continue to approach and peck the light on a high proportion of trials even if the experimenter arranges that any such response actually cancels the delivery of food on that trial. The light, as a CS, has been associated with food, as a US, and comes to elicit the same pattern of behavior as food, approach and pecking, regardless of its consequences (Mackintosh 1983).

Most research in COMPARATIVE PSYCHOLOGY accepts that the conditioning process is of wide generality, common at least to most vertebrates, and allows them to learn about the important contingencies in their environment—what events predict danger, what signs reliably indicate the availability of food, how to take effective action to avoid predators or capture prey; in short, to learn about the causal structure of their world. But why should cognitive scientists pay attention to conditioning? One plausible answer is that conditioning experiments provide the best way to study simple associative LEARNING, and associative learning is what NEURAL NETWORKS implement. Conditioning experiments have unique advantages for the study of associative learning: experiments on eyelid conditioning in rabbits, conditioned suppression in rats, or autoshaping in pigeons reveal the operation of simple associative processes untrammeled by other, cognitive operations that people bring to bear when asked to solve problems. And through such preparations researchers can directly study the rules governing the formation of single associations between elementary events. As many commentators have noted, there is a striking similarity between the Rescorla-Wagner (1972) model of Pavlovian conditioning and the Widrow-Hoff or delta rule frequently used to determine changes in connection weights in a parallel distributed processing (PDP) network (Sutton and Barto 1981). The phenomenon of "blocking" in Pavlovian conditioning provides a direct illustration of the operation of this rule: if a given reinforcer is already well predicted by CS1, further conditioning trials on which CS2 is added to CS1 and the two are followed by the reinforcer results in little or no conditioning to CS2. The Rescorla-Wagner model explains this by noting that the strength of an association between a CS and reinforcer will change only when there is a discrepancy between the reinforcer that actually occurs and the one that was expected to occur. According to the delta rule, connections between elements in a network are changed only insofar as is necessary to bring them into line with external inputs to those elements.

But conditioning theorists, not least Rescorla and Wagner themselves, have long known that the Rescorla-Wagner model is incomplete in several important respects. A second determinant of the rate of change in the strength of an association between a CS and a US is the associability of the CS—which can itself change as a consequence of experience. For example, in the phenomenon of latent inhibition, a novel CS will enter into association with a US rapidly, but a familiar one will condition only slowly. Inhibitory conditioning, when a CS signals the absence of an otherwise predicted US, is not the symmetrical opposite of excitatory conditioning, when the CS signals the occurrence of an otherwise unexpected US. Even the rather simple stimuli used in most conditioning experiments are, at least sometimes, represented as configurations of patterns of elements rather than as a simple sum of their elements (Pearce 1994). This last point has indeed been incorporated into many connectionist networks because a simple, elementary representation of stimuli makes the solution of many discriminations impossible. A familiar example is the XOR (exclusive or) problem: if each of two stimuli, A and B, signaled the delivery of a US when presented alone, but their combination, AB, predicted the absence of the US, a simple elementary system would respond more vigorously to the AB compound than to A or B alone, and thus fail to learn the discrimination. The solution must be to represent the compound as something more than, or different from, the sum of its components. But apart from this, not all connectionist models have acknowledged the modifications to error-correcting associative systems that conditioning theorists have been willing to entertain to supplement the simple Rescorla-Wagner model. Conversely, some of the phenomena once thought to contradict, or lie well outside the scope of, standard conditioning theory, such as evidence of so-called constraints on learning (Seligman and Hager 1972), turn out on closer experimental and theoretical analysis to require little more than minor parametric changes to the theory (Mackintosh 1983). Conditioning theory and conditioning experiments may still have some important lessons to teach.

Conditioning and the Brain

How the brain codes, stores, and retrieves memories is among the most important and baffling questions in science. The uniqueness of each human being is due largely to the MEMORY store—the biological residue of memory from a lifetime of experience. The cellular basis of this ability to learn can be traced to simpler organisms. In the past generation, it has become clear that various forms and aspects of LEARNING and memory involve particular systems, networks, and circuits in the brain, and it now appears possible we will identify these circuits, localize the sites of memory storage, and ultimately analyze the cellular and molecular mechanism of memory.

All aspects of learning share a common thrust. As Rescorla (1988) has stressed, basic associative learning is the way organisms, including humans, learn about causal relationships in the world. It results from exposure to relations among events in the world. For both modern Pavlovian and cognitive views of learning and memory, the individual learns a representation of the causal structure of the world and adjusts this representation through experience to bring it in tune with the real causal structure of the world, striving to reduce any discrepancies or errors between its internal representation and external reality.

Most has been learned about the simplest forms of learning: nonassociative processes of habituation and sensitization, and basic associative learning and memory. Here we focus on CONDITIONING in the mammalian brain. We emphasize classical or Pavlovian conditioning because far more is known about brain substrates of this form of learning than about more complex instrumental learning. Pavlovian conditioning involves pairing a "neutral" stimulus, for example, a sound- or light-conditioned stimulus (CS) with an unconditioned stimulus (US) that elicits a response, the unconditioned response (UR). As a result of repeated pairings, with the CS onset preceding the US onset by some brief period of time, the CS comes to elicit a conditioned response (CR). Conditioning may be the way organisms, including humans, first learn about the causal structure of the world. Contemporary views of Pavlovian conditioning emphasize the predictive relations between the CS and the US, consistent with cognitive views of learning and memory. The key factor is the contingencies among events in the organism's environment.

When animals, including humans, are faced with an aversive or threatening situation, at least two complementary processes of learning occur. Learned fear or arousal develops very rapidly, often in one trial. Subsequently, the organism learns to make the most adaptive behavioral motor responses to deal with the situation. These observations led to theories of "two-process" learning: an initial learned fear

or arousal, followed by slower learning of discrete, adaptive behavioral responses (Rescorla and Solomon 1967). As the latter learning develops, fear subsides. We now think that at least in mammals a third process of "declarative" memory for the events and their relations also typically develops (cf. EPISODIC VS. SEMANTIC MEMORY).

Learned fear develops rapidly, often in one trial, and involves changes in autonomic responses (heart rate, blood pressure, pupillary dilation) and nonspecific skeletal responses (freezing, startle). The afferent limb of the conditioned fear circuit involves projections from sensory relay nuclei via thalamic projections to the AMYGDALA. Although lesions of the appropriate regions of the amygdala can abolish all signs of learned fear, lesions of the efferent targets of the amygdala can have selective effects, for example, lateral hypothalamic lesions abolish cardiovascular signs of learned fear but not behavioral signs (e.g., freezing), whereas lesions of the periqueductal gray abolish learned freezing but not the autonomic signs of learned fear (see, for example, Le Doux et al. 1988). This double disassociation of conditioned responses stresses the key role of the amygdala in learned fear, as do studies involving recording of neuronal activity and electrical stimulation (Davis 1992). The amygdala is critically involved in unlearned fear responses as well. The structures most involved in generating the appropriate responses in basic associative learning and memory seem also to be the most likely sites of memory storage (see below).

Higher brain structures also become critically engaged in learned fear under certain circumstances. Thus when an organism experiences strong shock in a particular environment, reexperiencing that environment elicits learned fear. This context-dependent learned fear involves both the amygdala and the HIPPOCAMPUS for a time-limited period after the experience, a temporal property characteristic of more cognitive aspects of declarative memory (Kim and Fanselow 1992).

A vast amount of research has been done using Pavlovian conditioning of the eye blink response in humans and other mammals (Gormezano, Kehoe, and Marshall-Goodell 1983). The eye blink response exhibits all the basic laws and properties of Pavlovian conditioning equally in humans and other mammals. The basic procedure is to present a neutral CS such as a tone or a light followed a quarter of a second or so later by a puff of air to the eye or a periorbital (around-the-eye) shock (US), the two stimuli terminating together. This is termed the *delay procedure*. If a period of no stimuli intervenes between CS offset and US onset, it is termed the *trace procedure*, which is much more difficult to learn than the delay procedure. Initially, there is no response to the CS and a reflex eye blink to the US. After a number of such trials, the eyelid begins to close in response to the CS before the US occurs, and in a well-trained subject, the eyelid closure CR becomes very precisely timed so that the eyelid is maximally closed about the time that the air puff or shock US onset occurs. This very adaptive timing of the eye blink CR develops over the range of CS-US onset intervals where learning occurs, about 100 milliseconds to 1 second. Thus the conditioned eye blink response is a very precisely timed elementary learned motor skill. The same is true of other

discrete behavioral responses learned to deal with aversive stimuli (e.g., the forelimb or hindlimb flexion response, head turn, etc.).

Two brain systems become massively engaged in eye blink conditioning, hippocampus and CEREBELLUM (Thompson and Kim 1996). If the US is sufficiently aversive, learned fear also occurs, involving the amygdala, as noted above. Neuronal unit activity in the hippocampus increases in paired (tone CS–corneal air puff US) training trials very rapidly, shifts forward in time as learning develops, and forms a predictive "temporal model" of the learned behavioral response, both within and over the training trials. The growth of this hippocampal neuronal unit response is, under normal conditions, an invariable and strongly predictive concomitant of subsequent behavioral learning (Berger, Berry, and Thompson 1986).

Interestingly, in the basic delay procedure, hippocampal lesions do not impair the eye blink CR, although if the more difficult trace procedure is used, the hippocampal lesions massively impair learning of the CR and, in trained animals, impair memory in a time-limited manner. These results are strikingly consistent with the literature concerned with declarative memory deficit following damage to the hippocampal system in humans and monkeys, as is the hippocampus-dependent contextual fear discussed above. So even in "simple" learning tasks like eye blink and fear conditioning, hippocampus-dependent "declarative" memory processes develop.

The cerebellum has long been a favored structure for modeling a neuronal learning system, in part because of the extraordinary architecture of the cerebellar cortex, where each Purkinje neuron receives 100,000+ excitatory synapses from mossy-parallel fibers but only one climbing fiber from the inferior olive (see below). The reflex eye blink response pathways activated by the US (corneal air puff or periorbital shock) involve direct and indirect relays through the brain stem from the sensory (trigeminal) nucleus to the relevant motor nuclei (largely the seventh and accessory sixth). The CS (e.g., tone) pathway projects to the forebrain and also, via mossy fibers, to the cerebellum. The US (e.g., corneal air puff) pathway projects from the trigeminal nuclei to the forebrain and also, via the inferior olive, as climbing fibers to the cerebellum. These two projection systems converge on localized regions of the cerebellum, where the memory traces appear to be formed. The CR pathway projects from the cerebellar cortex and nuclei (interpositus nucleus) via the red nucleus to the motor nuclei generating the eye blink response. (The cerebellum does not participate in the reflex eye blink response.) A wide range of evidence, including electrophysiological recording, lesions, electrical stimulation, and reversible inactivation during training, has demonstrated conclusively that the cerebellum is necessary for this form of learning (both delay and trace) and that the cerebellum and its associated circuitry form the essential (necessary and sufficient) circuitry for this learning. Moreover, the evidence strongly suggests that the essential memory traces are formed and stored in the localized regions in the cerebellum (see Thompson and Krupa 1994; Lavond, Kim, and Thompson 1993; Yeo 1991).

These results constitute an extraordinary confirmation of the much earlier theories of the cerebellum as a neuronal learning system, first advanced in the classic papers of MARR (1969) and Albus (1971) and elaborated by Eccles (1977) and Ito (1984). These theories proposed that mossy-parallel fibers conveyed information about stimuli and movement contexts (CSs here) and the climbing fibers conveyed information about specific movement errors and aversive events (USs here) and they converged (e.g., on Purkinje neurons in cerebellar cortex and interpositus nucleus neurons).

The cerebellar system essential for a basic form of learning and memory constitutes the clearest example to date of localizing memory traces to particular sites in the brain (i.e., in the cerebellum).

Connectionism, Philosophical Issues

Since its inception, artificial intelligence (AI) research has had a growing influence on the philosophy of mind. Consequently, the recent development of a radically different style of cognitive modeling—commonly known as "connectionism" (see COGNITIVE MODELING, CONNECTIONIST)—has brought with it a number of important philosophical issues and concerns. Because connectionism is such a dramatic departure from more traditional accounts of cognition, it has forced philosophers to reconsider several assumptions based on earlier theories. Most of these cluster around three central themes: (1) the nature of psychological explanation, (2) forms of mental representation, and (3) nativist and empiricist accounts of learning.

Before the introduction of connectionism in the mid-1980s, the dominant paradigm in cognitive modeling was the COMPUTATIONAL THEORY OF MIND, sometimes referred to by philosophers as "GOFAI" (for "good old-fashioned artificial intelligence"; see also COGNITIVE MODELING, SYMBOLIC). GOFAI accounts treat the mind as a complex organization of interacting subsystems, each performing a specific cognitive function and processing information through the manipulation of discrete, quasi-linguistic symbols whose interactions are governed by explicitly encoded rules. Psychological explanation is treated as a form of FUNCTIONAL DECOMPOSITION, where sophisticated cognitive capacities are broken down and explained through the coordinated activity of individual components. The capacities of the individual components are further explained through a description of their internal symbolic operations (Cummins 1983; see also RULES AND REPRESENTATIONS and ALGORITHM).

Connectionism suggests a very different outlook on the nature of psychological theory. Connectionist networks model cognition through the spreading activation of numerous simple units. The processing is highly distributed throughout the entire system, and there are no task-specific modules, discrete symbols, or explicit rules that govern the operations (Rumelhart, McClelland, and PDP Research Group 1986; McClelland, Rumelhart, and PDP Research Group 1986; Smolensky 1988). This has forced researchers to abandon the functional decomposition approach and search for new ways to understand the structure of psychological explanation. In one popular alternative, DYNAMIC APPROACHES TO COGNITION, cognitive activity is understood as a series of mathematical state transitions plotted along different possible trajectories. Mental operations are described through equations that capture the behavior of the whole system, rather than focusing on the logical or syntactic transformations within specific subsystems. Some

writers believe this framework will provide a new paradigm for understanding the nature of COGNITIVE ARCHITECTURE and give rise to psychological explanations that depart dramatically from past accounts (van Gelder 1991; Horgan and Tienson 1996; see also COMPUTATIONAL NEUROSCIENCE).

GOFAI cognitive models rely heavily on explicit, syntactically structured symbols to store and process information. By contrast, connectionist networks employ a very different type of representation, whereby information is encoded throughout the nodes and connections of the entire network. These distributed representations (cf. DISTRIBUTED VS. LOCAL REPRESENTATION) lack the languagelike, syntactic structure of traditional GOFAI symbols. Moreover, their content and representational function is often revealed only through mathematical analysis of the activity patterns of the system's internal units.

The philosophical implications of this new account of representation are far-reaching. Some writers, unhappy with the quasi-linguistic character of GOFAI symbols, have embraced the connectionist picture to support nonsentential theories of representation, including prototype accounts of CONCEPTS (Churchland 1989). Others have suggested parallels between the connectionist representations and the biologically motivated theories of INFORMATIONAL SEMANTICS explored by writers such as Fred Dretske (1988). Many believe the internal units of connectionist networks provide a promising new way to understand MENTAL REPRESENTATION because of their similarity to real neural systems and their sensitivity to environmental stimuli (Bechtel 1989).

On the other hand, some philosophers have argued that the connectionist account of representation is seriously flawed. Jerry Fodor and Zenon Pylyshyn have claimed that the ability to represent some states of affairs (e.g., "John loves Mary") is closely linked to the ability to represent other states of affairs (e.g., "Mary loves John"; Fodor and Pylyshyn 1988). They argue that this feature of cognition, called "systematicity," must be explained by any plausible theory of mind. They insist that because connectionist representations do not have constituent parts, connectionist models cannot explain systematicity. In response to this challenge, several connectionists have argued that it is possible for connectionist representations to produce systematic cognition in subtle ways without merely implementing a symbolic system (Smolensky 1991; Clark 1991).

Connectionist accounts of representations have also influenced philosophical debate concerning the status of PROPOSITIONAL ATTITUDES. ELIMINATIVE MATERIALISM holds that our commonsense conception of the mind is so flawed that there is reason to be skeptical about the existence of states such as beliefs and desires. Some writers have suggested that the style of information encoding in networks is so radically different from what is assumed by common sense that connectionist models actually give credence to eliminativism (Churchland 1986; Ramsey, Stich, and Garon 1990). Others have gone a step further and argued that the internal elements of networks should not be viewed as representations at all (Brooks 1991; Ramsey 1997). In response, several writers have insisted that commonsense psychology and connectionism are quite compatible, once the

former is properly construed; moreover, because our commonsense notion of belief is not committed to any specific sort of cognitive architecture, it has nothing to fear from the success of connectionism (Dennett 1991; Bechtel and Abrahamsen 1993; see also FOLK PSYCHOLOGY).

Research in cognitive science has had an important influence on the traditional debate between nativists, who claim that we are born with innate knowledge, and empiricists, who claim that knowledge is derived from experience (see also NATIVISM and RATIONALISM VS. EMPRIRICISM). Nativism has enjoyed popularity in cognitive science because it has proven difficult to explain how cognitive capacities are acquired without assuming some form of preexisting knowledge within the system. Yet one of the most striking features of connectionist networks is their ability to attain capacities with very little help from antecedent knowledge. By relying on environmental stimuli and powerful learning algorithms, networks often appear to program themselves. This has led many to claim that connectionism offers a powerful new approach to learning—one that will resurrect empiricist accounts of the mind.

A mainspring of nativism in cognitive science has been Chomsky's POVERTY OF THE STIMULUS ARGUMENT for the INNATENESS OF LANGUAGE (1975). Chomsky has argued that LANGUAGE ACQUISITION is impossible without a rich store of innate linguistic knowledge. Although several CONNECTIONIST APPROACHES TO LANGUAGE have been developed to demonstrate how areas of linguistic competence—such as knowing regular and irregular past tense forms of verbs—can be obtained without preexisting linguistic rules (Rumelhart, McClelland, and PDP Research Group 1986; Elman et al. 1996), the success of these models in establishing a nonnativist theory of linguistic competence has been heavily debated (Pinker and Prince 1988). One critical issue concerns the degree of DOMAIN SPECIFICITY employed in the learning strategies and initial configuration of the networks (Ramsey and Stich 1990).

A second motivation for nativism stems from the "classical" account of concept acquisition, which assumes that learning occurs when new complex concepts are constructed from more primitive concepts (Fodor 1981), and which suggests there must first exist a prior store of basic concepts that, by hypothesis, are unlearned. However, connectionism appears to offer a different model of concept acquisition. Networks seem to develop new classifications and abstractions that emerge without the recombination of preexisting representations. In other words, there is reason to think connectionist learning gives rise to new primitive concepts that are developed entirely in response to the system's training input (Munakata et al. 1997). To many, this captures the essence of empiricist learning and signals a new direction for understanding CONCEPTUAL CHANGE (Churchland 1989; Elman et al. 1996).

Connectionist Approaches to Language

In research on theoretical and COMPUTATIONAL LINGUISTICS and NATURAL LANGUAGE PROCESSING, the dominant formal approaches to language have traditionally been theories of RULES AND REPRESENTATIONS. These theories assume an underlying symbolic COGNITIVE ARCHITECTURE based in discrete mathematics, the theory of algorithms for manipulating symbolic data structures such as strings (e.g., of phonemes; see PHONOLOGY), trees (e.g., of nested syntactic phrases; see SYNTAX), graphs (e.g., of conceptual structures deployed in SEMANTICS), and feature structures (e.g., of phonological, syntactic, and semantic properties of nested phrases or their designations). In contrast, connectionist computation is based in the continuous mathematics of NEURAL NETWORKS: the theory of numerical vectors and tensors (e.g., of activation values), matrices (e.g., of connection weights), differential equations (e.g., for the dynamics of spreading activation or learning), probability and statistics (e.g., for analysis of inductive and statistical inference). How can linguistic phenomena traditionally analyzed with discrete symbolic computation be analyzed with continuous connectionist computation? Two quite different strategies have been pursued for facing this challenge.

The dominant, *model-centered* strategy proceeds as follows (see COGNITIVE MODELING, CONNECTIONIST; see also STATISTICAL TECHNIQUES IN NATURAL LANGUAGE PROCESSING): specific data illustrating some interesting linguistic phenomena are identified; certain general connectionist principles are hypothesized to account for these data; a concrete instantiation of these principles in a particular connectionist network—the model—is selected; computer simulation is used to test the adequacy of the model in accounting for the data; and, if the network employs learning, the network configuration resulting from learning is analyzed to discern the nature of the account that has been learned.

For instance, a historically pivotal model (Rumelhart and McClelland 1986) addressed the data on children's overgeneralization of the regular past tense inflection of irregular verbs; connectionist induction from the statistical preponderance of regular inflection was hypothesized to account for these data; a network incorporating a particular representation of phonological strings and a simple learning rule was proposed; simulations of this model documented considerable but not complete success at learning to inflect irregular, regular, and novel stems; and limited post hoc analysis was performed of the structure acquired by the network which was responsible for its performance.

The second, *principle-centered,* strategy approaches language by directly deploying general connectionist principles, without the intervention of a particular network model. Selected connectionist principles are used to directly derive a novel and general linguistic formalism, and this formalism is then used directly for the analysis of particular linguistic phenomena. An example is the "harmonic grammar" formalism (Legendre, Miyata, and Smolensky 1990), in which a grammar is a set of violable or "soft" constraints on the well-formedness of linguistic structures, each with a numerical strength: the grammatical structures are those that simultaneously best satisfy the constraints. As discussed below, this formalism is a consequence of general mathematical principles that can be shown to govern the abstract, high-level properties of the representation and processing of information in certain classes of connectionist systems.

These two connectionist approaches to language are complementary. Although the principle-centered approach is independent from many of the details needed to define a concrete connectionist model, it can exploit only relatively basic connectionist principles. With the exception of the simplest cases, the general emergent cognitive properties of the dynamics of a large number of interacting low-level connectionist variables are not yet characterizable by mathe-

matical analysis—detailed computer simulation of concrete networks is required.

We now consider several connectionist computational principles and their potential linguistic implications. These principles divide into those pertaining to the learning, the processing, and the representational components of connectionist theory.

Connectionist Inductive Learning Principles

These provide one class of solution to the problem of how the large numbers of interactions among independent connectionist units can be orchestrated so that their emergent effect is the computation of an interesting linguistic function. Such functions include those relating a verb stem with its past tense (MORPHOLOGY); orthographic with phonological representations of a word (READING and VISUAL WORD RECOGNITION); and a string of words with a representation of its meaning.

Many learning principles have been used to investigate what types of linguistic structure can be induced from examples. SUPERVISED LEARNING techniques learn to compute a given input or output function by adapting the weights of the network during experience with training examples so as to minimize a measure of the overall output error (e.g., each training example might be a pair consisting of a verb stem and its past tense form). UNSUPERVISED LEARNING methods extract regularities from training data without explicit information about the regularities to be learned, for example, a network trained to predict the next letter in an unsegmented stream of text extracts aspects of the distributional structure arising from the repetition of a fixed set of words, enabling the trained network to segment the stream (Elman 1990).

A trained network capable of computing, to some degree, a linguistically relevant function has acquired a certain degree of internal structure, manifest in the behavior of the learned network (e.g., its pattern of generalization to novel inputs), or more directly discernible under analysis of the learned connection weights. The final network structure is jointly the product of the linguistic structure of the training examples and the a priori structure explicitly and implicitly provided the model via the selection of architectural parameters. Linguistically relevant a priori structure includes what is implicit in the representation of inputs and outputs, the pattern of connectivity of the network, and the performance measure that is optimized during learning.

Trained networks have acquired many types of linguistically relevant structure, including nonmonotonic or "U-shaped" development (Rumelhart and McClelland 1986); categorical perception; developmental spurts (Elman et al. 1996); functional modularity (behavioral dissociations in intact or internally damaged networks; Plaut and Shallice 1994); localization of different functions to different spatial portions of the network (Jacobs, Jordan, and Barto 1991); finite-state, machinelike structure corresponding to a learned grammar (Touretzky 1991). Before a consensus can be reached on the implications of learned structure for POVERTY OF THE STIMULUS ARGUMENTS and the INNATENESS OF LANGUAGE, researchers will have to demonstrate incontrovert-

ibly that models lacking grammatical knowledge in their a priori structure can acquire such knowledge (Elman et al. 1996; Pinker and Mehler 1988; Seidenberg 1997). In addition to this model-based research, recent formal work in COMPUTATIONAL LEARNING THEORY based in mathematical statistics has made considerable progress in the area of inductive learning, including connectionist methods, formally relating the justifiability of induction to general a priori limits on the learner's hypothesis space, and quantitatively relating the number of adjustable parameters in a network architecture to the number of training examples needed for good generalization (with high probability) to novel examples (Smolensky, Mozer, and Rumelhart 1996).

Connectionist Processing Principles

The potential linguistic implications of connectionist principles go well beyond learning and the RATIONALISM VS. EMPIRICISM debate. The processing component of connectionist theory includes several relevant principles. For example, in place of serial stages of processing, a connectionist principle that might be dubbed "parallel modularity" hypothesizes that informationally distinct modules (e.g., phonological, orthographic, syntactic, and semantic knowledge) are separate subnetworks operating in parallel with each other, under continuous exchange of information through interface subnetworks (e.g., Plaut and Shallice 1994).

Another processing principle concerns the transformations of activity patterns from one layer of units to the next: In the processing of an input, the influence exerted by a previously stored item is proportional to both the frequency of presentation of the stored item and its "similarity" to the input, where "similarity" of activity patterns is measured by a training-set–dependent metric (see PATTERN RECOGNITION AND FEEDFORWARD NETWORKS). While such frequency- and similarity-sensitive processing is readily termed *associative,* it must be recognized that "similarity" is defined relative to the internal activation pattern encoding of the entire set of items. This encoding may itself be sensitive to the contextual or structural role of an item (Smolensky 1990); it may be sensitive to certain complex combinations of features of its content, and insensitive altogether to other content features. For example, a representation may encode the syntactic role and category of a word as well as its phonological and semantic content, and the relevant "similarity" metric may be strongly sensitive to the syntactic information, while being completely insensitive to the phonological and semantic information.

A class of RECURRENT NETWORKS with feedback connections is subject to the following principle: The network's activation state space contains a finite set of attractor states, each surrounded by a "basin of attraction"; any input pattern lying in a given basin will eventually produce the corresponding attractor state as its output (see DYNAMIC APPROACHES TO COGNITION). This principle relates a continuous space of possible input patterns and a continuous processing mechanism to a discrete set of outputs, providing the basis for many connectionist accounts of categorical perception, categorical retrieval of lexical

items from memory, and categorization processes generally. For example, the pronunciation model of Plaut et al. (1996) acquires a combinatorially structured set of output attractors encoding phonological strings including monosyllabic English words, and an input encoding a letter string yields an output activation pattern that is an attractor for a corresponding pronunciation.

A related principle governing processing in a class of recurrent networks characterizes the output of the network as an *optimal* activation pattern: among those patterns containing the given input pattern, the output is the pattern that maximizes a numerical well-formedness measure, harmony, or that minimizes "energy" (see also CONSTRAINT SATISFACTION). This principle has been used in combination with the following one to derive a general grammar formalism, harmonic grammar, described above as an illustration of principle-centered research. Harmonic grammar is a precursor to OPTIMALITY THEORY (Prince and Smolensky 1993), which adds further strong restrictions on what constitutes a possible human grammar. These include the universality of grammatical constraints, and the requirement that the strengths of the constraints be such as to entail "strict domination": the cost of violating one constraint can never be exceeded by any amount of violation of weaker constraints.

Connectionist Representational Principles

Research on the representational component of connectionist theory has focused on statistically based analyses of internal representations learned by networks trained on linguistic data, and on techniques for representing, in numerical activation patterns, information structured by linear precedence, attribute/value, and dominance relations (e.g., Smolensky 1990; see BINDING PROBLEM). While this research shows how complex linguistic representations may be realized, processed, and learned in connectionist networks, contributions to the theory of linguistic representation remain largely a future prospect.

Consciousness

Conscious mental states include sensations, such as the pleasure of relaxing in a hot bath or the discomfort of a hangover, perceptual experiences, such as the visual experience of a computer screen about half a meter in front of me, and occurrent thoughts, such as the sudden thought about how a problem can be solved. Consciousness is thus a pervasive feature of our mental lives, but it is also a perplexing one. This perplexity—the sense that there is something mysterious about consciousness despite our familiarity with sensation, perception, and thought—arises principally from

the question of how consciousness can be the product of physical processes in our brains.

Ullin Place (1956) introduced a precursor of central state materialism for conscious states such as sensations. But the idea that types of conscious experience are to be identified with types of brain processes raises an important question, which can be made vivid by using Thomas Nagel's (1974) idea of WHAT-IT'S-LIKE to be in a certain state—and, more generally, the idea of there being something that it is like to be a certain creature or system. The question is, why should there be something that it is like for certain processes to be occurring in our brains? Nagel's famous example of what it is like to be a bat illustrates that our grasp of facts about the subjective character of experiences depends very much on our particular perceptual systems. Our grasp on physical or neurophysiological theories, in contrast, is not so dependent. Thus it may appear that subjective facts are not to be identified with the facts that are spelled out in those scientific theories. This Nagelian argument about the elusiveness of QUALIA is importantly similar to Frank Jackson's (1982, 1986) "knowledge argument" and similar responses have been offered to both (Churchland 1985, 1988; and for a reply, Braddon-Mitchell and Jackson 1996).

Ned Block's (1978) "absent qualia argument" is different from the arguments of Nagel and Jackson because it is specifically directed against FUNCTIONALISM: the idea that mental states are individuated by the causal roles they play in the total mental economy, rather than by the particular neurophysiological ways these roles are realized. The problem for functionalism is that we can imagine a system (e.g., Block's homunculi-headed system) in which there is nothing that it is like to be that system, even though there are, within the system, devices that play the various functional roles associated with sensations, perceptions, and thoughts. This argument is not intended for use against a physicalist who (in the style of Place and subsequent central state materialists) simply identifies conscious mental states with brain processes (pain with C-fibers firing, for example). The examples used in the absent qualia argument may, however, be used to support the claim that it is even logically possible there could be a physical duplicate of a normal human being that nevertheless lacked qualia (a "zombie"; Chalmers 1996).

It is a disputed question whether arguments like Nagel's can establish an ontological conclusion that consciousness involves something nonphysical (see MIND-BODY PROBLEM). But even if they cannot, there still appears to be a problem about consciousness; namely, it is a mystery why there should be something that it is like to undergo certain physical processes. This is what Joseph Levine (1983) has called the EXPLANATORY GAP. Jackson and Block both join Nagel in seeing a puzzle at this point, and Colin McGinn (1989) has argued that understanding how physical processes give rise to consciousness is cognitively beyond us (for a critical appraisal of McGinn's argument, see Flanagan 1992).

One possible strategy for demystifying the notion of consciousness is to claim that consciousness is a matter of thought about mental states. This is the "higher-order thought theory of consciousness" favored by David Rosenthal (1986). In this theory, consciousness, considered as a property of mental states, is analyzed in terms of consciousness *of* mental states, while consciousness *of* something is analyzed in terms of having a thought about that thing. Thus for a mental state to be a conscious mental state is for the subject of that state to have a thought about it. If the higher-order thought theory were to be correct, then the occurrence of consciousness in the physical world would not be any more mysterious than the occurrence of mental states, which are not in themselves conscious states, or the occurrence of thoughts about mental states.

However, there are some quite serious problems for the higher-order thought theory. One is that the theory seems to face a kind of dilemma. If the notion of thought employed is a demanding one, then there could be something that it is like for a creature to be in certain states even though the creature did not have (perhaps, even, could not have) any thoughts about those states. In that case, higher-order thought is not necessary for consciousness. But if the notion of thought that is employed is a thin and undemanding one, then higher-order thought is not sufficient for consciousness. Suppose, for example, that thought is said to require no more than having discriminative capacities. Then it seems clear that a creature, or other system, could be in a certain type of mental state, and could have a capacity to detect whether it was in a state of that type, even though there was nothing that it was like to be that creature or system.

More generally, work toward the demystification of consciousness has a negative and a positive aspect. The negative aspect consists in seeking to reveal unclarities and paradoxes in the notion of the subjective character of experience (e.g., Dennett 1988, 1991). The positive aspect consists in offering putative explanations of one or another property of conscious experience in neural terms. Paul Churchland (1988, 148) clearly illustrates how to explain certain structural features of our experiences of color (for example, that an experience of orange is more like an experience of red than it is like an experience of blue). The explanation appeals to the system of neural coding for colors that involves triples of activation values corresponding to the illumination reaching three families of cones, and to structural properties of the three-dimensional space in which they are plotted (see COLOR VISION). But while this is a satisfying explanation of those structural features of color experiences, it seems to leave us without any account of why it is like *anything at all* to see red. Why there are *any* experiential correlates of the neural codes is left as a brute unexplained fact. The demystifier of consciousness may then reply that this appearance of residual mystery is illusory, and that it is a product either of fallacies and confusions that surround the notion of the subjective character of experience or else of an illegitimately high standard imposed on explanation.

The notion of consciousness associated with the idea of the subjective character of experience, and which generates the "hard problem" of consciousness (Chalmers 1996), is sometimes called "phenomenal consciousness." There are several other notions for which the term *consciousness* is sometimes used (Allport 1988), including being awake,

voluntary action, ATTENTION, monitoring of internal states, reportability, INTROSPECTION, and SELF-KNOWLEDGE. The distinctions among these notions are important, especially for the assessment of cognitive psychological and neuroscientific theories of consciousness (see CONSCIOUSNESS, NEUROBIOLOGY OF).

One particularly useful contrast is between phenomenal consciousness and "access consciousness" (Block 1995, 231): "A state is access-conscious if, in virtue of one's having the state, a representation of its content is (1) inferentially promiscuous, that is, poised to be used as a premise in reasoning, (2) poised for rational control of action, and (3) poised for rational control of speech. . . . [Access consciousness is] a cluster concept, in which (3)—roughly, reportability—is the element of the cluster with the smallest weight, though (3) is often the best practical guide to [access consciousness]." The two notions appear to be independent in the sense that it is possible to have phenomenal (P) consciousness without access (A) consciousness, and vice versa. An example of P-consciousness without A-consciousness would be a situation in which there is an audible noise to which we pay no attention because we are engrossed in conversation. As an example of A-consciousness without P-consciousness, Block (1995, 233) suggests an imaginary phenomenon of "superblindsight." In ordinary cases of BLINDSIGHT, patients are able to guess correctly whether there is, for example, an O or an X in the blind region of their visual field, even though they are unable to see either an O or an X there. The state that represents an O or an X is neither a P-conscious nor an A-conscious state. In superblindsight, there is still no P-consciousness, but now the patient is imagined to be able to make free use in reasoning of the information that there is an O, or that there is an X.

While the notion of phenomenal consciousness applies most naturally to sensations and perceptual experiences, the notion of access consciousness applies very clearly to thoughts. It is not obvious whether we should extend the notion of phenomenal consciousness to include thoughts as well as sensory experiences. But the idea of an important connection between consciousness and thought is an engaging one. Sometimes, for example, it seems hard to accept that there could be a fully satisfying reconstruction of thinking in the terms favored by the physical sciences. This intuition is similar to, and perhaps derives from, the intuition that consciousness somehow defies scientific explanation.

The question whether there is an important connection between consciousness and thought divides into two: Does consciousness require thought? Does thought require consciousness? The intuitive answer to the first question is that access consciousness evidently does require thought, but that phenomenal consciousness does not. (The appeal of this intuitive answer is the source of some objections to the higher-order thought theory of consciousness.) The answer to the second question as it concerns access consciousness is that there is scarcely any distance at all between the notion of thought and the notion of access consciousness. But when we focus on phenomenal consciousness, the answer to the second question is less clear.

John Searle (1990, 586) argues for the connection principle: "The ascription of an unconscious intentional phenom-enon to a system implies that the phenomenon is in principle accessible to consciousness." This is to say that, while we can allow for unconscious intentional states, such as unconscious thoughts, these have to be seen as secondary, and as standing in a close relation to conscious intentional states. Searle's argument is naturally interpreted as being directed toward the conclusion that central cases of thinking are at least akin to phenomenally conscious states.

Even if one does not accept Searle's argument for the connection principle, there is a plausible argument for a weaker version of his conclusion. The INTENTIONALITY of human thought involves modes of presentation of objects and properties (see SENSE AND REFERENCE); demonstrative modes of presentation afforded by perceptual experience of objects and their properties constitute particularly clear examples. For example, we think of an object as "that [perceptually presented] cat" or of a property as "that color." Suppose now that it could be argued that some theoretical primacy attaches to these "perceptual demonstrative" modes of presentation (Perry 1979). It might be argued, for example, that in order to be able to think about objects at all, a subject needs to be able to think about objects under perceptual demonstrative modes of presentation. Such an argument would establish a deep connection between intentionality and consciousness.

Finally, there is another way phenomenal consciousness might enter the theory of thought. It might be because a thinker's thoughts are phenomenally conscious states, that they also have the more dispositional properties (such as reportability) mentioned in the definition of access consciousness. This phenomenal consciousness property might also figure in the explanation of a thinker's being able to engage in critical reasoning—evaluating and assessing reasons and reasoning as such (Burge 1996). It is far from clear, however, whether this idea can be worked out in a satisfactory way. Would the idea require a sensational phenomenology for thinking? If it does require that, then it might be natural to suggest that phenomenally conscious thoughts are clothed in the phonological or orthographic forms of natural language sentences (Carruthers 1996).

Consciousness, Neurobiology of

After a hiatus of fifty years or more, the physical origins of CONSCIOUSNESS are being once again vigorously debated, in hundreds of books and monographs published in the last decade. What sparse facts can we ascertain about the neurobiological basis of consciousness, and what can we reasonably assume at this point in time?

By and large, neuroscientists have made a number of working assumptions that need to be justified more fully. In particular,

1. There is something to be explained, that is, the subjective content associated with a conscious sensation (what philosophers refer to as QUALIA; see also WHAT-IT'S-LIKE) does exist and has its physical basis in the brain.

2. Consciousness is one of the principal properties of the human brain, a highly evolved system; it must therefore have a useful function to perform. Crick and Koch (1995) assume that the function of visual consciousness is to produce the best current interpretation of the visual scene—in the light of past experiences—and to make it available for a sufficient time to the parts of the brain that contemplate, plan, and execute voluntary motor outputs (including language). This needs to be contrasted with the on-line systems that bypass consciousness but can generate stereotyped behaviors (see below).

3. At least some animal species (i.e., non-human primates such as the macaque monkey) are assumed to possess some aspects of consciousness. Consciousness associated with sensory events is likely to be very similar in humans and monkeys for several reasons. First, trained monkeys behave as humans do under controlled conditions for most sensory tasks (e.g., visual motion discrimination; see MOTION, PERCEPTION OF; Wandell 1995). Second, the gross neuroanatomy of humans and nonhuman primates is the same, once the difference in size has been accounted for. Finally, MAGNETIC RESONANCE IMAGING in humans is confirming the existence of a functional organization very similar to that discovered by single-cell electrophysiology in the monkey (Tootell et al. 1996). As a corollary, it follows that language is not necessary for consciousness to occur (although it greatly enriches human consciousness). In the following, we will mainly concentrate on sensory consciousness, and, in particular, on visual consciousness, because it is experimentally the most accessible and the best understood.

Cognitive and clinical research demonstrates that much complex information processing can occur without involving consciousness, both in normals as well as in patients. Examples of this include BLINDSIGHT (Weiskrantz 1997), priming, and the implicit recognition of complex sequences (Velmans 1991; Berns, Cohen, and Mintun 1997). Milner and Goodale (1995) have made a masterful case for the existence of so-called on-line visual systems that bypass consciousness, and that serve to mediate relative stereotype visual-motor behaviors, such as eye and arm movements as well as posture adjustments, in a very rapid manner. On-line systems work in egocentric coordinate systems and lack both certain types of perceptual ILLUSIONS (e.g. size illusion) and direct access to WORKING MEMORY. Milner and Goodale (1995; see also

Rossetti forthcoming) hypothesize that on-line systems are associated with the dorsal stream of visual information in the CEREBRAL CORTEX, originating in the primary VISUAL CORTEX (V1) and terminating in the posterior parietal cortex (see VISUAL PROCESSING STREAMS). This contrasts well with the function of consciousness alluded to above, namely, to synthesize information from many different sources and use it to plan behavioral patterns over time.

What is the neuronal correlate of consciousness? Most popular has been the belief that consciousness arises as an emergent property of a very large collection of interacting neurons (Popper and Eccles 1981; Libet 1995). An alternative hypothesis is that there are special sets of "consciousness" neurons distributed throughout cortex (and associated systems, such as the THALAMUS and the BASAL GANGLIA) that represent the ultimate neuronal correlate of consciousness (NCC), in the sense that activity of an appropriate subset of them is both necessary and sufficient to give rise to an appropriate conscious experience or percept (Crick and Koch 1995). NCC neurons would, most likely, be characterized by a unique combination of molecular, biophysical, pharmacological, and anatomical traits. It is also possible, of course, that all cortical neurons may be capable of participating in the representation of one percept or another, at one time or another, though not necessarily doing so for all percepts. The secret of consciousness would then consist of all cortical neurons representing that particular percept at that moment (see BINDING BY NEURAL SYNCHRONY).

Where could such NCC neurons be found? Based on clinical evidence that small lesions of the intralaminar nuclei of the thalamus (ILN) cause loss of consciousness and coma and that ILN neurons project widely and reciprocally into the cerebral cortex, ILN neurons have been proposed as the site where consciousness is generated (Bogen 1995; Purpura and Schiff 1997). It is more likely, however, that ILN neurons provide an enabling or arousal signal without which no significant cortical processing can occur. The great specificity associated with the content of our consciousness at any point in time can only be mediated by neurons in the cerebral cortex, its associated specific thalamic nuclei, and the basal ganglia. It is here, among the neurons whose very specific response properties have been extensively characterized by SINGLE-NEURON RECORDING, that we have to look for the NCC.

What, if anything, can we infer about the location of these neurons? In the case of visual consciousness, Crick and Koch (1995) surmised that these neurons must have access to visual information and project to the planning stages of the brain, that is, to premotor and frontal areas (Fuster 1997). Because in the macaque monkey, no neurons in primary visual cortex project to any area anterior to the central sulcus, Crick and Koch (1995) proposed that neurons in V1 do not directly give rise to consciousness (although V1 is necessary for most forms of vision, just as the retina is). Current electrophysiological, psychophysical, and imaging evidence (He, Cavanagh, and Intriligator 1996; Engel, Zhang, and Wandell 1997) supports the hypothesis that the NCC is not to be found among V1 neurons.

A promising experimental approach to locate the NCC has been the use of bistable percepts, that is, pairs of percepts, alternating in time, that arise from a constant visual stimulus as in a Necker cube (Crick and Koch 1992). In one such case, a small image, say of a horizontal grating, is presented to the left eye and another image, say of a vertical grating, is presented to the corresponding location in the right eye. In spite of the constant retinal stimulus, observers "see" the horizontal grating alternate every few seconds with the vertical one, a phenomenon known as "binocular rivalry" (Blake 1989). The brain does not allow for the simultaneous perception of both images.

It is possible, though difficult, to train a macaque monkey to report whether it is currently seeing the left or the right image. The distribution of the switching times and the way in which changing the contrast in one eye affects these times leaves little doubt that monkeys and humans experience the same basic phenomenon (Myerson, Miezin, and Allman 1981). In a series of elegant experiments, Logothetis and colleagues (Logothetis and Schall 1989; Leopold and Logothetis 1996; Sheinberg and Logothetis 1997) recorded from a variety of monkey cortical areas during this task. In early visual cortex, only a small fraction of cells modulated their response as a function of the percept of the monkey, while 20 to 30 percent of neurons in MT and V4 cells did. The majority of cells increased their firing rate in response to one or the other retinal stimulus with no regard to what the animal perceived at the time. In contrast, in a high-level cortical area, such as the inferior temporal cortex (IT), almost all neurons responded only to the perceptual dominant stimulus (in other words, a "face" cell only fired when the animal indicated by its performance that it saw the face and not the sunburst pattern in the other eye). This makes it likely that the NCC is located among—or beyond—IT neurons.

Finding the NCC would only be the first, albeit critical, step in understanding consciousness. We also need to know where these cells project to, their postsynaptic action, and what happens to them in various diseases known to affect consciousness, such as schizophrenia or AUTISM, and so on. And, of course, a final theory of consciousness would have to explain the central mystery—why a physical system with a particular architecture gives rise to feelings and qualia. (Chalmers 1996).

Consensus Theory

See CULTURAL CONSENSUS THEORY

Constraint Satisfaction

A *constraint satisfaction problem* (CSP) is defined over a *constraint network,* which consists of a finite set of *variables,* each associated with a *domain* of values, and a set of *constraints*. A *solution* is an assignment of a value to each variable from its domain such that all the constraints are satisfied. Typical constraint satisfaction problems are to determine whether a solution exists, to find one or all solutions, and to find an optimal solution relative to a given cost function. A well-known example of a constraint satisfaction problem is *k*-colorability, where the task is to color, if possible, a given graph with *k* colors only, such that any two adjacent nodes have different colors. A constraint satisfaction formulation of this problem associates the nodes of the graph with variables, the possible colors are their domains, and the inequality constraints between adjacent nodes are the constraints of the problem. Each constraint of a CSP may be expressed as a relation, defined on some subset of variables, denoting legal combinations of their values. Constraints can also be described by mathematical expressions or by computable procedures. Another typical constraint satisfaction problem is *SATisfiability,* the task of finding the truth assignment to propositional variables such that a given set of clauses is satisfied. For example, given the two clauses $(A \vee B \vee \neg C), (\neg A \vee D)$, the assignment of *false* to *A*, *true* to *B*, *false* to *C*, and *false* to *D*, is a satisfying truth value assignment.

The structure of a constraint network is depicted by a constraint graph whose nodes represent the variables and in which any two nodes are connected if the corresponding variables participate in the same constraint. In the *k*-colorability formulation, the graph to be colored is the constraint graph. In our SAT example the constraint graph has *A* connected to *D*, and *A*, *B*, and *C* are connected to each other.

Constraint networks have proven successful in modeling mundane cognitive tasks such as vision, language comprehension, default reasoning, and abduction, as well as in applications such as scheduling, design, diagnosis, and temporal and spatial reasoning. In general, constraint satisfaction tasks are computationally intractable ("NP-hard"; see COMPUTATIONAL COMPLEXITY).

ALGORITHMS for processing constraints can be classified into two interacting categories: (1) search and (2) consistency inference. Search algorithms traverse the space of partial instantiations, while consistency inference algorithms reason through equivalent problems. Search algorithms are either systematic and complete or stochastic and incomplete. Likewise, consistency inference algorithms have either complete solutions (e.g., variable-elimination algorithms) or incomplete solutions (i.e., local consistency algorithms).

Local consistency algorithms, also called "consistency-enforcing" or "constraint propagation" algorithms (Montanari 1974; Mackworth 1977; Freuder 1982), are polynomial algorithms that transform a given constraint network into an equivalent, yet more explicit network by deducing new constraints to be added onto the network. Intuitively, a consistency-enforcing algorithm will make any partial solution of a small subnetwork extensible to some surrounding network. For example, the most basic consistency algorithm, called an "arc consistency" algorithm, ensures that any legal value in the domain of a single variable has a legal match in the domain of any other selected variable. A "path consistency" algorithm ensures that any consistent solution to a two-variable subnetwork is extensible to any third variable, and, in general, *i-consistency* algorithms guarantee that any locally consistent instantiation of $i - 1$ variables is extensible to any *i*th variable. Enforcing *i*-consistency is time and space

exponential in *i*. Algorithms for *i*-consistency frequently decide *inconsistency*.

A network is *globally consistent* if it is *i*-consistent for *every i*, which means a solution can be assembled by assigning values using any variable ordering without encountering any dead end, namely, in a "backtrack-free" manner. However, it is enough to possess *directional* global consistency relative to a given ordering only. Indeed, an *adaptive consistency* (variable elimination) algorithm enforces global consistency in a given order only, such that every solution can be extracted, with no dead ends along this ordering. Another related algorithm, called a "tree-clustering" algorithm, compiles the given constraint problem into an equivalent tree of subproblems (Dechter and Pearl 1989) whose respective solutions can be efficiently combined into a complete solution. Adaptive consistency and tree-clustering algorithms are time and space exponential in a parameter of the constraint graph called an "induced-width" or "tree-width" (Arnborg and Proskourowski 1989; Dechter and Pearl 1987).

When a problem is computationally hard for the adaptive consistency algorithm, it can be solved by bounding the amount of consistency enforcing (e.g., arc or path consistency), and by augmenting the algorithm with a search component. Generally speaking, search will benefit from network representations that have a high level of consistency. However, because the complexity of enforcing *i*-consistency is exponential in *i*, there is a trade-off between the effort spent on consistency inference and that spent on search. Theoretical and empirical studies of this trade-off, prior to or during search, aim at identifying a problem-dependent cost-effective balance (Haralick and Elliot 1980; Prosser 1993; Sabin and Freuder 1994; Dechter and Rish 1994).

The most common algorithm for performing systematic search is the *backtracking* algorithm, which traverses the space of partial solutions in a depth-first manner. At each step, the algorithm extends a partial solution by assigning a value to one more variable. When a variable is encountered such that none of its values are consistent with the partial solution (a situation referred to as a "dead end"), backtracking takes place. The algorithm is time exponential, but requires only linear space.

Improvements of the backtracking algorithm have focused on the two phases of the algorithm: moving forward (look-ahead schemes) and backtracking (look-back schemes; Dechter 1990). When moving forward, to extend a partial solution, some computation (e.g., arc consistency) is carried out to decide which variable and value to choose next. For variable orderings, variables that maximally constrain the rest of the search space are preferred. For value selection, however, the least constraining value is preferred, in order to maximize future options for instantiations (Haralick and Elliot 1980; Dechter and Pearl 1987; Purdom 1983; Sabin and Freuder 1994).

Look-back schemes are invoked when the algorithm encounters a dead end. These schemes perform two functions: (1) they decide how far to backtrack, by analyzing the reasons for the dead end, a process often referred to as "backjumping" (Gaschnig 1979); (2) they record the reasons for the dead end in the form of new constraints so that the same conflicts will not arise again, a process known as "constraint learning" and "no-good recording" (Stallman and Sussman 1977; Dechter 1990).

Stochastic local search strategies have been recently reintroduced into the satisfiability and constraint satisfaction literature under the umbrella name (GSAT "greedy SATisfiability"; see GREEDY LOCAL SEARCH). These methods move in hill-climbing manner in the space of complete instantiations to all the variables (Minton et al. 1990). The algorithm improves its current instantiation by "flipping" a value of a variable that maximizes the number of constraints satisfied. Such search algorithms are incomplete, may get stuck in a local maxima, and cannot prove inconsistency. Nevertheless, when equipped with some heuristics for randomizing the search walksat or for revising the guiding criterion function (constraint reweighting), they prove successful in solving large and hard problems that are frequently hard for backtracking search algorithms (Selman, Levesque, and Mitchell 1992).

Structure-driven algorithms cut across both search and consistency inference algorithms. These techniques emerged from an attempt to topologically characterize constraint problems that are tractable. *Tractable classes* were generally recognized by realizing that enforcing low-level consistency (in polynomial time) guarantees global consistency for some problems. The basic network structure that supports tractability is a tree (Mackworth and Freuder 1985). In particular, enforcing arc consistency on a tree-structured network ensures global consistency along some ordering. Most other graph-based techniques can be viewed as transforming a given network into a metatree. Adaptive consistency, tree clustering, and constraint learning, are all time and space exponentially bounded by the tree width of the constraint graph; the *cycle cutset scheme* combines search and inference and is exponentially bounded by the constraint graph's *cycle-cutset;* the *biconnected component method* is bounded by the size of the constraint graph's largest biconnected component (Freuder 1982); and backjumping is exponentially bounded by the depth of the graph's depth-first search tree. The last three methods require only polynomial space.

Tractable classes were also identified by the properties of the constraints themselves. Such tractable classes exploit notions such as tight domains and tight constraints (van Beek and Dechter 1997), row-convex constraints (van Beek and Dechter 1995), implicational and max-ordered constraints (Kirousis 1993; Jeavons, Cohen, and Gyssens 1997), as well as causal networks. A connection between tractability and algebraic closure was recently discovered (Cohen, Jeavons, and Gyssens 1995).

Finally, special classes of tractable constraints associated with TEMPORAL REASONING have received much attention in the last decade. These include subsets of qualitative interval algebra (Golumbic and Shamir 1993) expressing relationships such as "time interval *A* overlaps or precedes time interval *B*," as well as quantitative binary linear inequalities over the real numbers of the form $X - Y \leq a$ (Dechter, Meiri, and Pearl 1990).

Theoretical evaluation of constraint satisfaction algorithms is accomplished primarily by worst-case analysis

(i.e., determining a function of the problem's size that sets the upper bound to the algorithm's performance over all problems of that size), or by dominance relationships (Kondrak and van Beek 1997). However, because worst-case analysis by its nature is too pessimistic and often does not reflect actual performance, empirical evaluation is necessary. Normally, a proposed algorithm is evaluated empirically on a set of randomly generated instances taken from the relatively "hard" "phase transition" region (Selman, Levesque, and Mitchell 1992). Other benchmarks based on real-life applications such as scheduling are also used. Currently, dynamic variable ordering and value selection heuristics that use various forms of constraint inference, backjumping, and constraint learning have been shown to be very effective for various problem classes (Prosser 1993; Frost and Dechter 1994; Sabin and Freuder 1994).

Context and Point of View

The content of most linguistic expressions in one way or other depends on the context of utterance; in fact, in logical semantics (literal) meaning is analyzed as a function assigning contents (or intensions) to contexts. The most prominent way for the context to determine content is by way of INDEXICALS, that is, by expressions whose sole function is to contribute a component of the situation in which an utterance is made to the content expressed by that utterance. Indexicals can be either lexical items, such as the English personal pronoun *I*, which always refers to the speaker, or grammatical forms, such as the first person verbal suffix in Latin, which has the same function. Indexicals are special cases of *deictic expressions* whose reference depends on context—a case in point being the possessive pronoun *my*, which describes something as belonging to the speaker as determined by the utterance situation (Zimmermann 1995).

All languages seem to contain deictic expressions and to make ample use of them. Traditionally, deictics are classified according to the aspect or feature of the utterance context that determines their reference. Three major kinds of deixis are usually distinguished: (1) *person deixis,* where the context provides one or more participants of the conversation (speaker, addressee), or a group to which they belong; (2) *spatial deixis,* where the context provides a location or a direction, especially as a reference point for spatial orientation on which other deictics depend (an "origo," in Bühler's 1934 sense); and (3) *temporal deixis,* with the context contributing a specific time, which may be the time of utterance, the time of a reported event, or the like. Among the clear cases of deixis in English are (1) the first and second person pronouns, *I, you, we;* (2) the local adverbs *here* and *there;* and (3) the temporal adverbs *now* and *yesterday.* Other examples of deixis, including demonstratives such as *this* whose referents depend on an accompanying gesture plus the speaker's referential intentions (Kaplan 1989a, 1989b), do not clearly fall under 1–3. DISCOURSE anaphors, such as *aforementioned,* or third person pronouns, such as *he, her,* receive their interpretation by reference to their linguistic context and are thus sometimes also considered as deictic. As has become clear by work in DYNAMIC SEMANTICS, however, such anaphoric elements quite regularly undergo variable binding processes, as in *Every man who owns a donkey beats it,* resulting in a quantified, rather than context-dependent reading. The same has been observed for the context dependence of certain relational nouns (Partee 1989) such as *enemy* whose arguments are usually given by the utterance situation, as in *The enemy is approaching,* but may also be quantified over, as in *Every participant faced an enemy.*

Languages differ considerably in the number and kinds of deictic locutions they have. Some have the place of utterance as their only spatial parameter, where others have complex systems classifying space according to various criteria (Frei 1944), including distance from the speaker's position as measured in varying degrees (up to seven in Malagasy, according to Anderson and Keenan 1985), visibility (also in Malagasy, and in many other languages), and perspective (as

in English *left* and *right*). Person deixis, too, is subject to variation: many languages (e.g., French) distinguish more than one second person, depending on the social relationship between speaker and hearer, a phenomenon known as "social deixis" (Levinson 1979); another common distinction (to be found, for example, in Tagalog) is between an inclusive and an exclusive first person plural, depending on whether the addressee does or does not belong to the group designated. The variation in temporal deixis is harder to estimate, partly because it is not always clear whether tenses are truly deictic, but also because languages tend to be more or less *localistic,* extending their system of spatial deixis to time by analogy and frozen metaphor (cf. TENSE AND ASPECT).

The role of the context in providing the perspective from which the utterance is interpreted becomes particularly vivid in *shifted contexts,* also known as "relativized deixis" (Fillmore 1975), or "Deixis am Phantasma" (Bühler 1934), where at least some of the deictic parameters are not provided by the utterance situation. Among these shifts are various forms of pretense like play-acting, impersonation, *analogous* deixis (Klein 1978)—the speaker of *We took <u>this</u> road* may refer to what is represented by the map in front of her—or even first-person inscriptions on gravestones (Kratzer 1978).

Speakers often take the hearer's perspective in describing the spatial location of objects (Schober 1993), as in *Please press the left button/the button to your left.* This context shift can be made out of politeness or, especially when the hearer does not know the speaker's location, for communicative efficiency. In the latter case, however, deictic orientation may also be replaced by an intrinsic perspective provided by an object with a canonical front (as in *behind the house,* denoting the backyard).

A rather coherent area of regular context shift is known as "free indirect speech" in narrative analysis (Banfield 1982; Ehrlich 1990). In a passage such as *Mary looked out of the window. Her husband was coming soon,* the second sentence is understood to report Mary's thoughts from her own point of view: it is Mary, not the narrator, who believes her husband to be on his way and, whereas the verb *come* normally expresses movement toward the speaker as determined by the context, in this case it is Mary's position toward which her husband is reported to move (Rossdeutscher 1997). Similarly, the adverb *soon* is understood to describe an event as happening shortly after the scene described, rather than the utterance, has taken place. This simultaneous replacement of some (but not all) contextual parameters can be seen as a shift of the *logophoric center* (Kuno 1987), which comprises a large part of the more subjective parameters, including those that determine the interpretation of evaluative adjectives (e.g., *boring*) and free reflexives. Whereas free indirect speech is a rather well understood phenomenon with predictable features (including a restricted choice of tenses), other shifts of the logophoric center are less easily accounted for. Among these are the optional perspectives in overt attitude reports (Mitchell 1987), as in *The CIA agent knows that John thinks that a KGB agent lives <u>across the street</u>,* where the underlined phrase can be evaluated from the speaker's, the CIA agent's, or John's point of view.

Control Theory

The modern development of automatic control evolved from the regulation of tracking telescopes, steam engine control using fly-ball governors, the regulation of water turbines, and the stabilization of the steering mechanisms of ships. The literature on the subject is extensive, and because feedback control is so broadly applicable, it is scattered over many journals ranging from engineering and physics to economics and biology. The subject has close links to optimization including both deterministic and stochastic formulations. Indeed, Bellman's influential book on dynamic optimization, *Dynamic Programming* (1957), is couched largely in the language of control.

The successful use of feedback control often depends on having an adequate model of the system to be controlled and suitable mechanisms for influencing the system, although recent work attempts to bypass this requirement by incorporating some form of adaptation, learning, or both. Here we will touch on the issues of modeling, regulation and tracking, optimization, and stochastics.

Modeling

The oldest and still most successful class of models used to design and analyze control systems are input-output models, which capture how certain controllable input variables influence the state of the system and, ultimately, the observable outputs. The models take the form of differential or difference equations and can be linear or nonlinear, finite or infinite dimensional. When possible, the models are derived from first principles, adapted and simplified to be relevant to the situation of interest. In other cases, empirical approaches based on regression or other tools from time series analysis are used to generate a mathematical model from data. The latter is studied under the name of "system identification" (Willems 1986). To fix ideas, consider a linear differential equation model with input vector u, state vector x, and output y

$$\frac{dx}{dt} = Ax + Bu; \quad y = Cx$$

Such models are of fundamental importance because they not only capture the essential behavior of important classes of linear systems but also represent the small signal approximation to a large class of strongly nonlinear systems. Questions of control often center around the design of an auxiliary system, called the "compensator" or "controller," which acts on the measurable variable y to produce a feedback signal that, when added to u, results in better performance. The concepts of controllability, observability, and model reduction play a central role in the theory of linear models (Kalman et al. 1969; Brockett 1970).

There are important classes of systems whose performance can only be explained by nonlinear models. Many of these are prominent in biology. In particular, problems that involve pattern generation, such as walking or breathing, are not well modeled using linear equations. The description of numerically controlled machine tools and robots, both of which convert a formal language input into an analog (continuous) output are also not well modeled by the linear theory, although linear theory may have a role in explaining the behavior of particular subsystems (Brockett 1997, 1993).

Regulation and Tracking

The simplest and most frequently studied problem in automatic control is the regulation problem. Here one has a desired value for a variable, say the level of water in a tank, and wants to regulate the flow of water into the tank to keep the level constant in the face of variable demand. This is a special case of the problem of tracking a desired signal, for example, keeping a camera focused on a moving target (see STEREO AND MOTION PERCEPTION), or orchestrating the motion of a robot so that the end effector follows a certain moving object. The design of stable regulators is one of the oldest problems in control theory. It is often most effective to incorporate additional dynamic effects, such as *integral action,* in the feedback path, thus increasing the complexity of the dynamics and making the issue of stability less intuitive. In the case of systems adequately modeled by linear differential equations, the matter was resolved long ago by the work of Routh, and Hurwitz, which yields, for example, the result that the third-order linear, constant-coefficient differential equation

$$\frac{d^3 y}{dt^3} + a\frac{d^2 y}{dt^2} + b\frac{dy}{dt} + cy = 0$$

is stable if a, b, and c are all positive and $ab - c \geq 0$. Motivated by feedback stability problems associated with high-gain amplifiers, Nyquist (1932) took a fresh look at the feedback stability problem and formulated a stability criterion directly in terms of the frequency response of the system. This criterion and variations of it form the basis of classical feedback compensation techniques as described in the well-known book of Kuo (1967). In the case of nonlinear systems, the design of stable regulators is more challenging. Liapunov stability theory (Lefschetz 1965) provides a point of departure, but general solutions are not to be expected.

Optimization

A systematic approach to the design of feedback regulators can be based on the minimization of the integral of some positive function of the error and the control effort. For the linear system defined above this might take the form

$$\eta = \int_0^\infty (x^T Q x + u^T u)dt$$

which leads, via the calculus of variations, to a linear feedback control law of the form $u = -B^T K x$, with K being a solution to the quadratic matrix equation $A^T K + KA -$ $KBB^T K + Q = 0$. This methodology provides a reasonably systematic approach to the design of regulators in that only the loss matrix Q is unspecified. Different types of optimization problems associated with trajectory optimization in aerospace applications and batch processing in chemical plants are also quite important. A standard problem formulation in this latter setting would be concerned with problems of the form

$$\frac{dx}{dt} = f(x, u); \quad \eta = \int_0^T L(x, u, t)dt + \phi(x(T))$$

Chapter 7 of Sontag (1990) provides a short introduction including a discussion of the relationships between DYNAMIC PROGRAMMING and the more classical Hamilton-Jacobi theory.

Stochastics

The Kalman-Bucy (1961) filter, one of the most widely appreciated triumphs of mathematical engineering, is used in many fields to reduce the effects of measurement errors and has played a significant role in achieving the first soft landing on the moon, and more recently, achieving closed-loop control of driverless cars on the autobahns of Germany. Developed in the late 1950s as a state space version of the Wiener-Kolomogorov theory of filtering and prediction, it gave rise to a rebirth of this subject. In its basic form, the Kalman-Bucy filter is based on a linear system, white noise (written here as $\dot{w}$ and $\dot{n}$) model

$$\dot{x} = Ax + B\dot{w}; \quad y = Cx + \dot{n}$$

The signal Cx is generated from the white noise $\dot{w}$ by passing it into the linear system, although it is not observed directly, but only after it is corrupted by the additive noise $\dot{n}$. The theory tells us that the best (in several senses including the least squares) way to recover x from y is to generate an estimate $\hat{x}$ using the equation

$$\frac{d\hat{x}}{dt} = A\hat{x} - PC^T(C\hat{x} - y)$$

with P being the solution of the variance equation

$$\dot{P} = AP + PA^T + BB^T - PC^T CP$$

The development of similar theories for counting processes, queuing systems, and the like is more difficult and remains an active area for research (Brémaud 1981).

Cooperation and Competition

Cooperation is a hallmark of all social organisms. Social groups are, in effect, cooperative solutions to the day-to-day problems of survival and reproduction. For some or all members of the group, however, group living invariably incurs costs, which may be reflected in social subordination, restricted access to the best feeding or resting sites, the social suppression of reproduction, or increased ecological costs. Because individuals (or at least, their genes) are by definition in evolutionary competition with each other, this creates a paradox that is not easy to explain in Darwinian terms: Cooperation is a form of ALTRUISM in which one individual gives up something to the benefit of another (see also SOCIOBIOLOGY).

Evolutionary theory identifies three ways cooperation can evolve, which differ in the delay before the "debt" incurred by cooperating is repaid (see Bertram 1982). In *mutualism,* both individuals gain an immediate advantage from cooperating. This may be an appropriate explanation for many cases of group living where individuals gain mutually and simultaneously from living together (e.g., through increased protection from predators, group defense of a territory, etc). In *reciprocal altruism,* the debt is repaid at some future time, providing this is during the lifetime of the altruist. This may be an appropriate explanation for cases where individuals who are unrelated to each other form a coalition for mutual protec-

tion. The ally, even though in no immediate danger, will come to the aid of a beleaguered partner, on the implicit assumption that the partner will come to the ally's aid on some future occasion. And in *kin selection,* the debt is repaid after the death of the altruist because the extra fitness that accrues to the recipient contributes to the altruist's *inclusive fitness,* defined as the number of copies of a given gene contributed to the species' gene pool by an individual as a result of his or her own reproductive output plus the number contributed by his or her relatives as a direct result of that individual helping each relative to breed more successfully. Kin selection can only work when the two individuals are genetically related. It may provide an explanation for assistance freely given to relatives without prior demands for reciprocation.

Although cooperation and the exchange of services or resources occur widely among humans, such exchanges are not wholly altruistic, especially when the actor incurs a significant cost. A number of recent studies of humans have demonstrated that exchange of benefits occurs without preconditions for repayment when it involves relatives, but only with strict reciprocation when it involves nonrelatives, (for example, garden labor exchange among South American K'ekchi' horticulturalists and Nepalese hill farmers (Berté 1988; Panter-Brick 1989); alliance support among historical Vikings (Dunbar, Clark, and Hurst 1995); and exchange of information about good fishing grounds among contemporary Maine lobstermen (Palmer 1991).

Cooperation is an unstable strategy because it is susceptible to cheating by free riders. The ease with which selfish interests can undermine cooperativeness is most conspicuous in the case of common pool resources (e.g., forest resources, communally owned commons or oceanic fishing grounds). Although it may be obvious to everyone that a communal agreement to manage the use of these resources would benefit everyone because the resource would last longer, the advantages to be gained by taking a disproportionate share can be an overwhelming temptation. The result is often the complete destruction of the resource through overuse, the "tragedy of the commons" (see Ortsrom, Gardner, and Walker 1994). Tax avoidance and parking in no parking zones are everyday examples of a similar kind of cheating on socially agreed conventions.

The free rider problem is one of the most serious problems encountered by organisms living in large groups that depend on cooperation for their effectiveness. It acts as a dispersive force that, unless checked, leads inexorably to the disbanding of groups (and thus the loss of the very purpose for which the groups formed). The problem arises because the advantages of free riding are often considerable, especially when the risks of being caught (and thus of being punished or discriminated against) are slight. Perhaps as a result, strategies that help to detect or deter free riders are common in most human societies. These include being suspicious of strangers (whose willingness to cooperate remains in doubt), rapidly changing dialects (which helps identify the group of individuals with whom you grew up, who are likely to be either relatives or to bear obligations of mutual aid; see Nettle and Dunbar 1997), entering into conventions of mutual obligation (e.g., blood brotherhood, exchange of gifts, or formal treaties), and ostracizing or

punishing those who cheat on the system (e.g., castigating hunters who eat all their meat rather than sharing it, as among !Kung San bushmen: Lee 1979).

In addition to these purely behavioral mechanisms (perhaps the product of CULTURAL EVOLUTION), there is also evidence to suggest that there may be dedicated "cheat detection" modules hardwired in the human brain. The evidence for this derives from studies that consider abstract and social versions of the *Wason selection task* (a verbal task about logical reasoning: see Table 1). Although most people get the answer wrong when presented with the abstract version of the Wason task, they usually get it right when the task is presented as a logically identical social contract problem that involves detecting who is likely to be cheating the system (see Cosmides and Tooby 1992). This is assumed to happen because we have a cognitive module that is sensitive to social cheats, but that cannot easily recognize the same kind of logical problem in another form.

The mechanisms involved in the evolution of cooperation have been of considerable interest to economists and other social scientists, as well as to evolutionary psychologists (see EVOLUTIONARY PSYCHOLOGY). GAME THEORY, in particular, provides considerable insights into the stability of cooperative behavior. The situation known as "prisoner's dilemma" has been the focus of much of this research. It involves two allies who must independently decide whether to cooperate with each other (to gain a small reward) or defect (to gain a very large reward)—but with the risk of doing very badly if cooperation is met with defection. A computer tournament that pitted alternative algorithms against each other in an evolutionary game revealed that the very simplest rule of behavior is the most successful. This rule is known as "tit-for-tat" (or *TfT*): Cooperate on the first encounter with an opponent and thereafter do exactly what the opponent did on the previous round (cooperate if he cooperated, defect if he defected).

In more conventional face-to-face situations, cues provided by nonverbal behavior may be important in promoting both trust in another individual and the sense of obligation to others required for successful cooperation. Experiments have shown that simply allowing individuals to discuss even briefly which strategy is best greatly increases the frequency of cooperation. Allowing them to exert moral pressure or fines on defectors improves the level of group cooperativeness still further.

Table 1. The Wason Selection Task

Standard version	Logical equivalent	Social contract version
A	P	Drinking a beer
H	Not-P	Drinking a Coke
4	Q	21 years old
7	Not-Q	16 years old

The Wason selection task (table 1) was developed as a test of logical reasoning. When presented with four cards bearing letters and numbers (as shown in column 1) and informed that "an even number always has a vowel on its reverse," the subject has to decide which card or cards to turn over in order to check the validity of the rule. This rule has the standard structure of the logical statement "If P (= even number), then Q (= vowel on reverse)." Because the four cards correspond to the statements P, not-P, Q and not-Q, the correct logical solution is to choose the cards that correspond to P and not-Q. Most subjects incorrectly choose P alone or the P and the Q cards. In the social contract version, the cards correspond to people sitting around a table whose drinks or ages are specified (as in column 3). The rule in this case is "If you want to drink alcoholic beverages, you must be over the age of 21 years." Here it is obvious that only the age of the beer drinker (P) and the drink of the 16-year-old (not-Q) need to be checked. Even though most people get the original abstract Wason task wrong, they get the social contract version right.

Cortex

See CEREBRAL CORTEX; VISUAL CORTEX, CELL TYPES, AND CONNECTIONS IN

Cortical Localization, History of

During the first twenty-five centuries of studies of brain function, almost all investigators ignored or belittled the CEREBRAL CORTEX. One exception was the Alexandrian anatomist Erasistratus (fl. c. 290 B.C.E.), who on the basis of comparative studies attributed the greater intelligence of humans to their more numerous cortical convolutions. This view was ridiculed by Galen (129–199), the most influential of all classical biomedical scientists, whose sarcastic dismissal of any significant role for the cortex continued to be quoted into the eighteenth century. Another major exception was Thomas Willis (1621–1675), a founder of the Royal Society, and author of the first monograph on the brain. On the basis of his dissections, experiments on animals, and clinical studies of humans, he attributed memory and voluntary movement functions to the cortex. However, by far the dominant view on cortical function before the beginning of the nineteenth century was that the cortex was merely a protective rind (*cortex* means "rind" in Latin), a glandular structure (the early microscopists saw globules in cortex, probably artifacts), or a largely vascular structure made up of small blood vessels. The apparent insensitivity of the cortex to direct mechanical and chemical stimulation was used as an argument against the cortex having any important functions in sensation, mentation, or movement.

The systematic localization of different psychological functions in different regions of the cerebral cortex begins with Franz Joseph Gall (1758–1828) and his collaborator J. C. Spurzheim (1776–1832), the founders of phrenology. The central ideas of their phrenological system were that the brain was an elaborately wired machine for producing behavior, thought, and emotion, and that the cerebral cortex consisted of a set of organs with different functions. Postulating about thirty-five affective and intellectual faculties, they assumed that these were localized in specific cortical organs and that the size of each cortical organ was indicated by the prominence of the overlying skull, that is, by cranial bumps. Their primary method was to examine the skulls of a wide variety of people, from lunatics and criminals to the eminent and accomplished. Although the absurdity of their dependence on cranial morphology was quickly recognized in the scientific community, Gall's ideas about the cortex as a set of psychological organs stimulated investigation of the effects of cortical lesions in humans and animals and of structural variations across different cortical regions, and thus had a lasting influence on the development of modern neuroscience.

Examining a variety of animals, Pierre Flourens (1794–1867) found that different major brain regions had different functions; he implicated the cerebral hemispheres in willing, remembering, and perceiving, and the CEREBELLUM in movement. Within the cortex, however, he found no localization of function: only the size and not the site of the lesion mattered. Although these results appeared to refute the punctate localizations of Gall, they actually supported both the general idea of localization of function in the brain and the specific importance Gall had given to the cerebral hemispheres in cognition.

In 1861, Paul BROCA described several patients with longstanding difficulties in speaking, which he attributed to damage to their left frontal lobes. This was the first generally accepted evidence for localization of a specific psychological function in the cerebral cortex (and was viewed at the time as a vindication of Gall's ideas of localization). Soon after, Fritsch and Hitzig demonstrated specific movements from electrical stimulation of the cortex of a dog, and drew the inference that some psychological functions and perhaps all of them need circumscribed centers of the cortex. The next major development was Carl Wernicke's 1876 report of a second type of language difficulty, or APHASIA, namely, one in understanding language; he associated this type of aphasia with damage to the posterior cortex in the region where the occipital, temporal, and parietal areas meet. Furthermore, he extended the idea of specialized cortical areas by stressing the importance of the connections among different areas, particularly for higher mental functions.

The last years of the nineteenth century saw several acrimonious controversies about the location of the various cortical sensory areas, involving such figures as David Ferrier, E. A. Schafer, and Hermann Munk. These issues were resolved first in monkeys and then in humans, so that by the end of World War I (with its rich clinical material), the location and organization of the primary visual, auditory, somesthetic, and motor areas of the cortex had been defined. By this time, the cerebral cortex had been divided up into multiple regions on the basis of regional variations in its cellular or fiber structure. The more lasting of these cortical architectonic parcellations were those by Korbinian Brodmann and Constantin von Economo, who created the numbering and lettering schemes, respectively, that are still in use. Despite their new labels, however, the functions of vast regions of the cortex, other than the primary sensory and motor areas, remained mysterious. These regions were termed *association cortex*, initially because they were thought to be the site of associations among the sensory and motor areas. Under the influence of British association psychology (typified by John Stuart Mill and Alexander Bain), association cortex was believed to be the locus of the association of ideas, and after Pavlov, the locus of the linkage between conditioned stimuli and responses.

Parallel with the success of the localizers around the turn of the century, there was also a strong antilocalization tendency. Adherents of this view, such as C.E. Brown-Sequard, Friedrich Goltz, Camillo GOLGI, and Jacques Loeb, emphasized such phenomena as the variability and recovery of symptoms after brain damage. They stressed that higher cognitive functions, particularly INTELLIGENCE and MEMORY, could not be localized in specific regions of the cortex. Like Flourens, Goltz reported that it was the size and not the location of the lesion that determined the severity of its effects on such higher functions. This holistic view of brain function was reinforced by the rise of GESTALT PSYCHOLOGY.

The best-known investigator of the relative importance of the size and site of a cortical lesion was Karl S. LASHLEY, easily the foremost figure in the study of the brain in the 1940s and 50s. On the basis of a long series of experiments,

particularly on rats in a complex maze, he proposed two principles of brain organization, "equipotentiality" and "mass action" (Lashley 1929). *Equipotentiality* was the apparent capacity of any intact part of a functional area to carry out, with or without reduction in efficiency, the functions lost by destruction of the whole. Lashley assumed equipotentiality to vary with different brain areas and with different functions and thought it might only hold for association cortex and for functions more complex than sensory or motor ones such as maze learning. Furthermore, equipotentiality was not absolute but subject to a law of *mass action* whereby the efficiency of a whole complex function might be reduced in proportion to the extent of brain injury within an equipotential area. He stressed that both principles were compatible with cortical localization of functions and himself reported several findings of specific cortical localizations.

Lashley's most famous (or infamous) result was that both principles held for the entire cerebral cortex of rats learning a complex maze. That is, performance in this maze was independent of the site of the cortical lesion and only dependent on its size. We now know that these mass action results were due to increasing encroachment on multiple areas critical for different components of maze learning with increasing size of lesion. In recent years, Lashley's specific ideas on equipotentiality and mass action (and many of his other contributions) are often forgotten, and he is inaccurately described as an extreme "antilocalizer," who thought the brain was like a bowl of jelly.

Starting in the 1930s, systematic evidence for the localization of various cognitive functions in regions of association cortex began to emerge, particularly from students and associates of Lashley. In an experiment still at the core of contemporary research on the frontal lobes, Carlyle Jacobsen showed that frontal cortex lesions impair the performance of delayed response tasks, in which the monkey must remember which of two cups a peanut was placed under, a deficit Jacobsen described as one of short-term memory. (This result, through no fault of Jacobsen's, led directly to the introduction of frontal lobotomy as a psychosurgical procedure in humans.) In another seminal experiment, K.-L. Chow, in 1950, showed that lesions of temporal cortex yield a deficit in pattern recognition, a finding that helped spark the study of extrastriate mechanisms in vision.

Up to the 1950s, the advances in understanding the functions of the cerebral cortex had relied almost entirely on the study of brain damage in humans and other primates. The introduction of evoked response and SINGLE-NEURON RECORDING techniques provided powerful new methods for studying localization of cortical function, methods soon revealing that much of association cortex was made up of areas devoted to processing specific aspects of a single sensory modality. Furthermore, these higher sensory areas were often involved in attentional and mnemonic functions as well as perceptual ones.

Most recently, the introduction of functional MAGNETIC RESONANCE IMAGING (fMRI) and POSITRON-EMISSION TOMOGRAPHY (PET) scanning have begun to radically enhance our understanding of the functional specialization of the cerebral cortex. As we begin to understand the parallel serial and hierarchical ways that the cortex processes, stores, and retrieves information, the phrase "localization of function" sounds increasingly archaic and simplistic.

Creativity

In psychology, *creativity* is usually defined as the production of an idea, action, or object that is new and valued, although what is considered creative at any point in time depends on the cultural context.

The early history of research in creativity includes Cesare Lombroso's investigation of the relationship between genius and madness, and Sir Francis Galton's genetic studies of genius. Guilford (1967) developed a theory of cognitive functioning that took creativity into account, and a battery of tests that measured fluency, flexibility, and originality of thought in both verbal and visual domains. His model and the tests he developed, such as the "Brick Uses" and "Unusual Uses" tests, are still the foundation for much of creativity testing and research (e.g., Torrance 1988).

Contemporary approaches to creativity range from mathematical modeling and computer simulations of breakthroughs in science (Langley et al. 1987) to the intensive study of creative individuals (Gruber 1981; Gardner 1993). Other approaches include the historiographic method applied to the content of large numbers of creative works, or to biographies (Martindale 1990; Simonton 1990). Most studies, however, are still done with schoolchildren and students, and assess performance on Guilford-type tests (for reviews, see Sternberg 1988 and Runco and Albert 1990).

Stages of the Creative Process

Contrary to the popular image of creative solutions appearing with the immediacy of a popping flashbulb, most novel achievements are the result of a much longer process, sometimes lasting many years. We can differentiate five stages of this process (Wallas 1926), with the understanding that these stages are recursive, and may be repeated in several full or partial cycles before a creative solution appears.

1. *Preparation*   It is almost impossible to have a good new idea without having first been immersed in a particular symbolic system or domain. Creative inventors know the ins and outs of their branch of technology, artists are familiar with the work of previous artists, scientists have learned whatever there is to know about their specialty. One must also feel a certain unease about the state of the art in one's domain. There has to be a sense of curiosity about some unresolved problem—a machine that could be improved, a disease that has to be cured, a theory that could be made simpler and more elegant. Sometimes the problem is presented to the artist, scientist, or inventor by an outside emergency or requirement. The most important creative problems, however, are discovered as the individual is trying to come to terms with the problematic situation (Getzels 1964). In such cases, the problem itself may not be clearly formulated until the very end of the process. As Albert Einstein noted, the solution of an already formulated problem is relatively easy compared to the formulation of a problem no one had previously recognized.

2. *Incubation*   Some of the most important mental work in creative problems takes place below the threshold of consciousness, where problematic issues identified during the preceding stage remain active without the person controlling the process. By allowing ideas to be associated with the contents of memory more or less at random, incubation also allows completely unexpected combinations to emerge. As long as one tries to formulate or solve a problem consciously, previous habits of mind will direct thoughts in rational, but predictable directions.

3. *Insight*   When a new combination of ideas is strong enough to withstand unconscious censorship, it emerges into awareness in a moment of illumination—the "Eureka!" or "Aha!" experience usually thought to be the essence of creativity. Without preparation evaluation, and elaboration, however, no new idea or product will follow.

4. *Evaluation*   The insight that emerges must be assessed consciously according to the rules and conventions of the given domain. Most novel ideas fail to withstand critical examination. One can go wrong by being either too critical or not critical enough.

5. *Elaboration*   Thomas Edison made popular the saying "Genius is 1 percent inspiration and 99 percent perspiration." Even the most brilliant insight disappears without a trace unless the person is able and willing to develop its implications, to transform it into a reality. But this stage does not involve a simple transcription of a model perfectly formed in the mind. Most creative achievements involve drastic changes that occur as the creator translates the insight into a concrete product. A painter may approach the canvas with a clear idea of how the finished painting should look, but most original pictures evolve during the process of painting, as the combination of colors and shapes suggests new directions to the artist.

Creativity as a Systemic Phenomenon

No person can be creative without having access to a tradition, a craft, a knowledge base. Nor can we trust the subjective report of a person to the effect that his or her insight was indeed creative. It is one of the peculiarities of human psychology that most people believe their thoughts to be original and valuable. To accept such personal assessment at face value would soon deprive the concept of creativity of any specific meaning.

Creativity can best be understood as a confluence of three factors: a domain, which consists of a set of rules and practices; an individual, who makes a novel variation in the contents of the domain; and a field, which consist of experts who act as gatekeepers to the domain, and decide which novel variation is worth adding to it (Csikszentmihalyi 1996). A burst of creativity is generally caused, not by individuals being more creative, but by domain knowledge becoming more available, or a field being more supportive of change. Conversely, lack of creativity is usually caused, not by individuals lacking original thoughts, but by the domain having exhausted its possibilities, or the field not recognizing the most valuable original thoughts.

The Creative Person

Three aspects of creative persons are particularly important: cognitive processes, personality, and values and motivations. While, in most cases, a certain level of intelligence is a prerequisite—a threshold of 120 IQ is often mentioned (Getzels and Jackson 1962)—the relationship of IQ to creativity varies by domain, and after a relatively low threshold, there seems to be no further contribution of IQ to creativity. The first and longest study of high-IQ children (Terman 1947; see also Sears and Sears 1980) found little evidence of adult creativity in a sample whose mean IQ as children was 152, or even in a subsample with an IQ above 170.

The most obvious characteristic of original thinkers is what Guilford (1967) identified as "divergent thinking" or "thinking outside the box." *Divergent thinking* involves unusual associations of ideas, changing perspectives, and novel approaches to problems, in contrast to *convergent thinking,* which involves linear, logical steps. Correlations between divergent thinking tests and creative achievement tend to be low, however, and some scholars even claim that the cognitive approach of creative individuals does not differ qualitatively from that of normal people except in its speed (Simon 1988) and quantity of ideas produced (Simonton 1990).

Some forms of mental disease such as manic depression, addiction, and suicide are more frequent among individuals involved in artistic and literary pursuits (Andreasen 1987; Jamison 1989), but this might have less to do with creativity than with the lack of recognition that obtains in artistic domains. At the same time, creative individuals appear to be extremely sensitive to all kinds of stimuli, including aversive ones (Piechowski 1991), possibly accounting for their higher rates of emotional instability.

Personality traits often associated with creativity include openness to experience, impulsivity, self-confidence, introversion, aloofness, and rebelliousness (Getzels and Csikszentmihalyi 1976; Feist forthcoming). Such people also seem to have a remarkable ability to be both playful and hard-working, introverted and extroverted, aloof and gregarious, traditional and rebellious, as the occasion requires (Csikszentmihalyi 1996). The creative person might be less distinguished by a set of traits than by the ability to experience the world along modalities that in other people tend to be stereotyped. Throughout their lives, creative persons exhibit a childlike curiosity and interest in their domains, value their work above conventional monetary or status rewards (Getzels and Csikszentmihalyi 1976), and enjoy it primarily for intrinsic reasons (Amabile 1983). Creativity is its own reward.

Creoles

Creoles constitute a unique language group. Other groups consist either of languages derived from a hypothesized protolanguage (as Welsh, English, Greek, and Sanskrit derive from Proto Indo-European) or a single historical ancestor (as Portuguese, Spanish, and Italian derive from Latin). Creoles, however, have no clear affiliation. Although the term

creole has been used to characterize any language with an appearance of language mixture, languages generally accepted as creoles have all arisen in recent centuries from contacts between speakers of unrelated languages, usually as indirect results of European colonialism. They are found throughout the tropics, especially where large numbers of workers have been imported as slaves (or, occasionally, indentured laborers) to work on European-owned plantations. Because more work has been done on plantation creoles than on other types (those that developed in racially mixed communities on African and Asian coasts, or those derived initially from maritime contacts in the Pacific), most of what follows will apply primarily to plantation creoles.

Until recently, few scholars (e.g., Schuchardt 1882–91; Hesseling 1933) took these languages seriously; most treated them as deformed versions of European languages. Even to scholars who accepted them as true languages, their origins were controversial: some saw them as radical developments of French, English, and other languages, others as non-European languages thinly disguised by European vocabularies, still others as descendants of an Ur-creole perhaps springing from Afro-Portuguese contacts in the fifteenth and sixteenth centuries, perhaps even dating back to the medieval Lingua Franca. Other issues, such as whether creoles were necessarily preceded by, and derived from, some radically impoverished quasi-language (jargon or early-stage pidgin), or whether children or adults played the major role in their creation, were debated with equal heat but equally little agreement.

More than a century ago, Coelho (1880–86) pointed out that creoles showed structural similarities much greater than would be predicted given their wide distribution, their varied histories, and the large number of languages spoken in the contact situation where they arose. However, creoles would have held little interest for cognitive science had it not been proposed that, due to their mode of origin, they reflected universals of language more directly than "normal" languages.

This hypothesis of a species-specific biological program for language, providing default settings where acquisitional input is greatly reduced and/or deformed (often referred to as "bioprogram theory"), assumes a version of GENERATIVE GRAMMAR proposed by Borer (1983), and now widely accepted by generativists, in which parametric variation in SYNTAX arises solely from variability in grammatical MORPHOLOGY. In the (severely depleted) morphology of creoles, many (often most) grammatical morphemes are distinct from those of any language spoken in the contact situation. This indicates that grammatical morphemes, lost in the pidginization process, are replaced by the creation of new morphemes, often from semantically "bleached" referential items (thus the verb for "go" marks irrealis mode, locative verbs mark imperfective aspect, etc.). Some grammatical functions required immediate recreation of new morphemes, whereas morphemes for other functions were recreated centuries later, if at all (Bickerton 1988). The implication of these facts for the study of universal grammar remain, surprisingly, unexplored.

Bioprogram theory has obvious implications for other fields of inquiry. In LANGUAGE ACQUISITION, it suggests that creoles should be acquired more rapidly and with fewer errors than non-creoles, a prediction that has only recently begun to be tested (Adone 1994). In innateness studies (see INNATENESS OF LANGUAGE), it suggests in addition to syntactic principles a default SEMANTICS yielding highly specific analyses of TENSE AND ASPECT, modality, negation, articles, and purposive constructions, among others (an element missing from generative accounts of innateness of language). In the EVOLUTION OF LANGUAGE it suggests that syntactically structured language could have emerged abruptly from a structureless protolanguage (Bickerton 1990a).

Although bioprogram theory has had "an explosive impact . . . upon all aspects of the field" (McWhorter 1996), other approaches to creole genesis continue to flourish. Perhaps the most currently popular alternative is substratism, which claims that languages spoken by non-European ancestors of creole speakers served as sources for characteristically creole structures such as serial verb constructions (e.g., equivalents of "I carry X come give Y" for "I bring X to Y") and focusing of verbs by fronting and copying (e.g., equivalents of "is break he break the glass" for "he *broke* the glass" as opposed to merely cracking it). Alleyne (1980), Boretsky (1983), and Holm (1988–89), among others, exemplify this approach. However, substratists attribute these and other creole features to the Kwa language group in West Africa, heavily represented in some creole-speaking areas (Haiti, Surinam), but more lightly, if at all, in others (the Gulf of Guinea, Mauritius) and not at all in still others (Hawaii, the Seychelles).

Substratism's mirror-image, superstratism—the belief that creoles derive their syntax from colloquial versions of European language—is nowadays largely confined to French creolists (e.g., Chaudenson 1992). More widespread is a "componential" approach (Hancock 1986, Mufwene 1986) claiming that different mixtures of substratal, superstratal, and universal features contributed to different creoles, the mixture being determined in each case by social, historical, and demographic factors. However, because no one has yet proposed a formula for determining the relative contributions of the various components, this approach is at present virtually unfalsifiable, and it constitutes a research program rather than a theory.

Controversies have thus far centered around creole origins. But only recently, after decades of speculation and conjecture, have serious attempts been made to gather historical data (e.g., Arends 1995; Baker 1996). Not all this work is of equal value; claims of a scarcity of children in early colonies are refuted by contemporary statistics (Postma 1990; Bickerton 1990b). Documentation for the earliest stages of creole languages remains sparse, except for Hawaii, where rich data for all phases of the pidgin-creole cycle has been unearthed by Roberts (1995, 1998). These data confirm, at least for Hawaii, the main claims of bioprogram theory: that the creole was created (a) from a primitive, structureless pidgin (b) in a single generation (c) by children rather than adults. Hopefully, ongoing historical research on other creoles will determine the extent to which these conform to Hawaii's pattern.

Cross-Cultural Variation

See CULTURAL VARIATION; HUMAN UNIVERSALS; LANGUAGE AND CULTURE; LINGUISTIC UNIVERSALS AND UNIVERSAL GRAMMAR

Cultural Consensus Theory

Cultural consensus theory is a collection of formal statistical models designed to measure cultural knowledge shared by a set of respondents. Each respondent is given the same set of items designed to tap the respondents' shared knowledge. The data consist of a respondent-item matrix containing each respondent's answers to each of the items. An appropriate cultural consensus model provides estimates of each respondent's competence (knowledge) as well as an estimate of the culturally correct answer to each item. When the theory was developed in the mid-1980s it was motivated by the observation that when an anthropologist goes to a new culture and asks questions, neither the answers to the questions nor the cultural competence of the respondents is known. It has since been applied to a number of research questions, for example, folk medical beliefs, judgment of personality traits in a college sorority, semiotic characterizations of alphabetic systems, occupational prestige, causes of death, illness beliefs of deaf senior citizens, hot-cold concepts of illness, child abuse, national consciousness in Japan, measuring interobserver reliability, and three-way social network data.

Consensus theory uses much of the accumulated knowledge of traditional psychometric test theory without assuming knowledge of the "correct" answers in advance. Traditional test theory begins with respondent-item "performance" data (i.e., items' scores as "correct" or "incorrect"), whereas consensus theory begins with "response" data (items coded as responses given by the respondent, for example, "true" or "false," without scoring the responses). The different models of the theory depend on the format of the questions, for example, true-false, multiple choice, or ranking. Anthropology is the prototypical social science that can use such a methodology; however, research in other areas of social and behavioral science, such as cognitive psychology, social networks, and sociology, can also benefit from its use.

Cultural consensus theory fits into the category of information-pooling methods in which one has answers from several "experts" to a fixed body of "objective" questions. The goal is to aggregate rationally the experts' responses to select the most likely "correct answer" to each question, and also to assess one's degree of confidence in these selections. Cultural consensus theory provides an information-pooling methodology that does not incorporate a researcher's prior beliefs about the correct answers or any prior calibrations of the experts, and instead, it estimates both the respondents' competencies and the consensus answers from the same set of questionnaire data.

A central concept in the theory is the use of the pattern of agreement or consensus among respondents to make inferences about their differential knowledge of culturally shared information represented in the questions. It is assumed that the sole source of correspondence between the answers of any two respondents is a function of the extent to which the knowledge of each is correlated with (overlaps) this shared information. In other words, when responses are not based on shared information they are assumed to be uncorrelated. More formally, the model is derived from a set of three basic assumptions that are elaborated appropriately for each question format:

Assumption 1: *Common Truth.* There is a fixed answer key applicable to all respondents.

Assumption 2: *Local Independence.* The respondent-item response random variables satisfy conditional independence (conditional on the correct answer key).

Assumption 3: *Homogeneity of Items.* Each respondent has a fixed competence over all questions.

In some contexts Assumption 3 is replaced with a weaker one, *monotonicity*, that allows them to differ in difficulty: Basically, monotonicity says that respondents who have more competence on any subset of questions will have more competence on all subsets.

Formal process models have been derived for the analysis of dichotomous, multiple-choice, matching, and continuous item formats. Informal data models have also been developed for rank order and interval level formats. The theory has also been extended to the analysis of multiple cultures by relaxing the first axiom. In this situation each respondent belongs to exactly one culture, but different cultures may have different answer keys.

For very small sets of respondents (six or fewer), iterative maximum likelihood estimates of the parameters can be obtained by existing methods. For example, in the true-false case, the consensus model is equivalent to the two-class latent structure model with the roles of respondents and items interchanged; thus known estimation methods for that model can be used. For other situations, new estimation methods have been developed and assessed with Monte Carlo data. The theory enables the calculation of the minimal number of respondents needed to reconstruct the correct answers as a function of preselected levels of mean cultural competence of the respondents and levels of confidence in the reconstructed answers. It is also possible to estimate the amount of sampling variability among respondents and thus identify "actual" variance in cultural competence.

The theory performs better than does using a simple majority rule to reconstruct the answer key, especially in cases where there are small numbers of respondents with heterogeneous competence. The success of cultural consensus theory as an information-pooling method can be traced to several factors: (1) it is normally applied to items that tap high concordance cultural codes where mean levels of consensus are high; (2) the theory allows the differential weighting of the respondents' responses in reconstructing the answer key; and (3) the theory uses precise assumptions derived from successful formal models in test theory, latent structure analysis, and signal detection theory. The model has been subjected to extensive testing through simulation and Monte Carlo methods.

Cultural Evolution

Human cultures include among other things mental representations with some between-group differences and within-group similarities. Ecological constraints, historical conditions, and power relations may influence the transmission of culture. A *cognitive* account assumes that, all these being equal, some trends in culture result from universal properties of human minds. These may account for patterns of change as well as for stability over time and space.

In the past, various forms of evolutionism described cultures as cognitively different and some of them as intrinsically more complex or developed than others (see Ingold 1986). In this view, differences in social and economic complexity between human groups corresponded to cognitive differences between *peoples* or *races.* It is clear to modern cognitive scientists that this is untenable. Different environments make different demands on a cognitive system, but there is no hierarchy of complexity or development between them, and the relevant cognitive structures are typical of the human species as a whole.

A cognitive approach must address three related questions: (1) Is cultural transmission similar to genetic transmission? (2) How did hominization lead to the appearance of culture? and (3) How are cultural representations constrained by the human genotype?

1. Are cultural memes like genes? Many authors have suggested that cultural evolution could be modeled on terms derived from natural selection (Campbell 1970). Mentally represented units of information, usually called *memes* (Dawkins 1976), result in overt behavior, are passed on

through social interaction and modified by memory and inference. Different memes may have different *cultural fitness* values: culture evolves through *differential* transmission of ideas, values and beliefs (Durham 1991: 156).

Coevolution theories describe significant trends in meme transmission using the formal tools of population genetics (Lumsden and Wilson 1981; Boyd and Richerson 1985; Durham 1991). Patterns of transmission and change depend on quantitative factors, such as the frequency of a trait in cultural elders or the number of variants available in a given group, but also on cognitive processes. Durham, for instance, makes a distinction between *primary values*, a set of evolved, universal propensities toward certain representations, and *secondary values*, socially acquired expectations concerning the possible consequences of behavior (1991: 200, 432).

An alternative to replication is an *epidemiological* model, in which cultural evolution is construed as the outcome of mental contagion (Sperber 1985). This approach emphasizes the differences between gene and meme transmission. Cultural representations are not literally *replicated*, because human communication is intrinsically inferential and works by producing publicly available tokens (e.g., utterances, gestures) designed to change other agents' representations (Sperber and Wilson 1986). Cultural epidemics are distinct from a replication process in that acquisition typically produces variants rather than copies of the representations of others; rough replication, then, is an exception that must be explained, rather than the norm (Sperber 1996).

2. What made (and makes) culture possible? There are important differences between various types of animal traditions and complex, flexible human cultures, which often show an accumulation of modifications over generations (i.e., the ratchet effect; Tomasello, Kruger, and Ratner 1993: 508). Humans may have developed very general learning capacities that allow them to acquire whatever information can be found in their environment. Alternatively, EVOLUTION may have given humans a more numerous and complex set of specialized cognitive capacities.

The first type of explanation can be found in Donald's account of the appearance of cognitive plasticity as a crucial evolutionary change. The primate mind became *modern* by developing a powerful learning device without constraining restrictions as to the range of mental contents that could be learned (Donald 1993). An explanation in terms of more specific capacities is Tomasello, Kruger, and Ratner's (1993) account of cultural learning, as distinct from social learning based on IMITATION and found in higher primates. Cultural learning requires *mind-reading* and perspective-taking capacities. Obviously, these capacities would have been boosted by the appearance of verbal communication.

One may push this further and argue that the appearance of culture depended, not on a more powerful general learning capacity, but on a multiplication of specialized capacities (Rozin 1976, Tooby and Cosmides 1989). This would have been less costly in evolutionary terms. It only required gradual addition of small *modules* rather than the sudden appearance of a general and flexible mind. Also, it makes more computational sense. An unbiased all-purpose learning capacity could be overloaded with many adaptively irrelevant facts and correlations in the environment. These considerations lead to the research program of EVOLUTIONARY PSYCHOLOGY, which specifies a large number of *cognitive adaptations*. These are specialized in particular aspects of experience that would have been of plausible relevance to fitness in the environment of evolutionary adaptation, though not necessarily in a modern environment. To some extent, the archaeological record supports this notion of specialized microcapacities appearing side by side and making up an ever more complex mind. However, late developments (in particular, the cultural differences between Neanderthals and modern humans) may also suggest that communication between modules was as important as development in each of them (Mithen 1996).

3. Is culture constrained by genes? What are the connections between the genotype and recurrent features of culture? Coevolution theories have challenged the assumption of early human SOCIOBIOLOGY that people's concepts and values generally tend to maximize their reproductive potential (Cavalli-Sforza and Feldman 1973). Most cultural variants are adaptively neutral, and many are in fact maladaptive, so coevolution models postulate different evolution tracks for genes and memes. Beyond this, one may argue that evolved properties of human cognition influence cultural evolution in two different ways.

First, human minds comprise a set of ready-made behavioral recipes that are activated by particular cues in the natural and social environment. Whether those cues are present and which capacities are activated may vary from place to place. So different environments set parameters differently for such universal capacities as social exchange, detection of cheaters, or particular strategies in mate-selection and in the allocation of parental investment (see Barkow, Cosmides, and Tooby 1992 for a survey of these domains).

Second, humans develop universal conceptual structures that constrain the transmission of particular representations. This can be observed even in beliefs and values whose overt content seems culturally variable. Children gradually develop a set of quasi-theoretical, domain-specific assumptions about the different types of objects in the world as well as expectations about their observable and underlying properties. The experimental evidence demonstrates the effects of such principles in domains like THEORY OF MIND, the perception of mechanical causation or the specific properties of living things (Hirschfeld and Gelman 1994). This *intuitive ontology* has direct effects on the acquisition of cultural representations.

In some domains, information derived from cultural input is acquired inasmuch as it tends to *enrich* early skeletal principles. This is the case for number systems, for instance, as cultural input provides names for intuitive concepts of *numerosity* (Gallistel and Gelman 1992). In the same way, FOLK PSYCHOLOGY is built by using cultural input, for instance about motivation, emotion, through-processes, and so on, that provide explanations for the intuitions delivered by our theory of mind. In folk biology, too, cultural input that is spontaneously selected tends to enrich intuitive principles about the taxonomic ordering of living species or possession of an *essence* as a feature of each species (Atran 1990). Even such social constructs as kinship

terms or notions of *family* and *race* can be construed as enriching an intuitive apprehension of social categories (Hirschfeld 1994).

In other domains, cultural input is selectively attended to inasmuch as it *violates* the expectations of intuitive ontology. Religious ontologies, for instance, postulate agents whose physical or biological properties are counterintuitive, given ordinary expectations about intentional agents. Such combinations are very few in number and account for most cultural variants in religious systems (Boyer 1994). Their presence in individual religious representations can be demonstrated experimentally (Barett and Keil 1996).

In some domains more complex processes are involved. This is the case for scientific theories and other forms of scholarly knowledge that diverge from intuitive ontology. Such systems of representations generally require considerable social support (intensive tuition and specialized institutions like schools). They generally include an explicit description of their divergence from intuitive ontology, and therefore a METAREPRESENTATION of ordinary representations about the natural world. This is why such systems typically require LITERACY, which boosts metarepresentational capacities and provides external memory storage, allowing for incremental additions to cultural representations.

Human cognition comprises a series of specialized capacities. Transmission patterns probably vary as a function of which domain-specific conceptual predispositions are activated. So there may be no overall process of cultural transmission, but a series of domain-specific *cognitive tracks* of transmission. Models of cultural evolution are tautological if they state only that whatever got transmitted must have been better than what did not (Durham 1991: 194). This is where cognitive models are indispensable. Experimental study of cognitive predispositions provides independent evidence for the underlying mechanisms of cultural evolution.

Cultural Models

See METAPHOR AND CULTURE; MOTIVATION AND CULTURE

Cultural Psychology

The most basic assumption of cultural psychology can be traced back to the eighteenth-century German romantic philosopher Johann Gottfried von Herder, who proposed that "to be a member of a group is to think and act in a certain way, in the light of particular goals, values, pictures of the world; and to think and act so is to belong to a group" (Berlin 1976: 195). During the past twenty-five years there has been a major renewal of interest in cultural psychology, primarily among anthropologists (D'Andrade 1995; Geertz 1973; Kleinman 1986; Levy 1973; Shore 1996; Shweder 1991; Shweder and LeVine 1984; White and Kirkpatrick 1985), psychologists (Bruner 1990; Cole 1996; Goodnow, Miller, and Kessel 1995; Kitayama and Markus 1994; Markus and Kitayama 1991; Miller 1984; Nisbett and Cohen 1995; Russell 1991; Yang forthcoming) and linguists

(Goddard 1997; Wierzbicka 1992*a*), although relevant work has been done by philosophers as well (Harre 1986; MacIntyre 1981; Taylor 1989). The contemporary field of cultural psychology is concerned, as was Herder, with both the psychological foundations of cultural communities and the cultural foundations of mind. It is concerned with the way culture and psyche make each other up, over the history of the group and over the life course of the individual.

The word "cultural" in the phrase "cultural psychology" refers to local or community-specific conceptions of what is true, good, beautiful, and efficient ("goals, values and pictures of the world") that are socially inherited, made manifest in the speech, laws, and customary practices of members of some self-monitoring group, and which serve to mark a distinction between different ways of life (the Amish way of life, the way of life of Hindu Brahmans in rural India, the way of life of secular urban middle-class Americans).

A community's cultural conception of things will usually include some vision of the proper ends of life; of proper values; of proper ways to speak; of proper ways to discipline children; of proper educational goals; of proper ways to determine kinship connections and obligations; of proper gender and authority relations within the family; of proper foods to eat; of proper attitudes toward labor and work, sexuality and the body, and members of other groups whose beliefs and practices differ from one's own; of proper ways to think about salvation; and so forth.

A community's cultural conception of things will also usually include some received, favored, or privileged "resolution" to a series of universal, scientifically undecidable, and hence existential questions. These are questions with respect to which "answers" must be given for the sake of social coordination and cooperation, whether or not they are logically or ultimately solvable by human beings, questions such as "What is me and what is not me?", "What is male and what is female?", "How should the burdens and benefits of life be fairly distributed?", "Are there community interests or cultural rights that take precedence over the freedoms (of speech, conscience, association, choice) associated with individual rights?" and "When in the life of a fetus or child does social personhood begin?" Locally favored and socially inherited "answers" to such questions are expressed and made manifest (and are thus discernible) in the speech, laws, and customary practices of members of any self-monitoring group. In sum, local conceptions of the true, the good, the beautiful, the efficient, plus discretionary "answers" to cognitively undecidable existential questions, all made apparent in and through practice, is what the word "cultural" in "cultural psychology" is all about.

The word "psychology" in the phrase "cultural psychology" refers broadly to mental functions, such as perceiving, categorizing, reasoning, remembering, feeling, wanting, choosing, valuing, and communicating. What defines a function as a "mental" function per se (over and above, or in contrast to a "physical" function) has something to do with the capacity of the human mind to grasp ideas, to do things for reasons or with a purpose in mind, to be conscious of alternatives and aware of the content or meaning of its own experience. This is one reason that "mental" states are sometimes referred to as "intentional" or "symbolic" states. Cultural psychology is the study of those intentional and symbolic states of individuals (a belief in a reincarnating soul, a desire to purify one's soul and protect it from pollutions of various kinds) that are part and parcel of a particular cultural conception of things made manifest in, and acquired by means of involvement with, the speech, laws and customary practices of some group.

It has been noted by Clifford Geertz, and by others interested in lived realities, that "one does not speak language; one speaks a language." Similarly, one does not categorize; one categorizes something. One does not want; one wants something. On the assumption that what you think about can be decisive for how you think, the focus of cultural psychology has been on content-laden variations in human mentalities rather than on the abstract common denominators of the human mind. Cultural psychologists want to know why Tahitians or Chinese react to "loss" with an experience of headaches and back pains rather than with the experience of "sadness" so common in the Euro-American cultural region (Levy 1973; Kleinman 1986). They seek to document population-level variations in the emotions that are salient or basic in the language and feelings of different peoples around the world (Kitayama and Markus 1994; Russell 1991; Shweder 1993; Wierzbicka 1992a). They aim to understand why Southern American males react more violently to insult than Northern American males (Nisbett and Cohen 1996) and why members of sociocentric subcultures perceive, classify, and moralize about the world differently than do members of individualistic subcultures (Markus and Kitayama 1991; Triandis 1989; Shweder 1991).

It is precisely because cultural psychology is the study of the content-laden intentional/symbolic states of human beings that cultural psychology should be thought of as the study of peoples (such as Trobriand Islanders or Chinese Mandarins), not people (in general or in the abstract). The psychological subject matter definitive of cultural psychology thus consists of those aspects of the mental functioning of individuals that have been ontogenetically activated and historically reproduced by means of some particular cultural conception of things, and by virtue of participation in, observation of, and reflection on the activities and practices of a particular group. This definition of research in cultural psychology sets it in contrast (although not necessarily in opposition) to research in general psychology, where the search is for points of uniformity in the psychological functioning of people around the world. Without denying the existence of some empirically manifest psychological uniformities across all human beings, the focus in cultural psychology is on differences in the way members of different cultural communities perceive, categorize, remember, feel, want, choose, evaluate, and communicate. The focus is on psychological differences that can be traced to variations in communally salient "goals, values, and pictures of the world."

Cultural psychology is thus the study of the way the human mind can be transformed, given shape and definition, and made functional in a number of different ways that are not uniformly distributed across cultural communities

around the world. "Universalism without the uniformity" is one of the slogans cultural psychologists sometimes use to talk about "psychic unity," and about themselves.

Cultural Relativism

How are we to make sense of the diversity of beliefs and ethical values documented by anthropology's ethnographic record? Cultural relativism infers from this record that significant dimensions of human experience, including morality and ethics, are inherently local and variable rather than universal. Most relativists (with the exception of developmental relativists discussed below) interpret and evaluate

such diverse beliefs and practices in relation to local cultural frameworks rather than universal principles.

There are many variations on the theme of cultural relativism. Six important variants are described below:

1. *Epistemological relativism,* the most general phrasing of cultural relativism, proposes that human experience is mediated by local frameworks for knowledge (Geertz 1973). Most epistemological relativism assumes that experienced reality is largely a social and cultural construction and so this position is often called "social constructionism" (Berger and Luckmann 1966).

2. *Logical relativism* claims that there are no transcultural and universal principles of rationality, logic and reasoning. This claim was debated in the 1970s in a series of publications featuring debates among English philosophers, anthropologists, and sociologists about the nature and universality of rationality in logical and moral judgment (B. Wilson 1970).

3. *Historical relativism* views historical eras as a cultural and intellectual history of diverse and changing ideas, paradigms, or worldviews (Burckhardt 1943; Kuhn 1977).

4. *Linguistic relativism* focuses on the effects of particular grammatical and lexical forms on habitual thinking and classification (Whorf 1956; Lucy 1992).

5. *Ethical relativism* claims that behavior can be morally evaluated only in relation to a local framework of values and beliefs rather than universal ethical norms (Ladd 1953). Proponents advocate tolerance in ethical judgments to counter the presumed ethnocentricism of universalistic judgments (Herskovitz 1972; Hatch 1983). Opponents claim that extreme ethical relativism is amoral and potentially immoral since it can justify, by an appeal to local or historical context, any action, including acts like genocide that most people would condemn (Vivas 1950; Norris 1996). This debate engages the highly visible discourse on the doctrine of universal human rights, and the extent to which it reflects natural rights rather than the cultural values of a politically dominant community (R. Wilson 1997). Important and emotionally salient issues engaged in this debate include the status of women, abortion, religious tolerance, the treatment of children, arranged marriages, female circumcision, and capital punishment. A common thread linking many of these issues is the status of "the individual" and by implication social equality versus social hierarchy, and cultural relativism can be used to justify relations of inequality (Dumont 1970).

6. Distinct from evolutionary psychologists mentioned above are *developmental relativists* who ascribe differences in thought or values to different stages of human development, either in terms of evolutionary stages or developmental differences in moral reasoning between individuals. A commonplace assumption of Victorian anthropology, evolutionism still has echoes in the *genetic epistemology* of developmental psychologists like PIAGET, Kohlberg, and Werner (Piaget 1932; Kohlberg 1981, 1983; Werner 1948/1964). Genetic epistemology acknowledges the cultural diversity and relativity of systems of reasoning and symbolism but links these differences to a universalistic developmental (and, by common implication, evolutionary) trajectory.

Both a philosophical and a moral stance, cultural relativism makes two different sorts of claims: (1) an *ontological claim* about the nature of human understanding, a claim subject to empirical testing and verification, and (2) a *moral/political claim* advocating tolerance of divergent cultural styles of thought and action.

Cultural relativism implies a fundamental human psychic diversity. Such diversity need not preclude important universals of thought and feeling. Relativism and universalism are often seen as mutually exclusive. At the relativist end of the spectrum are proponents of CULTURAL PSYCHOLOGY who argue that the very categories and processes by which psychologists understand the person are themselves cultural constructs, and who imply that academic psychology is actually a Western ETHNOPSYCHOLOGY (Shweder 1989). From this perspective comparative or cross-cultural psychology become impossible, inasmuch as the psychology of each community would need to be studied in its own analytical terms. At the universalist end of the spectrum is EVOLUTIONARY PSYCHOLOGY, which looks at human cognitive architecture as having evolved largely during the upper Paleolithic, subject to the general Darwinian forces of natural selection and fitness maximization (Barkow, Cosmides, and Tooby 1992). Local cultural differences are viewed as relatively trivial compared with the shared cognitive abilities that are the products of hominid evolution.

Many cognitive anthropologists see in the relativist/universalist distinction a false dichotomy. An adequate model of mind must encompass both universal and variable properties. Although they acknowledge the importance of a shared basic cognitive architecture and universal process of both information processing and meaning construction, many cognitive anthropologists do not see cultural variation as trivial but stress the crucial mediating roles of diverse social environments and variable cultural models in human cognition (D'Andrade 1987; Holland and Quinn 1987; Hutchins 1996; Shore 1996).

Although cultural relativism has rarely been treated as a problem of cognitive science, COGNITIVE ANTHROPOLOGY is a useful perspective for reframing the issues of cultural relativism. For cognitive anthropologists, a cultural unit comprises a population sharing a large and diverse stock of *cultural models,* which differ from community to community. Once internalized, cultural models become conventional cognitive models in individual minds. Cultural models thus have a double life as both *instituted models* (public institutions) and conventional *mental models* (individuals' mental representations of public forms; Shore 1996). Other kinds of cognitive models include "hardwired" schemas (like those governing facial recognition) and personal/idiosyncratic mental models that differ from person to person. Thus viewed, culture is not a bounded unit but a dynamic social distribution of instituted and mental models.

When culture is conceived as a socially distributed system of models, the sources of cultural relativity become more complex and subtle but are easier to specify. Rather than draw simple oppositions between distinct cultures, we can specify which models (rather than which cultures) are different and how they differ. Thus the similarity or differ-

ence between communities is not an all-or-nothing phenomenon, but is a matter of particular differences or similarities.

In addition, significant conflict or contradiction among cultural models within a community becomes easier to account for, as do conflicts between cultural models and personal models or between cultural models and relatively unmodeled (diffuse/inarticulate) feelings and desires. Such internal conflicts do not argue against the intersubjective sharing of cultural models within a community or the important difference between communities. But they suggest a softening of the oppositions between discrete cultures that has been the hallmark of much of the discourse of cultural relativism.

Many within-culture conflicts suggest existential dilemmas that have no final resolution (e.g., autonomy versus dependency needs, equality and hierarchy; Fiske 1990; Nuckolls 1997). There are models and countermodels, as in political discourse. Cultural models sometimes provide temporary resolutions, serving as salient cognitive and emotional resources for clarifying experience. Sometimes, as in religious ritual, cultural models simply crystallize contradictions, representing them as sacred paradox. Such resolutions are never complete, and never exhaust the experience of individuals. In this way, the relativity *between cultures* is complemented by a degree of experiential relativity *within cultures* (variation and conflict) and periodically within individuals (ambivalence).

Cultural Symbolism

At about 50,000 B.P., the archaeological record shows a sudden change in the nature and variety of artifacts produced by modern humans, with the massive production of cave paintings, elaborate artifacts of no practical utility, the use of ocher, the introduction of burial practices, and so on. Here we have the first traces of the emergence of cultural symbolism (although the phenomenon itself may have appeared earlier). The term has a wider extension for anthropologists who are not limited to preserved artifacts and can observe such cultural products as public utterances, ritual, clothing, music, etiquette, dance, and prohibitions. All these productions have three main characteristics: (1) their particular features are to a large extent unmotivated by immediate survival needs and are often devoid of any practical purpose; (2) they seemingly involve a capacity to "reify" mental representations, so that certain communicative or memory effects can be achieved by producing material objects and observable events; (3) their features vary from one human group to another.

In the social sciences, the loose term *symbolism* was applied to all such productions for a simple reason: although they often seemed to convey some overt "meaning," this meaning did not seem sufficient to explain their occurrence or transmission. A common strategy, then, was to explain symbolism as a symptom of social relations. Durkheim, for instance, treats religion as a symbol of social order and superhuman agency as a symbol of society itself. For Marx, an ideology symbolizes (and distorts) social relations. Alternatively, hermeneutic approaches to culture emphasize common concerns of mankind that find their expression in cultural symbolism. Religion, for instance, is described as expressing universal metaphysical questions or anxieties. The common thread in these very different frameworks is that cultural productions stand for something else, which may or may not be accessible to people's consciousness and which is encoded in public representations.

From a cognitive perspective, the main question is to account for the capacities that make symbolism possible, and for the causes of acquisition and transmission of particular patterns (see CULTURAL EVOLUTION). An important attempt in this direction can be found in D. Sperber's cognitive account of symbolism (Sperber 1975, 1996). For Sperber, certain cultural phenomena are "symbolic" to particular actors inasmuch as their rational interpretation does not lead to a limited and predictable set of inferences. This triggers a search for conjectural representations that, if true, would make a rational interpretation possible. The production and use of public representations is then described in terms of communicative intentions. What people do with public representations, just as they do with verbal utterances, is to engage in a goal-directed, relevance-optimizing search for possible descriptions of the communicator's intentions (see RELEVANCE).

This conception has two interesting consequences. First, it suggests that there are no such things as "symbols" as a particular class of cultural products. Any conceptual or perceptual item can become symbolic, if there is some index

that a rational interpretation is unavailable or insufficient. This conception of cultural symbolism also implies that we cannot assume that material and other public symbols "contain" meanings in the form of a code, in much the same way as the letters of a writing system contain phonological information. Symbolism does not work in that way in our species. Bees or vervet monkeys do produce signals that are reliable indicators of the states of affairs that caused their production. Cultural symbols, much like human communication in general, trigger inferential processes that are not constrained by the features of the public representation itself, but by what these features reveal of the communicator's communicative intentions. In other words, you cannot achieve communication (and this extends to cultural "meanings") unless you activate a rich intuitive psychology (see THEORY OF MIND). This argument finds some support from studies showing that even artifact production among humans requires such perspective-taking and inferences about the other's intentions (see, e.g., Tomasello, Kruger, and Ratner 1993).

Cultural symbolism often combines universal, intuitive concepts (e.g., a theory of physical objects as cohesive, a theory of living things as internally propelled) in counterintuitive ways (e.g., a theory of superhuman agents as nonmaterial and nonbiological; Boyer 1994). This, too, requires an ability to rearrange representations that derive from basic cognitive dispositions. This is why the appearance of cultural symbolism has been linked to the emergence of a "metarepresentational" capacity riding piggyback on more specialized "modular" cognitive systems (Mithen 1996).

All this may explain why, as soon as it appears in the archaeological record and wherever it is found in the anthropological evidence, cultural symbolism is "cultural" in the sense of varying between human groups. Humans tend to talk about the same topics the world over and make use of a similar evolved cognitive architecture (see EVOLUTIONARY PSYCHOLOGY). However, inferences produced on the basis of a public representation depend on cues revealing intentions, which themselves may largely depend on the group's history, in particular on the fact that certain public representations, or elements thereof, have been used in the same group before. Such historical variations may result in different implicit schemata and therefore in differences of cultural "style" between groups (see CULTURAL PSYCHOLOGY).

Cultural Universals

See CULTURAL RELATIVISM; HUMAN UNIVERSALS; LINGUISTIC UNIVERSALS AND UNIVERSAL GRAMMAR

Cultural Variation

Cultural variation refers to differences in knowledge or belief among individuals. This article focuses on intracultural variation, on differences in belief among individual members of the same cultural group. For example, Americans differ in their environmental beliefs and values (Kempton, Boster, and Hartley 1995); Mexicans differ in their beliefs about disease (Weller 1984); Ojibway differ in their knowledge of hypertension (Garro 1988); Aguaruna women differ in their knowledge of the names of manioc varieties (Boster 1985); and Americans differ in their familiarity, vocabulary size, and recognition ability in various semantic domains (Gatewood 1984). Cross-cultural variation, the general differences between cultural groups, is discussed elsewhere (see HUMAN UNIVERSALS, CULTURAL RELATIVISM, and COGNITIVE ANTHROPOLOGY).

Cultural variation (studied by anthropologists) contrasts both with sociolinguistic variation (studied by linguists) and with individual differences (studied by psychologists). "Cultural (or cognitive) variation" refers to relatively stable substantive differences in belief. "Sociolinguistic (or contextual) variation" usually refers to transient stylistic differences in speech. In this case, speakers share a model of what their choices of register say about themselves and make different choices of self-representation in different social contexts. For example, they may choose to show solidarity with other members of their social group in one setting and compete for status in another. "Individual differences" usually refers to differences in task performance attributable to intrinsic differences in the way individuals process information. These differences, though sometimes produced by training, are often interpreted as (biologically based) variation in intelligence, temperament, or cognitive style.

Various patterns of intracultural variation have been proposed. The simplest pattern is one implicit in most classic ethnography and often incorporated into the concept of culture itself: Individual members of a cultural group share knowledge and beliefs with other members of the group. This assumption of within-group uniformity is often coupled with an assumption of between-group divergence. For a classic review of the culture concept, see Kroeber and Kluckhorn (1952).

Wallace (1961), building on Sapir's (e.g., 1938) and Hallowell's (e.g., 1955) emphasis on the uniqueness of individuals, argued against this uniformitarian view of culture and asserted that cognitive *non-sharing* is a "functional prerequisite of society." He identified six possible patterns of the organization of cognitive diversity:

1. Zero diversity (high concordance)
2. Unorganized diversity (random differences or idiosyncrasy)
3. Ad hoc communication (enhanced agreement among individuals engaged in the same task)
4. Inclusion (systematic differences between experts and novices)
5. End linkage (systematic differences between experts engaged in complementary tasks)
6. Administration (systematic differences between managers and subordinates executing sub-plans)

The first two patterns were regarded as logical extremes, the latter four as ways of accepting and organizing cognitive diversity.

Subsequent authors have emphasized one or another of these patterns. Roberts studied high concordance codes (pattern 1) for color, kin, and clothing, among other domains. He argued that "such codes merit the heavy cultural investment made in them, for they aid rapid and accurate communication" (Roberts 1987: 267). D'Andrade (1976) suggested that most cultural beliefs were either generally shared or were idiosyncratic (patterns 1 and 2), using as an example the distribution of disease beliefs in the United States and Mexico. He later (1981) suggested that the division of labor in society would augment the total cultural information pool from two to four orders of magnitude beyond what an individual knows (pattern 5; cf. Gatewood 1983). Gardner (1976) describes Dene bird classification as a case in which cultural norms are absent and most knowledge is unique to the individual (pattern 2). In contrast, Boster describes Aguaruna manioc identification as a case in which there is a single cultural model known to varying degrees by different informants and in which "deviations from the model are patterned according to the sexual division of labor, membership in kin and residential groups, and individual expertise" (1985: 193; patterns 3, 4, and 5).

There appear to be many similar instances in which one can infer the knowledge of individuals from their degree of agreement with others (e.g., Boster 1985, 1991; D'Andrade 1987; Garro 1986; Gatewood 1984; Romney, Weller, and Batchelder 1986; Weller 1984; see CULTURAL CONSENSUS THEORY). In these instances, individuals who give the model responses are more likely to be reliable on retest (Boster 1985), consistent (Weller 1984), and experienced with the domain (Boster 1985; Gatewood 1984; Garro 1986; Weller 1984). This pattern holds even in cases, such as a word association task, in which there are no culturally normative responses (D'Andrade 1987). However, there are some cases in which domain novices agree with each other more than do experts (e.g., similarity judgment of fish; Boster and Johnson 1989). The exceptions are often instances in which domain novices can generate consistent responses with a simple heuristic. It is important to ensure that any task used to assess cultural knowledge be representative of natural uses of domain knowledge and have ECOLOGICAL VALIDITY.

Just as authors have differed in the patterns of intracultural variation they emphasize, they differ in their description of the processes that generate those patterns. For Wallace, cognitive diversity mainly reflects the division of

labor: different patterns emerge depending on how tasks are divided among individuals (cf. Durkheim 1933).

Roberts (1964) developed a view of cultures, similar to Wallace's, as "information economies" that create, distribute, and use information. He showed how aspects of social organization affect how cultural groups as a whole store and retrieve information. Elsewhere, he demonstrated how explicit cultural models of error are used to evaluate and correct mistakes, in trapshooting, tavern pool playing, and flying. See Roberts (1987) for a review.

Boster (1991) extended Roberts's model of culture as an information economy. He proposed that patterns of intracultural variation reflect the "quality, quantity, and distribution of individuals' opportunities to learn" (1991: 204). He argues that domains observable by direct inspection (e.g., FOLK BIOLOGY) or introspection (e.g., COLOR CLASSIFICATION) give individuals equal and ample opportunities to learn regardless of their cultural background. These properties give rise to high cross-cultural and intracultural agreement. In contrast, domains that can only be learned from others (e.g., mythologies) are likely to be highly variable both within and between societies, and have a distribution that reflects the social communication network.

Hutchins (1995), like Roberts, sees whole groups as computational engines. But for Hutchins, cognition is distributed not just among humans but also among artifacts such as navigation charts and compasses, for they serve to store, transform, and transmit information, just as do the humans who use them.

Darwin, Charles

Charles Darwin (1809–1882) formulated the most important biological theory of the last century and a half: his theory of EVOLUTION by natural selection. By explaining that "mystery of mysteries," the origin of species, Darwin over-

turned long-entrenched biological and religious assumptions. He applied his general theory to the human animal and thereby rendered an account of moral behavior and rational mind that has formed the foundation for many complementary theories today.

Charles Darwin was born on February 12, 1809, the son of Robert Waring Darwin, a Shrewsbury physician, and Susannah Wedgwood Darwin, daughter of Josiah Wedgwood, who founded the famous pottery firm. When he was sixteen, Darwin went to Edinburgh medical school, following in the shadows of his famous grandfather Erasmus Darwin, and of his father and older brother. At Edinburgh, he came into contact with Robert Grant, who helped him cultivate the study of invertebrates and introduced him to the evolutionary works of his own grandfather and of Lamarck. After Darwin left Edinburgh without a degree, his father, greatly disappointed, sent him to Cambridge to become a country parson. He spent most of his time at university in the pursuits of a gentleman, with some added beetle collecting. A teacher and friend, John Henslow, nevertheless detected a spark in the young man and recommended him to serve as naturalist on a vessel that would sail around the world charting the seas for British naval and commercial craft.

Under the command of the twenty-six-year-old Robert FitzRoy, *H.M.S. Beagle* sailed from Falmouth Harbor on December 29, 1831, and reached the coast of South America two months later. While on board, Darwin occupied himself with reading Alexander von Humboldt's *Personal Narrative of Travels* and steering clear of FitzRoy's foul moods. The *Beagle* charted the waters along the east and west coasts of South America, the Pacific islands, and Australia. Darwin traveled into the interior of these lands to record geological information, as well as to collect fossils and animal specimens to be shipped back to London for careful description and cataloguing. The ship docked at Falmouth on October 4, 1836, almost five years after it had departed. During the voyage Darwin seems not to have seriously considered the possibility that species had transmuted, though he may have had some suspicions. Only in March 1837, as he tried to make sense of the morphology of mockingbirds collected on the Galápagos Islands, did his biological orthodoxy begin to crumble.

During the spring and summer of 1837, Darwin became gradually committed to the idea that species had been transformed over time, and he started to develop hypotheses concerning the causes of change. Initially he supposed that the direct impact of the environment and inherited habit had altered species' forms—notions he retained in his later theorizing. He thought that innate behavior, instincts, also underwent transformations through time, being first acquired as habits. On September 28, 1838, Darwin read Malthus's *Essay on the Principle of Population,* which allowed him to formulate, in the words of his *Autobiography,* "a theory by which to work," his theory of natural selection.

Darwin did not wish to exempt human beings from the evolutionary process. During the late 1830s and early 1840s, he devised theories of the evolution of mind and conscience. Influenced by the empiricism of David HUME and his grandfather, Darwin regarded intelligence as a generalizing and loosening of the cerebral structures that underlay instinct.

Human reason, he believed, gradually emerged out of instincts, which themselves derived from inherited habits and selection operating on such habits. From late 1838 to early 1840, in a set of notebooks ("M" and "N") and in loose notes, he worked out a theory of conscience, which would be elaborated thirty years later in the *Descent of Man* (1871).

Darwin continued to work on his basic theory of evolution through the 1840s and into the early 1850s, simultaneously undertaking the time-consuming labor that produced four large volumes on barnacles. In 1856, after prodding by his friend the eminent geologist Charles Lyell, Darwin began to compose a volume that would detail his theory. In mid-June 1858, he received from Alfred Russel Wallace, then in Malaya, a letter describing a theory of species origin that was nearly identical to his own. Darwin thought his originality had now vanished under a veil of honor. It took Lyell and other of Darwin's friends to convince him that he should continue working on his book, which he did, though in abbreviated form. *On the Origin of Species by Means of Natural Selection* was published in November 1859 and sold out within a few weeks. During Darwin's lifetime, the *Origin* went through six editions, each incorporating alterations and responses to critics. With the last edition, the book had changed by some 50 percent.

The *Origin* had barely mentioned humankind. Critics, however, immediately understood the theory's implications, and most of their objections focused on the problem of human evolution. In 1870, when Wallace seemed to have excluded human beings from the natural process of species change, Darwin felt compelled to reveal his full conception. The *Descent of Man and Selection in Relation to Sex,* appearing in 1871, made his theories of the evolution of mind and conscience quite explicit. Mind reached its human form under the aegis of natural selection and language, the latter producing heritable modifications in brain patterns. Darwin argued that human moral instincts would be acquired through community selection, inasmuch as self-sacrificing behavior would do the agent little good but would benefit the clan, which would include many relatives of the agent. In competition among clans, those whose members exercised more altruistic instincts would have the advantage; and so moral conscience would gradually increase in humankind. Because the pricks of such conscience would little directly benefit the moral individual, Darwin thought his theory quite different from those that were based in utilitarian selfishness—the philosophical ground for many comparable theories today in SOCIOBIOLOGY. Darwin had intended to discuss thoroughly the EMOTIONS in the *Descent,* but saved his theories of emotional instinct for his *Expression of the Emotions in Man and Animals* (1872). Though Konrad Lorenz regarded this book as the foundational document for ETHOLOGY, Darwin had explained emotional instincts solely through the inheritance of acquired habit. And so the Darwinian shade that yet hovers over current biology does bear but passing resemblance to the man who lived in the last century.

Decision Making

Decision making is the process of choosing a preferred option or course of action from among a set of alternatives. Decision making permeates all aspects of life, including decisions about what to buy, whom to vote for, or what job to take. Decisions often involve uncertainty about the external world (e.g., What will the weather be like?), as well as conflict regarding one's own preferences (e.g., Should I opt for a higher salary or for more leisure?). The decision-making process often begins at the information-gathering stage and proceeds through likelihood estimation and deliberation, until the final act of choosing.

The study of decision making is an interdisciplinary enterprise involving economics, political science, sociology, psychology, statistics, and philosophy. Decisions are made by individuals and by groups. Important results have been obtained both in the theoretical and experimental study of group decision making. With an eye toward the cognitive sciences, this article focuses on the empirical study of decision making at the individual level. (The focus is on choice behavior; for more on judgment, see JUDGMENT HEURISTICS.)

One can distinguish three approaches to the analysis of decision making: normative, descriptive, and prescriptive. The normative approach assumes a rational decision-maker who has well-defined preferences that obey certain axioms of rational behavior. This conception, known as RATIONAL CHOICE THEORY, is based primarily on a priori considerations rather than on empirical observation. The descriptive approach to decision making is based on empirical observation and on experimental studies of choice behavior. It is concerned primarily with the psychological factors that guide behavior in decision-making situations. Experimental evidence indicates that people's choices are often at odds with the normative assumptions of the rational theory. In light of this, the prescriptive enterprise focuses on methods of improving decision making, bringing it more in line with normative desiderata (see, e.g., von Winterfeld and Edwards 1986).

In some decision contexts, the availability of the chosen option is essentially certain (as when choosing among dishes from a menu, or cars at a dealer's lot). Other decisions are made under UNCERTAINTY: they can be "risky," where the probabilities of the outcomes are known (e.g., gambling or insurance), or they can be "ambiguous," as are most real world decisions, in that their precise likelihood is not known and needs to be judged "subjectively" by the decision maker. When making decisions under uncertainty, a person has to consider both the desirability of the potential outcomes and their probability of occurrence (see PROBABILISTIC REASONING). Indeed, part of the study of decision-making concerns the manner in which these factors are combined.

Presented with a choice between a risky prospect that offers a 50 percent chance to win $200 (and a 50 percent chance to win nothing) and an alternative of receiving $100 for sure, most people prefer the sure gain over the gamble, although the two prospects have the same expected value. (The expected value is the sum of possible outcomes

weighted by their probability of occurrence. The expected value of the gamble above is .50 × \$200 + .50 × 0 = \$100.) Preference for a sure outcome over a risky prospect of equal expected value is called *risk aversion*; indeed, people tend to be risk averse when choosing between prospects with positive outcomes. The tendency towards risk aversion can be explained by the notion of *diminishing sensitivity,* first formalized by Daniel Bernoulli (1738), who thought that "the utility resulting from a fixed small increase in wealth will be inversely proportional to the quantity of goods previously possessed." Bernoulli proposed that people have a concave utility function that captures their subjective value for money, and that preferences should be described using expected utility instead of expected value (a function is concave if a line joining two points on the curve lies below it). According to expected utility, the worth of a gamble offering a 50 percent chance to win \$200 (and 50 percent chance to win nothing) is .50 × $u(\$200)$, where u is the person's utility function ($u(0) = 0$). It follows from a concave function that the subjective value attached to a gain of \$100 is more than 50 percent of the value attached to a gain of \$200, which entails preference for the sure \$100 gain and, hence, risk aversion.

Expected UTILITY THEORY and the assumption of risk aversion play a central role in the standard economic analysis of choice between risky prospects. In fact, a precipitating event for the empirical study of decision making came from economics, with the publication of von Neumann and Morgenstern's (1947) normative treatment of expected utility, in which a few compelling axioms, when satisfied, were then shown to imply that a person's choices can be thought of as favoring the alternative with the highest subjective expected utility. The normative theory was introduced to psychologists in the late 1950s and early 1960s (Edwards 1961; Luce and Raiffa 1957), and has generated extensive research into "behavioral decision theory." Because the normative treatment specifies simple and compelling principles of rational behavior, it has since served as a benchmark against which behavioral studies of decision making are compared. Research over the last four decades has gained important insights into the decision-making process, and has documented systematic ways in which decision-making behavior departs form the normative benchmark (see ECONOMICS AND COGNITIVE SCIENCE).

When asked to choose between a prospect that offers a 50 percent chance to lose \$200 (and a 50 percent chance at nothing) and the alternative of losing \$100 for sure, most people prefer to take an even chance at losing \$200 or nothing over a sure \$100 loss. This is because diminishing sensitivity applies to negative as well as to positive outcomes: the impact of an initial \$100 loss is greater than that of an additional \$100. The worth of a gamble that offers a 50 percent chance to lose \$200 is thus greater (i.e., less negative) than that of a sure \$100 loss; $.50 × u(-\$200) > u(-\$100)$. This results in a convex function for losses and a risk-seeking preference for the gamble over a sure loss. Preference for a risky prospect over a sure outcome of equal expected value is called *risk seeking*. With the exception of prospects that involve very small probabilities, risk aversion is generally observed in choices involving gains, whereas risk seeking tends to hold in choices involving losses.

An S-shaped value function, based on these attitudes toward risk, forms part of prospect theory (Kahneman and TVERSKY 1979), an influential descriptive theory of choice. The value function of prospect theory has three important properties: (1) it is defined on gains and losses rather than total wealth, which captures the fact that people normally treat outcomes as departures from a current reference point, rather than in terms of final assets, as posited by the rational theory of choice; (2) it is steeper for losses than for gains: thus, a loss of \$X is more aversive than a gain of \$X is attractive. The fact that losses loom larger than corresponding gains is known as *loss aversion*; and (3) it is concave for gains and convex for losses, which yields the risk attitudes described above: risk aversion in the domain of gains and risk seeking in the domain of losses.

These attitudes seem compelling and unobjectionable, yet their combination can lead to normatively problematic consequences. In one example (Tversky and Kahneman 1986), respondents are asked to assume themselves to be \$300 richer and are then asked to choose between a sure gain of \$100 or an equal chance to win \$200 or nothing. Alternatively, they are asked to assume themselves to be \$500 richer, and made to choose between a sure loss of \$100 and an equal chance to lose \$200 or nothing. In accord with the properties described above, most subjects choosing between gains are risk averse and prefer the certain \$100 gain, whereas most subjects choosing between losses are risk seeking, preferring the risky prospect over the sure \$100 loss. The two problems, however, are essentially identical: when the initial \$300 or \$500 payment is added to the respective outcomes, both problems amount to a choice between \$400 for sure as opposed to an even chance at \$300 or \$500. This is known as a *framing effect*. It occurs when alternative framings of what is essentially the same decision problem give rise to predictably different choices. The way a problem is described—in terms of gains or losses—can trigger conflicting risk attitudes; similarly, different methods of eliciting preference—for example, through choice versus independent evaluation—can lead people to weigh certain aspects of the options differently. This leads to violations of the normative requirements of "description invariance" and "procedure invariance," according to which logically equivalent representations of a decision problem as well as logically equivalent methods of elicitation should yield the same preferences.

Monetary gambles have traditionally served as metaphors for uncertain awards and as frequent stimuli in decision research. However, much attention has also been devoted to choices between nonmonetary awards, which tend to be multidimensional in nature—for example, the need to choose between job options that differ in prestige, salary, and rank, or between apartments that differ in size, price, aesthetic attractiveness, and location. People are typically uncertain about how much weight to assign to the different dimensions of options; such assignments are often contingent on relatively immaterial changes in the task, the description, and the nature of the options under consideration (Hsee 1998; Tversky, Sattath, and Slovic 1988).

The study of decision-making incorporates issues of PLANNING, PROBLEM SOLVING, PSYCHOPHYSICS, MEMORY, and SOCIAL COGNITION, among others. Behavioral studies of decision-making have included process-tracing methods, such as verbal protocols (Ericsson and Simon 1984), information-acquisition sequences (Payne, Bettman, and Johnson 1993), and eye-movement data (Russo and Dosher 1983). Decision patterns involving hypothetical problems have been replicated in real settings and with experts, for example, physicians' decisions regarding patient treatment (McNeil et al. 1982; Redelmeier and Shafir 1995), academics' retirement investment decisions (Benartzi and Thaler 1995), and taxi drivers' allocation of working hours (Camerer et al. 1997). Some replications have provided substantial as opposed to minor payoffs (e.g., the equivalent of a month's salary paid to respondents in the Peoples' Republic of China; Kachelmeier and Shehata 1992).

People's choices are influenced by various aspects of the decision-making situation. Among these are the conflict or difficulty that characterize a decision (March 1978; Tversky and Shafir 1992), the regret anticipated in cases where another option would have been better (Bell 1982), the role that reasons play in justifying one choice over another (Shafir, Simonson, and Tversky 1993), the attachment that is felt for options already in one's possession (Kahneman, Knetsch, and Thaler 1990), the influence exerted by costs already suffered (Arkes and Blumer 1985), the effects of temporal separation on future decisions (Loewenstein and Elster 1992), and the occasional inability to predict future or remember past satisfaction (Kahneman 1994). Research in decision-making has uncovered psychological principles that account for empirical findings that are counterintuitive and incompatible with normative analyses. People do not always have well-ordered preferences: instead, they approach decisions as problems that need to be solved, and construct preferences that are heavily influenced by the nature and the context of decision.

Decision Theory

See RATIONAL AGENCY; RATIONAL CHOICE THEORY; RATIONAL DECISION MAKING; UTILITY THEORY

Decision Trees

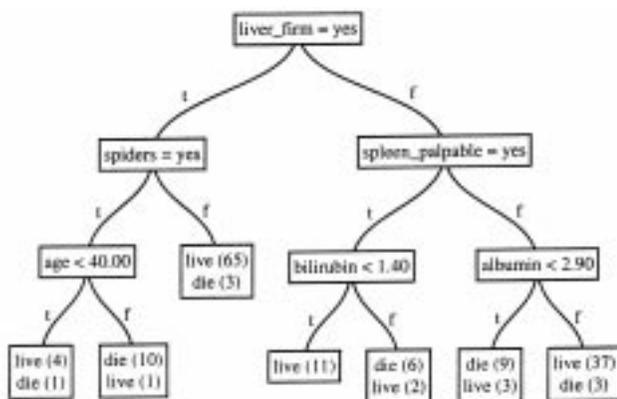
A *decision tree* is a graphical representation of a procedure for classifying or evaluating an item of interest. For example, given a patient's symptoms, a decision tree could be used to determine the patient's likely diagnosis, or outcome, or recommended treatment. Figure 1 shows a decision tree for forecasting whether a patient will die from hepatitis, based on data from the University of California at Irvine repository (Murphy and Aha 1994). A decision tree represents a function that maps each element of its domain to an element of its range, which is typically a class label or numerical value. At each leaf of a decision tree, one finds an element of the range. At each internal node of the tree, one finds a test that has a small number of possible outcomes. By branching according to the outcome of each test, one arrives at a leaf that contains the class label or numerical value that corresponds to the item in hand. In the figure, each leaf shows the number of examples of each class that fall to that leaf. These leaves are usually not of one class, so one typically chooses the most frequently occurring class label.


Figure 1.

A decision tree with a range of discrete (symbolic) class labels is called a *classification tree*, whereas a decision tree with a range of continuous (numeric) values is called a *regression tree.* A domain element is called an *instance* or an *example* or a *case*, or sometimes by another name appropriate to the context. An instance is represented as a conjunction of variable values. Each variable has its own domain of possible values, typically discrete or continuous. The space of all possible instances is defined by set of possible instances that one could generate using these variables and their possible values (the cross product).

Decision trees are attractive because they show clearly how to reach a decision, and because they are easy to construct automatically from labeled instances. Two well known programs for constructing decision trees are C4.5 (Quinlan 1993) and CART (Classification and Regression Tree) (Breiman et al. 1984). The tree shown in figure 1 was generated by the ITI (Incremental Tree Inducer) program (Utgoff, Berkman, and Clouse 1997). These programs usually make quick work of training data, constructing a tree in a matter of a few seconds to a few minutes. For those who prefer to see a list of rules, there is a simple conversion, which is available in the C4.5 program. For each leaf of the tree, place its label in the right-hand side of a rule. In the left-hand side, place the conjunction of all the conditions that would need to be true to reach that leaf from the root.

Decision trees are useful for automating decision processes that are part of an application program. For example, for the optical character recognition (OCR) task, one needs to map the optical representation of a symbol to a symbol name. The optical representation might be a grid of pixel values. The tree could attempt to map these pixel values to a symbol name. Alternatively, the designer of the system might include the computation of additional variables, also called *features*, that make the mapping process simpler. Decision trees are used in a large number of applications, and the number continues to grow as practitioners gain experience in using trees to model decision making processes. Present applications include various pixel classification tasks, language understanding tasks such as pronoun resolution, fault diagnosis, control decisions in search, and numerical function approximation.

A decision tree is typically constructed recursively in a top-down manner (Friedman 1977; Quinlan 1986). If a set of labeled instances is sufficiently pure, then the tree is a leaf, with the assigned label being that of the most frequently occurring class in that set. Otherwise, a test is constructed and placed into an internal node that constitutes the tree so far. The test defines a partition of the instances according to the outcome of the test as applied to each instance. A branch is created for each block of the partition, and for each block, a decision tree is constructed recursively.

One needs to define when a set of instances is to be considered sufficiently pure to constitute a leaf. One choice would be to require absolute purity, meaning that all the instances must be of the same class. Another choice would be to require that the class distribution be significantly lopsided, which is a less stringent form of the complete lopsidedness that one gets when the leaf is pure. This is also

known as *prepruning* because one restricts the growth of the tree before it occurs.

One also needs a method for constructing and selecting a test to place at an internal node. If the test is to be based on just one variable, called a *univariate test*, then one needs to be able to enumerate possible tests based on that variable. If the variable is discrete, then the possible outcomes could be the possible values of that variable. Alternatively, a test could ask whether the variable has a particular value, making just two possible outcomes, as is the case in figure 1. If the variable is continuous, then some form of discretization needs to be done, so that only a manageable number of outcomes is possible. One can accomplish this by searching for a *cutpoint*, and then forming a test whether the variable value is less than the cutpoint, as shown in figure 1.

If the test is to be based on more than one variable, called a *multivariate test*, then one needs to be able to search quickly for a suitable test. This is often done by mapping the discrete variables to continuous variables, and then finding a good linear combination of those variables. A univariate test is also known as an *axis-parallel split* because in a geometric view of the instance space, the partition formed by a univariate test is parallel to the axes of the other variables. A multivariate test is also known as an *oblique split* because it need not have any particular characteristic relationship to the axes (Murthy, Kasif, and Salzberg 1994).

One must choose the best test from among those that are allowed at an internal node. This is typically done in a *greedy* manner by ranking the tests according to a heuristic function, and picking the test that is ranked best. Many heuristic tests have been suggested, and this problem is still being studied. For classification trees, most are based on entropy minimization. By picking a test that maximizes the purity of the blocks, one will probably obtain a smaller tree than otherwise, and researchers and practitioners alike have a longstanding preference for smaller trees. Popular heuristic functions include *information gain, gain ratio, GINI,* and *Kolmogorov-Smirnoff distance.* For regression trees, most tests are based on variance minimization. A test that minimizes the variance within the resulting blocks will also tend to produce a smaller tree than one would obtain otherwise.

It is quite possible that a tree will overfit the data. The tree may have more structure than is helpful because it is attempting to produce several purer blocks where one less pure block would result in higher accuracy on unlabeled instances (instance not used in training). This can come about due to inaccurate variable measurements or inaccurate label or value assignments. A host of *postpruning* methods are available that reduce the size of the tree after it has been grown. A simple method is to set aside some of the training instances, called the *pruning set*, before building the tree. Then after the tree has been built, do a postorder traversal of the tree, reducing each subtree to a leaf if the proposed leaf would not be significantly less accurate on the pruning set than the subtree it would replace. This issue of balancing the desire for purity with the desire for accuracy is also called the *bias-variance trade-off.* A smaller tree has higher bias because the partition is coarser, but lower variance because the leaves are each based on more training instances.

During the mid-1990s, researchers developed methods for using ensembles of decision trees to improve accuracy (Dietterich and Bakiri 1995; Kong and Dietterich 1995; Breiman 1996). To the extent that different decision trees for the same task make independent errors, a vote of the set of decision trees can correct the errors of the individual trees.

Decompositional Strategies

See FUNCTIONAL DECOMPOSITION

Deductive Reasoning

Deductive reasoning is a branch of cognitive psychology investigating people's ability to recognize a special relation between statements. *Deductive LOGIC* is a branch of philosophy and mathematics investigating the same relation. We can call this relation *entailment*, and it holds between a set of statements (the *premises*) and a further statement (the *conclusion*) if the conclusion must be true whenever all the premises are true. Consider the premises "Calvin bites his nails while working" and "Calvin is working" and the conclusion "Calvin is biting his nails." Because the latter statement must be true whenever both the former statements are, these premises entail the conclusion. By contrast, the premises "Calvin bites his nails while working" and "Calvin is biting his nails" does not entail "Calvin is working," inasmuch as it is possible that Calvin bites his nails off the job.

Historically, logicians have constructed systems that describe entailments among statements in some domain of discourse. To compare these systems to human intuition, psychologists present to their subjects *arguments* (premise-conclusion combinations), some of which embody the target entailments. The psychologists ask the subjects to identify those arguments in which the conclusion "follows logically" from the premises (or in which the conclusion "must be true whenever the premises are true"). Alternatively, the psychologist can present just the premises and ask the subjects to produce a conclusion that logically follows from them. Whether a subject's answer is correct or incorrect is usually determined by comparing it to the dictates of the logic system.

One purpose of investigating people's ability to recognize entailments is to find out what light (if any) entailment sheds on thinking and to use these findings as a basis for revising theories of logic and theories of mind. Given this goal, certain differences between entailments and psychological decisions about them are uninformative. Subjects' inattention, memory limits, and time limits all restrict their success in distinguishing entailments from nonentailments, but factors such as these affect all human thinking and tell us nothing new about deductive reasoning.

Investigating the role of entailment in thought requires some degree of abstraction from everyday cognitive foibles. But it is not always easy to say how far such abstraction should go. According to GRICE (1989), Lewis (1979), and Sperber and Wilson (1986), among others, ordinary conversational settings impose restrictions on what people say, restrictions that can override entailments or supplement entailments (see PRAGMATICS). If Martha says, "Some of my in-laws are honest," we would probably understand her to imply that some of her in-laws are dishonest. This follows from a conversational principle that enjoins her to make the most informative statement available, all else being equal. If Martha believes that all her in-laws are honest, she should have said so; because she did not say so, we infer that she believes not all are honest. We draw this conversational IMPLICATURE even if we recognize that "Some of my in-laws are honest" does not entail "Some of my in-laws are dishonest."

Experimental results suggest that people do not abandon their conversational principles when they become subjects in reasoning experiments (e.g., Fillenbaum 1977; Sperber, Cara, and Girotto 1995). Moreover, conversational implicatures are just one among many types of nondeductive inferences that people routinely employ. In many situations it is satisfactory to reach conclusions that are plausible on the basis of current evidence, but where the conclusion is not necessarily true when the evidence is. It is reasonable to conclude from "Asteroid gamma-315 contains carbon compounds" that "Asteroid gamma-359 contains carbon compounds," even though the first statement might be true and the second false. Attempts to reduce these plausible inferences to entailments have not been successful (as Osherson, Smith, and Shafir 1986 have argued).

Subjects sometimes misidentify these plausible arguments as deductively correct, and psychologists have labeled this tendency a *content effect* (Evans 1989 contains a review of such effects). These content effects, of course, do not mean that people have no grasp of individual entailments (see, e.g., Braine, Reiser, and Rumain 1984; Johnson-Laird and Byrne 1991; and Rips 1994, for evidence concerning people's mastery of entailments that depend on *logical constants* such as "and," "if," "or," "not," "for all," and "for some"). Subjects may rely on plausible inferences when it becomes difficult for them to judge whether an entailment holds; they may rely on entailments only when the context pushes them to do so; or they may falsely believe that the experiment calls for plausible inferences rather than for entailments.

However, if there is a principled distinction between entailments and other inference relations and if people routinely fail to observe this distinction, then perhaps they have difficulties with the concept of entailment itself. Some psychologists and some philosophers believe that there is no reasoning process that is distinctive to entailments (e.g., Harman 1986). Some may believe that people (at least those without special logic or math training) have no proper concept of entailment that distinguishes it from other inference relations. The evidence is clouded here, however, by meth-

odological issues (see Cohen 1981). For example, psychologists rarely bother to give their subjects a full explanation of entailment, relying instead on phrases like "logically follows." Perhaps subjects interpret these instructions as equivalent to the vaguer sort of relation indicated in natural language by "therefore" or "thus."

The problem of whether people distinguish entailments is complicated on the logic side by the existence of multiple logic systems (see MODAL LOGIC). There is no one logic that captures all purported entailments, but many proposed systems that formalize different domains. Some systems are supersets of others, adding new logical constants to a core logic in order to describe entailments for concepts like time, belief and knowledge, or permission and obligation. Other systems are rival formulations of the same domain. Psychologists sometimes take subjects' rejection of a specific logic principle as evidence of failure in the subjects' reasoning; however, some such rejections may be the result of an incorrect choice of a logic standard. According to many philosophers (e.g., Goodman 1965), justification of a logic system depends in part on how close it comes to human intuition. If so, subjects' performance may sometimes be grounds for revision in logic.

The variety of logic systems also raises the issue of whether human intuitions about entailment are similarly varied. According to one view, the intuitions belong to a unified set that incorporates the many different types of entailment. Within this set, people may recognize entailments that are specialized for broad domains, such as time, obligation, and so on; but intuitions about each domain are internally consistent. Rival analyses of a specific constant (e.g., "it ought to be the case that . . .") compete for which gives the best account of reasoning. According to a second view, however, there are many different intuitions about entailment, even within a single domain. Rival analyses for "it ought to be the case that. . ." may then correspond to different (psychologically real) concepts of obligation, each with its associated inferences (cf. Lemmon 1959).

The first view lends itself to a theory in which people automatically translate natural language arguments into a single LOGICAL FORM on which inference procedures operate. The second view suggests a more complicated process: when subjects decide whether a natural language argument is deductively correct, they may perform a kind of model-fitting, determining if any of their mental inference packages makes the argument come out right (as Miriam Bassok has suggested, personal communication, 1996). Both views have their advantages, and both deserve a closer look.

Depth Perception

Depth perception is one of the oldest problems of philosophy and experimental psychology. It has always intrigued people because of the two-dimensionality of the retinal image, although this is not really relevant because, as Descartes (1637) realized, we do not perceive the retinal image. DESCARTES was one of the first to suggest that depth could be computed from changes in the accommodation and convergence of the eyes. Accommodation is the focusing of the lenses and convergence is the inward/outward turning of the eyes stimulated by a change in the distance of the object of regard. Unfortunately, convergence and accommodation vary little beyond a meter or two and we clearly have a sense of depth well beyond that. Cutting and Vishton (1995) note that different cues to depth seem to be operative for near (personal) space, ambient (action) space, and vista (far) space. Convergence and accommodation clearly apply best to the space approximately within arm's reach, but even in that region their effectiveness in giving an impression of absolute distance varies among persons and is imprecise.

Interposition, or the hiding of one object by another, creates an ordinal sense of depth at all distances. But how is interposition specified in visual stimulation? Interposition or occlusion can be indicated monocularly by such contour arrangements as T junctions and alignments (Kanisza 1979) or binocularly by the fact that parts of background objects or regions are hidden from one eye and not the other (Leonardo da Vinci 1505). Current evidence suggests that unlike monocular occlusion cues, binocular occlusion cues can elicit a sense of metric depth (Gillam, Blackburn, and Nakayama 1999).

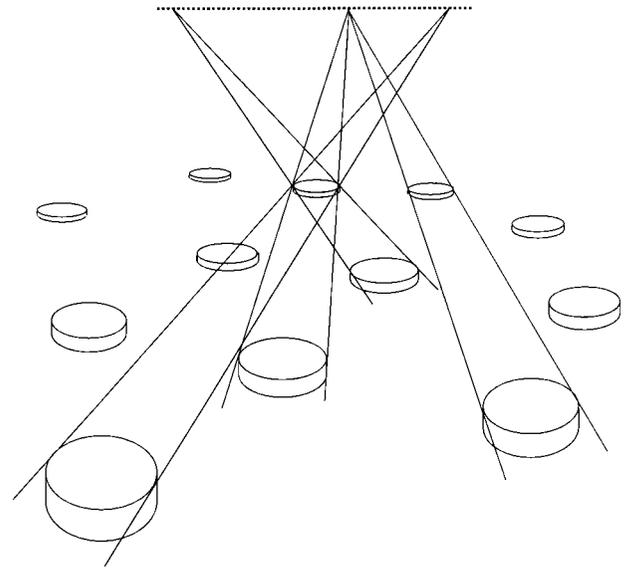
It is generally found that people are quite accurate in judging ambient distance (up to approximately twenty feet). This is typically demonstrated by having them survey the scene, close their eyes, and walk to a predesignated object (Loomis et al. 1992). Perhaps the most important source of distance information in ambient and far space is spatial layout information of the kind first analyzed by James Jerome GIBSON (1950, 1966), although much of the underlying perspective geometry was known by artists of the Renaissance (Alberti 1435). Gibson pointed out that objects are nearly always located on a ground plane and that if the ground is homogeneously textured, it provides a scale in the "optic array" (the projection of the layout to a station point) which can be used to compare distances between elements in any direction at any distance. If the size of the units of texture are known, for example by their relationship to the observer, the scale may also specify absolute distance. In practice it has been found that random dot textures give a much poorer sense of depth than regular textures, especially regular textures that include lines converging toward a vanishing point. Vanishing points and horizons provide depth information in their own right. (A horizon is the locus of the vanishing


Figure 1.

points of all sets of parallel lines on a planar surface.) For example, the angular extent in the optic array of a location on a surface and the horizon of that surface specifies the absolute distance of that location to a scale factor given by the observer's eye height. Furthermore, the angular distances from two locations on a surface to the horizon can give the relative distances of those locations independently of eye height (Sedgwick 1986). The horizon can be implicitly specified by converging lines even if they do not extend to a vanishing point and also by randomly arranged elements of finite uniform size (see figure 1).

It is generally agreed that the familiar size of isolated objects is not used to derive distance from their angular size although this is possible in principle. However, relative size, especially for objects of a similar shape, is an excellent cue to relative distance. Likewise, an object changing size is normally seen as looming or receding in depth.

Parallax, defined as the difference in the projection of a static scene as viewpoint changes relative to the scene, is a potent source of information about depth. Motion parallax refers to successive viewpoint changes produced by motion of the observer, whereas binocular parallax refers to the simultaneous differences in viewpoint provided by two horizontally separated eyes. The disparate images thus produced result in "stereoscopic vision." Wheatstone (1838), who discovered stereoscopic vision, showed that the projections of a scene to the two eyes differ in a number of ways (see figure 2), and there is some evidence that the visual system responds directly to certain higher order image differences such as contour orientation. Binocular disparity is usually specified, however, as the difference in the horizontal angles subtended at the two eyes by two points separated in depth.

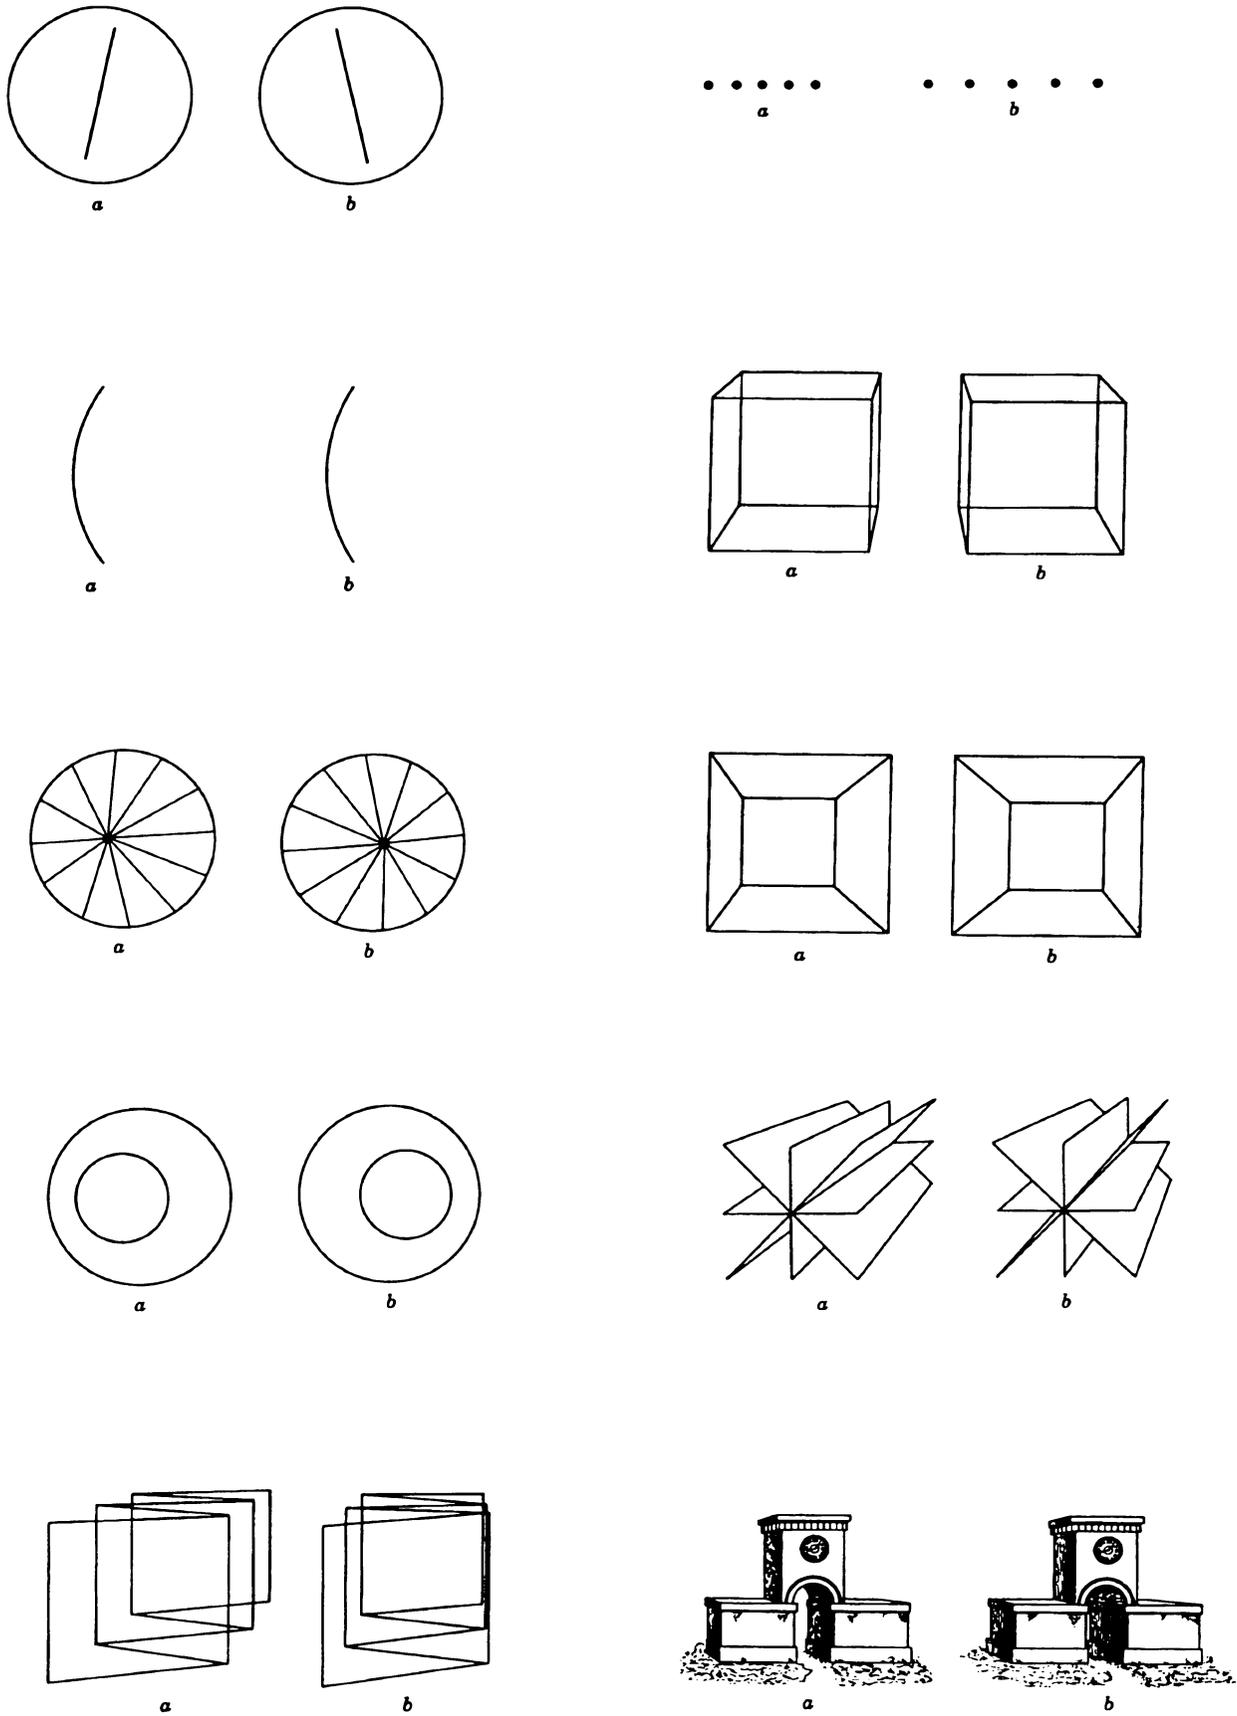
Stereoscopic vision really comes into its own in near vision where it is important in eye-hand coordination, and in ambient vision where it allows discrete elements that do not provide perspective cues, such as the leaves and branches of a forest, to be seen in vivid relief. The disparity produced by a given depth interval declines rapidly as the distance of the


Figure 2.

interval from the observer increases. Nevertheless it is possible with moderate stereoscopic acuity to detect that an object at about five hundred meters is nearer than infinity. Because the binocular disparity produced by a given depth interval declines with its distance, the depth response to disparity must be scaled for distance to reflect depth accurately. Scaling has largely been studied at close distances where it is excellent under full cue conditions although it is not yet clear how the scaling is achieved (Howard and Rogers 1995). The accuracy of scaling in vista space is not known. Stereoscopic depth is best for objects that are laterally close to each other (Gogel 1963). At such separations stereoscopic depth is a "hyperacuity" because disparities of only 10–30 sec of arc can be responded to as a depth separation (Westheimer 1979).

Despite the fact that binocular and motion parallax have identical geometry, stereopsis is the superior sense for depth perception under most conditions, especially when there are only two objects separated in depth. Motion parallax is almost as good as stereopsis, however, in eliciting perception of depth in densely patterned corrugated surfaces (Rogers and Graham 1979). A strong sense of solidity is also obtained monocularly when a skeletal object, such as a tangled wire, is rotated in depth and viewed with a stationary eye (kinetic depth effect). The depth variations in densely textured surfaces can also be perceived on the basis of the monocular transformations they undergo during motion.

Many of the possible sources of information about depth have not yet been adequately investigated, especially the sources used in ambient and vista space. There are also unresolved theoretical issues such as the relationship between the apparent distances of objects to the observer and their apparent distances from each other.

Descartes, René

A dominant figure of mid-seventeenth century philosophy and science, René Descartes (1596–1650) developed a sweepingly anti-Aristotelian, mechanist theory of nature, while also advocating a conception of the "rational soul" as a distinct, immaterial entity, endowed by God with certain innate intellectual concepts. Generations of anglophone philosophers have tended (with some notable exceptions) to construe Descartes's importance as deriving mainly from his radical development of problems of scepticism, and his sharp dualistic distinction between mind and body, in his central philosophical work, the *Meditations on First Philosophy* (1641). Today, however, this conception is often criticized as historically naive. On one hand, the *Meditations* themselves were intended by Descartes to provide a "foundation" for his comprehensive mechanistic account of natural phenomena; the doctrines and arguments of the work need to be interpreted in this light. On the other hand, Descartes's vision of a comprehensive, unified theory of nature, grounded in a small number of "distinctly conceivable," quantitatively expressible concepts (especially size, figure and motion) was in itself of incalculable significance in the history of Western thought (cf. UNITY OF SCIENCE).

Prominent among Descartes's aims as a systematic scientist was the incorporation of biological phenomena (such as nutrition and growth), and many psychological phenomena as well (such as reflex behaviors and some kinds of learning), in the universal mechanistic physics that he envisaged. Works in which he develops mechanist approaches to physiology and psychology include the early *Treatise on Man* (published only after his death); the *Dioptrics* (published, together with the *Geometry and Meteors*, with the wide-ranging, partly autobiographical work, *Discourse on the Method of Rightly Conducting One's Reason and Seeking Truth in the Sciences,* 1637); parts of the compendious *Principles of Philosophy* (1644); and the late *Passions of the Soul* (1649).

Basic to Descartes's approach to the understanding of animal (including human) behavior is the notion that one should push mechanistic-materialist explanations as far as one can. From early in his career he proclaimed that all the

behavior of nonhuman animals ("brutes") can be explained in mechanistic terms. In the *Discourse on the Method* (Part V) he defended this position by arguing that the behavior of brutes uniformly fails two tests that he considers to be crucial to establishing the presence of some principle other than the strictly mechanistic. The first is the ability to respond adaptively to a variety of challenging circumstances in appropriate ways. A bird, for instance, might seem to show more "skills" in building a nest that we can summon; but so does a clock show more "skill" than we command in measuring time. Yet neither the bird nor the clock is able to respond to novel circumstances in the inventive way characteristic of humans. Descartes's other, more famous, test for the presence of a nonmechanistic principle is the ability to use language: to "express our thoughts to others," no matter what may be said in our presence. He acknowledges that brutes can utter cries and grunts that have some kind of communicative effect, but he stresses that these fall short, drastically, of the range and versatility of human language. In the case of human beings, however, behavioral adaptability and "true language" demonstrate the presence of a nonmechanistic principle, a conscious rational soul.

Descartes's *Discourse* conception of nonhuman animals as "automata, or self-moving machines" is today sometimes characterized as "mechanomorphism." Widely rejected and even ridiculed in his lifetime, it remains a target, or stalking horse, for contemporary advocates of animal intelligence, consciousness, and (in some species) perhaps language (cf. COGNITIVE ETHOLOGY, PRIMATE LANGUAGE).

In the *Meditations* (as anticipated by Part IV of the *Discourse*) Descartes approaches issues of reason and consciousness from a first-person rather than a behavioral perspective. He argues, first, that all his apparent perceptions of a physical world are initially subject to doubt (in that they could in principle occur even if no physical world existed). In fact, he is able to find reason to doubt even the simplest and most evident propositions. But second, even in the face of such skepticism his own existence as a "thinking thing" at least is indubitable. Later he argues that he is the creature of a perfect God; hence his clearest and most distinct "perceptions" (mainly the deliverances of pure intellect) are beyond doubt. Finally he concludes that as a thinking thing, he is a substance distinct from any body, though (as he goes on to say) one at present closely joined with a body, with which he, as a mind, interacts (cf. SELF and MIND-BODY PROBLEM). He further maintains that, given the goodness of God, his normal conviction that his seeming perceptions of bodies are in fact caused by external physical things must be correct.

Along the way, however, Descartes repeatedly underscores the point that bodies are not in fact as they appear in ordinary sense experience. For instance, their appearances as colored are misleading, in that we tend to suppose that (say) green as we sensibly experience it is a real quality of some bodies; whereas in fact it is just a sensation in our minds, resulting from the effect of external things (constituted of bits of matter in motion) on our nervous systems, and of the latter on us as immaterial mental substances.

In the *Meditations* Descartes characterizes both sensations and our intellectual apprehensions (such as our representation of God) as *ideas*. The Cartesian theory of ideas had great impact on subsequent philosophy. It involves complex notions about representation and misrepresentation that continue to attract the interest of philosophers and scholars today (cf. MENTAL REPRESENTATION).

There is substantial—probably conclusive—evidence in Descartes's post-*Meditations* writings that he intended to limit strictly mental phenomena to those states that are accessible to an individual's conscious awareness. But this austere aspect of his mind-body dualism sits uneasily with some features of his impressive accounts of human visual perception in the first half of the *Dioptrics*; and of human emotions in the *Passions of the Soul*. In both works he not only blends sensational with intellectual states in his explanations of mental phenomena, but also invokes considerations that are hard to apportion between the "conscious-mental" and "purely mechanistic-material" divide. This is particularly true of his account of distance perception in the *Dioptrics*, in which Descartes certainly seems to invoke a kind of COMPUTATION that cannot plausibly be regarded as accessible to consciousness (cf. COMPUTATIONAL VISION).

Discourse

Discourse is the ground of our experience of language and of linguistic meaning. It is in discourse that we learn language as children, and in discourse that we most adequately convey our thought. The individual utterances in a discourse are notoriously vague and full of potential AMBIGUITY. Yet in the context of the discourse in which they occur, vagueness and ambiguity are rarely a problem. That is, the overall discourse profoundly influences the interpretation of individual linguistic constituents within it, as witnessed by our discomfort with the ethics of taking what someone says out of context.

Discourse can be characterized in three principal ways. We may think of discourse as a type of event, in which human agents engage in a *verbal exchange*; in the limit case, the monologue, there is only one agent, but even then there is an intended audience, if only reflexive or imaginary. We may also think of discourse as the *linguistic content* of that exchange, an ordered string of words with their associated syntactic and prosodic structures. Or we may characterize discourse as the more complex *structure of information* that is presupposed and/or conveyed by the interlocutors during the course of the discourse event in view of the explicit linguistic content of the exchange. The information structure of a discourse may be characterized as an ordered set containing several distinguished kinds of information, for example: a set of discourse participants (the *interlocutors*); the linguistic content of the discourse, with each utterance indexed by the speaker; the information presupposed or proffered by speakers during the discourse via the linguistic content of their utterances; an association of the proffered information with various topics or questions under discussion, the topics and subtopics hierarchically organized by virtue of their relations to the (often only inferred) goals and intentions of the various speakers (the *intentional structure* of the discourse); a set of entities discussed (the *domain* of discourse); a changing set of the entities and topics which the interlocutors focus on during their discussion, organized as a function of time (the *attentional structure* of discourse); and other kinds of information and structures on information, as well (Lewis 1979; Grosz and Sidner

1986; Roberts 1996). The information structure of a discourse is far richer than its linguistic content alone. Only the full range of contextual information for a given discourse, including a grasp of the interlocutors' inferred intentions, the intended rhetorical relations among their utterances, and other nonlinguistically given information that they share, can resolve all the potential ambiguities in the linguistic strings uttered, clarify the often inexplicit connections between utterances, and lead us to grasp what the speaker(s) intend to convey.

These three ways of characterizing discourse—as an event revolving around verbal exchange, as the linguistic content of that exchange, and as the structure on the information involved—are not mutually exclusive; there is no verbal exchange without linguistic content, and the latter can be taken as one aspect of the abstract information structure of the exchange. However, most of the work on discourse in artificial intelligence, linguistics, philosophy of language, PSYCHOLINGUISTICS, sociology, and anthropology can be classified according to which of the three aspects it focuses on. For example, sociologists, sociolinguists, and ethnographers interested in *conversational analysi*s (Sacks, Schegloff, and Jefferson 1978) focus on the discourse event itself and its social character, including the way that interlocutors organize their participation in such events in an orderly, apparently conventional manner, varying somewhat from culture to culture. Speakers take turns, the opportunity for taking a turn being cued by a number of conventional means (including set phrases, intonation, and pauses), and negotiate the beginning and end of a discourse as well as the shift from topic to topic within it. In sociologically informed anthropological linguistics (Duranti 1997), discourse events are taken to play a crucial role in the creation, reproduction, and legitimation of a community's social alliances and cleavages. Those working in the tradition of *discourse analysis* (see van Dijk 1985; Carlson 1983) focus instead on the linguistic content of the verbal exchange, the text, some arguing that it is generated by the syntactic rules of a text grammar. But probably the majority of theorists who work on discourse today would agree that discourse is not a linguistic structure generated by a grammar, but instead is structured by nonlinguistic, logical, and intentional factors—aspects of what we have called the information structure of discourse.

A number of *prima facie* unrelated pragmatic phenomena depend on the information structure of discourse, suggesting that this aspect of discourse can provide the basis for a unified theory of the role of pragmatic factors in linguistic interpretation. Dynamic theories of semantic interpretation take the meaning of an utterance to be a function from contexts (the context of utterance) to contexts (the context of utterance updated with the information proffered in the utterance). One can view the three basic types of *speech acts*—assertions, questions, and orders—as functions that update the information structure of a discourse in different ways. Assertions update the information proffered in the discourse (see DYNAMIC SEMANTICS; Stalnaker 1979); a question sets up a new (sub)topic for discussion, hence affecting the intentional structure of the discourse (Ginzburg 1996; Roberts 1996); an order, if accepted, commits the person ordered to

behave in accordance with the order, and this commitment is part of the information indirectly conveyed by the discourse. Many secondary subtypes of these three basic types of speech acts have been proposed in the literature, including, for example, predictions, confirmations, concessives, and promises; rhetorical questions as well as probes for information; requests, permissions, advisories, and commands; and so forth (see Searle 1969). Work in artificial intelligence on plan inference (see Cohen, Morgan, and Pollack 1990) has argued that the secondary speech act type of an utterance can be derived from its basic speech act type and proffered content, its inferred role in the intentional structure of the discourse, and the inferred *domain goals* of the interlocutor at the time of utterance (i.e., her general goals at that time, not necessarily just those expressed in discourse).

In his important work on meaning in conversation, H. Paul GRICE argued that much of the MEANING conveyed in discourse is not directly proffered via the linguistic content of the utterances in the discourse, but instead follows from what is said in view of the intentions of the interlocutors and a set of guidelines, the conversational maxims, which characterize the rational behavior of agents in a communicative situation (see IMPLICATURE and RELEVANCE). Although the crucial role of interlocutors' intentions is sometimes overlooked in older work on implicature, contemporary work (e.g., McCafferty 1987; Welker 1994) pays considerable attention to the role of that facet of the information structure of discourse that we have called its intentional structure in explaining how implicatures are generated. Similarly, work on ANAPHORA in discourse, especially from a computational point of view (e.g., Grosz and Sidner 1986), emphasizes the role both of intentional structure and of attentional structure in constraining the set of possible antecedents for a given pronoun or other anaphoric element across discourse; see also the related work on *centering* (Walker, Joshi, and Prince 1998). And the intentional structure of discourse may be seen to reflect strategies of inquiry which correspond to classical *rhetorical structures* (Mann and Thompson 1987), connecting work on the role of such structures in interpretation to the general notion of information structure.

Finally, the information structure of discourse is reflected in a number of ways in the structure of linguistic constituents—sentences and sentence fragments. These reflections involve the phenomena variously referred to as *topic* and *comment*, *theme* and *rheme*, *link*, and *focus*, among others. Some have argued that (some subset of) these notions play a role as primitive notions in syntactic structure (e.g., Sgall, Hajicova, and Panevová 1986; Vallduví 1992), while others have argued that they are, instead, only functional characterizations of the accidental role of syntactic constituents in particular discourse contexts. However, it is clear that particular sentential constructions (e.g., topicalization in English) and prosodic features (e.g., prosodic prominence) may be specially associated with these functions via associated conventional presuppositions about the information structure of the discourse in which they occur. Such linguistic structures, along with anaphora and ellipsis, are designed to increase discourse coherence and to help interlocutors keep track of the common ground and other features of the information structure of discourse.

Dissonance

Festinger's (1957) theory of cognitive dissonance is, by far, the most prominent of several social-psychological theories based on the premise that people are motivated to seek consistency among their beliefs, attitudes, and actions (Abelson et al. 1968). It asserts that people find inconsistency, or "dissonance," among their cognitions to be emotionally aversive and seek to eliminate or reduce any inconsistency.

According to Festinger, cognitive dissonance is a tension state that arises whenever an individual simultaneously holds two or more cognitions that are mutually inconsistent with one another. In this model, any two cognitions, considered by themselves, stand in one of three relations to one another—dissonant (contradictory or inconsistent), consonant (consistent), or irrelevant. The total amount of dissonance for a given person in any particular situation is defined as the ratio of dissonant relations to total relevant relations, with each relation weighted for its importance to that person:

Total Dissonance = (Dissonant Relations) / (Dissonant + Constant Relations)

When cognitive dissonance arises, the individual is motivated to reduce the amount of dissonance. This can be done in many ways—by decreasing the number and/or the importance of dissonant relations, or by increasing the number and/or the importance of consonant relations. Precisely how dissonance is reduced in any particular situation depends on the resistance to change of the various cognitions involved. The resistance-to-change of any cognition in a particular context depends, in turn, on the extent to which a change would produce new dissonant relations, the degree to which the cognition is firmly anchored in reality, and the difficulty of changing those aspects of reality.

Consider a prototypic case: a cigarette smoker, circa 1960, encountering the first medical reports linking smoking to lung cancer, emphysema, and heart disease. His two cognitions, "I smoke," and, "Smoking causes serious diseases," are dissonant because both cognitions are of substantial importance to him and are inconsistent. To reduce this dissonance, he could quit smoking or, if this proved too difficult, could cut back on cigarettes or switch to a brand with lower tar and nicotine. Similarly, he could question the significance of "merely statistical" evidence regarding smoking and disease processes, downplay the relevance or importance of such evidence to his personal situation, avoid subsequent medical reports on the topic, and/or exaggerate the pleasures and positive consequences of smoking (e.g., how it helps him relax or control his weight).

Festinger (1957) used dissonance theory to account for a wide array of psychological phenomena, ranging from the transmission of rumors following disasters to the rationalization of everyday decisions, the consequences of counterattitudinal advocacy, selectivity in information search and interpretation, and responses to the disconfirmation of central beliefs. Of the many new research directions produced by the theory, three paradigms proved most influential.

The first major paradigm involved the attitudinal consequences of making a decision (Brehm 1956). Any choice among mutually exclusive options is postulated to produce dissonance, because any nonoverlapping bad features of the chosen alternative(s) or good features of the rejected alternative(s) are dissonant with the choice itself. To reduce this postdecisional dissonance, the individual is likely to exaggerate the advantages of the option(s) selected and to disparage the advantages of the option(s) rejected. Through this postdecisional reevaluation and "spreading apart" of the alternatives, individuals come to rationalize their decisions. Such effects appear most strongly when the decision is both difficult and irrevocable, and have proved to be highly replicable across a variety of decision contexts (Festinger 1964; Wicklund and Brehm 1976).

A second popular paradigm concerned the selectivity of information-seeking following a decision (Ehrlich et al. 1957). If the decision is difficult to undo (and not all of the attendant dissonance has already been reduced through reevaluation of the alternatives), the individual is motivated both to avoid subsequent information that seems likely to be dissonant with that decision and to seek out subsequent information that seems likely to support that decision. Empirical evidence concerning this aspect of the theory, however, has been much more mixed; and the precise conditions under which such selective exposure effects occur remain unclear (Freedman and Sears 1965; Frey 1986).

Finally, the third, and most influential paradigm examined the effects of "forced compliance," in which an individual is induced to engage in some counterattitudinal action with minimal, "psychologically insufficient," external coercion or incentive (e.g., Aronson and Carlsmith 1963; Festinger and Carlsmith 1959). In this case, dissonance derives from a conflict between the person's action and attitudes. To the extent that an overt action is harder to change than a personal opinion, attitudes are changed to conform more closely to behavior. The less the external pressure used to induce the behavior, the more such subsequent justification of one's actions occurs, because any external pressures provide added consonant relations. Such "insufficient justification" effects have been observed, under free-choice conditions, in a wide variety of situations, particularly when the person's counterattitudinal behavior has aversive consequences for which he/she feels personally responsible (Cooper and Fazio 1984; Harmon-Jones and Mills forthcoming; Lepper 1983).

More recent research on cognitive dissonance has emphasized three additional issues. Some authors have focused on the role of physiological arousal (e.g., Cooper and Fazio 1984) and psychological discomfort (e.g., Elliot and Devine 1994) in the production and reduction of cognitive dissonance, showing the importance of the motivational factors that distinguish dissonance theory from self-perception the-

ory (Bem 1967, 1972) and other nonmotivational alternative explanations. Others have emphasized the importance of the self-concept in cognitive dissonance, arguing that dissonance effects may depend on threats to one's self-concept and may be alleviated by procedures that affirm the SELF (e.g., Steele 1988; Thibodeau and Aronson 1992).

Most recently, computational models of dissonance reduction have sought to quantify dissonance more precisely and have simulated many of the subtleties of psychological findings (e.g., Read and Miller 1994; Shultz and Lepper 1996). These models use artificial NEURAL NETWORKS that treat dissonance reduction as a gradual process of satisfying constraints imposed on the relationships among beliefs by a motive for cognitive consistency. Their success suggests that dissonance, rather than being exotic and unique, may have much in common with other psychological phenomena (e.g., memory retrieval or analogical reasoning) that can also be understood in constraint-satisfaction terms.

The general success of dissonance theory—and the particular power of the "reevaluation of alternatives" and "insufficient justification" paradigms—seems to derive, in large part, from the breadth of the theory and from the ways that apparently "rational" consistency-seeking can, under certain conditions, produce unexpectedly "irrational" changes in actions and attitudes.

Distinctive Features

Every speech sound shares some articulatory and acoustic properties with other speech sounds. For example, the consonant [*n*] shares nasality with [*m*], complete oral closure with the set [*pbmtdkg*], and an elevated tongue-tip with the set [*tdsz*].

Most contemporary theories of PHONOLOGY posit a universal set of distinctive features to encode these shared properties in the representation of the speech sounds themselves. The hypothesis is that speech sounds are represented mentally by their values for binary distinctive features, and that a single set of about twenty such features suffices for all spoken languages. Thus, the distinctive features, rather than the sounds built from them, are the primitives of phonological description. The sound we write as [*n*] is actually a bundle of distinctive feature values, such as [+nasal], [–continuant] (complete oral closure), and [+coronal] (elevated tongue-tip).

Three principal arguments can be presented in support of this hypothesis:

1. The union of the sound systems of all spoken languages is a smaller set than the physical capabilities of the human vocal and auditory systems would lead one to

expect. The notion "possible speech sound" is defined by higher-level cognitive requirements (the distinctive features) and not lower-level physiological considerations.

2. Distinctive features help to explain the structure of sound systems. For example, many languages have no sounds from the set [*bdg*], but if a language has one of them, it is likely to have all of them. These sounds are all [+voice] (referring to the presence of vocal fold vibration); having the full [*bdg*] set together in a language maximizes the cross-classificatory effect of that distinctive feature.

3. PHONOLOGICAL RULES AND PROCESSES depend on the classes of sounds defined by distinctive feature values, and so the notion "possible phonological process" is, in part, determined by the universal feature theory. The English plural suffix is a typical example. This suffix agrees in the value of [voice] with the sound at the end of the noun: [–voice] in *caps*, *chiefs*, *cats*, *tacks* versus [+voice] in *labs*, *shelves*, *pads*, *bags*. This suffix is pronounced with a vowel if the noun ends in a [+strident] consonant, characterized by turbulent airflow and consequent [s]-like hissing noise: *passes*, *roses*, *lashes*, *garages*. Classes like these—[+voice], [–voice], and [+strident]—are frequently encountered in the phonological processes of the world's languages. In contrast, logically possible but featurally arbitrary classes like [*pbsk*] are rarely or never needed to describe phonological processes.

These considerations not only support the claim that there must be *some* set of universal distinctive features; in their particulars, they also serve as the principal basis for determining what is the *correct* set of distinctive features. Primarily, arguments in support of a feature theory turn on how well it explains the observed structure of sound systems and of well-attested phonological processes. Secondarily, the correct feature theory should support a plausible interface between phonology on one hand and the PHONETICS of ARTICULATION and SPEECH PERCEPTION on the other. This prioritization of phonological evidence over phonetic is appropriate because a theory of distinctive features is, above all, a claim about the mind and not about the mouth or the ear.

The idea that speech sounds can be classified in phonologically relevant ways goes back to antiquity, but the concept of a universal classification is a product of the twentieth century. It emerges from the work of the prewar Prague School theorists, principally N. S. Trubetzkoy and Roman JAKOBSON, who sought to explain the nature of possible phonological contrasts in sound systems. The first fully elaborated theory of distinctive features appeared with the publication in 1952 of Jakobson, Fant, and Halle's *Preliminaries to Speech Analysis*. The *Preliminaries* features are defined in acoustic terms; that is, they are descriptions of the spectral properties of speech sounds. This model was largely superseded in 1968 by the distinctive feature system of Chomsky and Halle's *The Sound Pattern of English* (*SPE*). Nearly all of the *SPE* features are defined in articulatory terms; that is, they are descriptions of vocal tract configurations during the production of speech sounds. Despite these differences of definition, the empirical consequences of the *SPE* model do not differ dramatically from the *Preliminaries* model.

There has been no single broad synthesis of feature theory since *SPE*, but there have been many significant developments in specific areas. The most important is the emergence of autosegmental or nonlinear phonology, with its fundamental thesis that distinctive features are, like TONES, independent objects not necessarily tied to any particular speech sound. In the South American language Terena, the feature [+nasal] is, by itself, the first person prefix; for example, [*owoku*] "house" becomes "my house" by attaching [+nasal] to the initial [*owo*] sequence. This freeing of distinctive features from individual speech sounds has yielded new insights into the nature of the most common phonological process, assimilation (where one sound takes on features from a nearby sound).

A further evolution of the autosegmental view is the theory of feature geometry, which asserts that the distinctive features are hierarchically organized into functionally related classes. The features that characterize states of the larynx, for instance, appear to have a considerable degree of functional cohesion in phonological systems. This leads to the positing of a kind of metafeature [Laryngeal], which has within its scope [voice] and other features.

Along other lines, an improved understanding of feature theory has been achieved through the study of particular types of features (such as those pertaining to the larynx or to degree of oral constriction) and of particular groups of speech sounds (such as the various [*l*]- and [*r*]-like sounds of the world's languages). Much has also been achieved by considering alternatives to binary features, in the direction of both single-valued features (marked only by their presence) and ternary or higher-order features (which are particularly useful for characterizing some natural scales, like degree of oral constriction or tongue height).

Finally, research on SIGN LANGUAGES has showed that they too have representations composed of distinctive features. Thus, while the distinctive features of spoken languages are modality-specific, the existence of a featural level of representation apparently is not.

Distributed AI

See DISTRIBUTED VS. LOCAL REPRESENTATION; MULTI-AGENT SYSTEMS

Distributed vs. Local Representation

A central problem for cognitive science is to understand how agents represent the information that enables them to behave in sophisticated ways. One long-standing concern is whether representation is localized or distributed (roughly, "spread out"). Two centuries ago Franz Josef Gall claimed that particular kinds of knowledge are stored in specific, discrete brain regions, whereas Pierre Flourens argued that all knowledge is spread across the entire cortex (Flourens 1824; Gall and Spurzheim 1809/1967). This debate has continued in various guises through to the present day (e.g.,

Farah 1994). Meanwhile, the concept of distribution has found mathematical elaboration in fields such as optics and psychology, and the rise of connectionist models has generated interest in a range of related technical and philosophical issues.

In the most basic sense, a distributed representation is one that is somehow "spread out" over some more-than-minimal extent of the resources available for representing. Unfortunately, however, this area is a semantic mess; the terms *local* and *distributed* are used in many different ways, often vaguely or ambiguously. Figure 1 sketches the most common meanings.

Suppose that we have some quantity of resources available for representing items, and that these resources are naturally divisible into minimal chunks or aspects. Connectionist neural processing units are obvious examples, but the discussion here is pitched at a very abstract level, and the term "unit" in what follows might just as well refer to bits in a digital computer memory, single index cards, synaptic interconnections, etc.

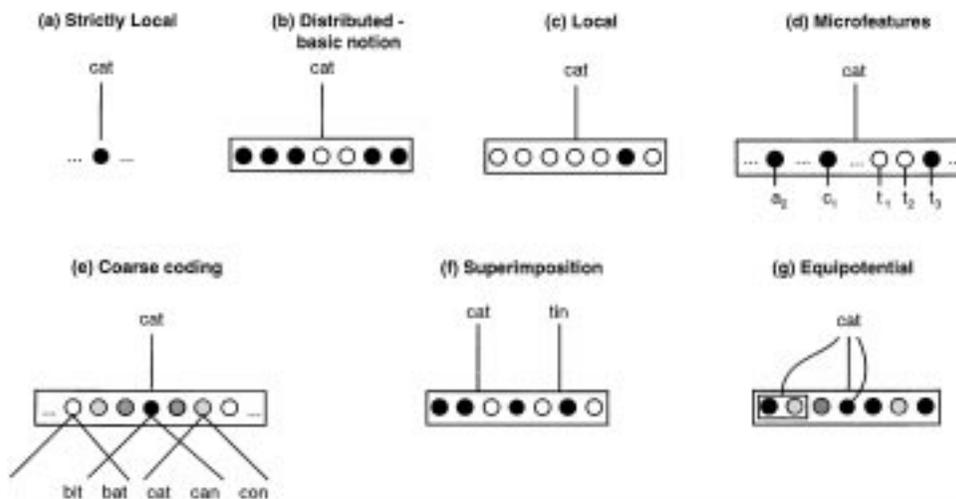
- *Strictly Local* The item (in this case, the word "cat") is represented by appropriately configuring a single dedicated unit. The state of the other units is irrelevant.
- *Distributed—basic notion* The word is represented by a distinctive configuration pattern over some subset or "pool" of the available resources (see Hinton, McClelland, and Rumelhart 1986). A different word would be represented by an alternative pattern over that pool or another pool. Each unit in the pool participates in representing the word; the state of units outside the pool are irrelevant. In a *sparse* (*dense*) distributed representation, a small (large) proportion of units in the pool are configured in a non-default or "active" state (Kanerva 1988).
- *Local* The limiting case of a sparse distributed representation is one in which only a single unit in the pool is active. These representations are often also referred to as "local" (e.g., Thorpe 1995). The key difference with strictly local representations is that here it matters what state the other units in the pool are in, viz., they must not be active.


Figure 1. Seven ways to represent the word "cat," illustrating varieties of local and distributed representation.

- *Microfeatures* Sometimes individual units are used to represent "microfeatures" of the domain in strictly local fashion. The pattern representing a given macro-level item is then determined by these microfeatural correspondences. In the example in Figure 1, individual units represent the presence of a letter at a certain spot in the word; the word "cat" is represented just in case the active units are the ones for *c* in the first spot, *a* in the second spot, and *t* in the third spot.
- *Coarse Coding* In these schemes the (micro or macro) features of the domain represented by individual units are relatively broad, and overlapping.

The reader seeking a detailed illustration of these ideas may care to examine the well-known "verb-ending" paper of Rumelhart and McClelland (1986). In that case, verb-base and past-tense forms are represented by sparse distributed patterns over pools of units. Individual units represent microfeatures (ordered triples of phonetic features) in strictly local fashion. Because these triples overlap, the scheme is also coarse.

- *Superimposition* Two or more items are simultaneously represented by one and the same distributed pattern (Murdock 1979). For example, it is standard in feedforward connectionist networks for one and the same set of synaptic weights to represent many associations between input and output.
- *Equipotentiality* In some cases, an item is represented by a pattern over a pool of units, and the pattern over any subpool (up to some resolution limit) also suffices to represent the item. Thus every part or aspect of the item is represented in superimposed fashion over the whole pool. The standard example is the optical hologram (Leith and Uptanieks 1965); see also Plate's "holographic reduced" representations (Plate 1993).

With these various distinctions on board, we can return to the central question: is human knowledge represented in distributed form? This question has been approached at a number of levels, ranging from detailed neurophysiology to pure philosophy of mind. Thus, neuroscientists have debated whether the patterns of neural firing responsible for representing some external event are a matter of single cells (Barlow 1972) or patterns of activity distributed over many cells; if the latter, whether the patterns are sparse, dense, or coarse-coded (e.g., Földiák and Young 1995). At a higher level, they have debated whether knowledge is distributed over large areas of the brain, perhaps in equipotential fashion (LASHLEY 1929/1963), or whether at least some kinds of knowledge are restricted to tightly circumscribed regions (Fodor 1983).

These issues have also been pursued in the context of computer-based cognitive modeling. Connectionists have paid considerable attention to the relative merits of distributed versus local encoding in their networks. Advantages of distribution are generally held to include greater representational capacity, content addressability, automatic generalization, fault tolerance, and biological plausibility. Disadvantages include slow learning, catastrophic interference (French 1992), and binding problems.

In a famous critique of connectionist cognitive science, Fodor and Pylyshyn (1988) argued that connectionists must either implement "classical" architectures with their traditional symbolic representations or fail to explain the alleged "systematicity" of cognition. The standard connectionist response has been to insist that they can in fact explain systematicity without merely implementing classical architectures by using distributed representations encoding complex structures in a nonconcatenative fashion (e.g., Smolensky 1991).

Implicit in this connectionist response is the idea that distributed representations and standard symbolic representations are somehow deeply different in nature. For millennia, philosophers have attempted to develop a taxonomy of representations. At the highest level, they have usually distinguished just two major kinds—the generically linguistic or symbolic, and the generically imagistic or pictorial. Is distribution just an accidental property of these more basic kinds, or do distributed representations form a third fundamental category?

Answers to questions like these obviously depend on exactly what we mean by "distributed." The standard approach, as exemplified in the preceding discussion, has been to define various notions of distribution in terms of structures of correspondence between the represented items and the representational resources (e.g., van Gelder 1992). This approach may be misguided; the essence of this alternative category of representation might be some other property entirely. For example, Haugeland (1991) has suggested that whether a representation is distributed or not turns on the nature of the knowledge it encodes.

It has been argued that some of the most intransigent problems confronting orthodox artificial intelligence are rooted in its commitment to representing knowledge by means of digital symbol structures (Dreyfus 1992). If this is right, there must be some other form of knowledge representation underlying human capacities. If distributed representation is indeed a fundamentally different form of representation, it may be suited to playing this role (Haugeland 1978).

Domain Specificity

Cognitive abilities are *domain-specific* to the extent that the mode of reasoning, structure of knowledge, and mechanisms for acquiring knowledge differ in important ways across distinct content areas. For example, many researchers have concluded that the ways in which language is learned and represented are distinct from the ways in which other cognitive skills are learned and represented (Chomsky 1988; but see Bates, Bretherton, and Snyder 1988). Other candidate domains include (but are not limited to) number processing, face perception, and spatial reasoning. The view that thought is domain-specific contrasts with a long-held position that humans are endowed with a general set of reasoning abilities (e.g., memory, attention, inference) that they apply to any cognitive task, regardless of specific content. For example, Jean PIAGET's (1983) theory of cognitive development is a domain-general theory, according to which a child's thought at a given age can be characterized in terms of a single cognitive level. In contrast, evidence for domain-specificity comes from multiple sources, including variability in cognitive level across domains within a given individual at a given point in time (e.g., Gelman and Baillargeon 1983), neuropsychological dissociations between domains (e.g., Baron-Cohen 1995), innate cognitive capacities in infants (Spelke 1994), evolutionary arguments (Cosmides and Tooby 1994), ethological studies of animal learning (e.g., Marler 1991), coherent folk theories (Gopnik and Wellman 1994), and domain-specific performance in areas of expertise (Chase and Simon 1973).

Domain-specificity is not a single, unified theory of the mind. There are at least three distinct approaches to cognition that assume domain-specificity. These approaches include modules, theories, and expertise (see Hirschfeld and Gelman 1994; Wellman and Gelman 1997).

The most powerful domain-specific approach is modularity theory, according to which the mind consists of "separate systems [i.e., the language faculty, visual system, facial recognition module, etc.] with their own properties" (Chomsky 1988: 161). Proposals regarding modularity have varied in at least two respects: whether modularity is restricted to perceptual processes or affects reasoning processes as well, and whether modularity is innate or constructed. Modularity need not imply evolved innate modules (see Karmiloff-Smith 1992) but for most modular proponents it does. Nonetheless, all modularity views assume domain-specificity. Chomsky's focus was on language, and more specifically SYNTAX or universal grammar. Evidence for the status of syntax as a module was its innate, biologically driven character (evident in all and only humans), its neurological localization and breakdown (the selective impairment of syntactic competence in some forms of brain damage), its rapid acquisition in the face of meager environmental data (abstract syntactic categories are readily acquired by young children), and the presence of critical periods and maturational timetables (see Pinker 1994).

Fodor (1983) extended the logic of modules to cognitive abilities more broadly. He distinguished between central logical processes and perceptual systems, arguing for modularity of the latter. In Fodor's analysis, modules are innately specified systems that take in sensory inputs and yield necessary representations of them. The visual system as characterized by MARR (1982) provides a prototypical example: a system that takes visual inputs and generates 2.5-dimensional representations of objects and space. Like the visual system, by Fodor's analysis, modules are innately specified, their processing is mandatory and encapsulated, and (unlike central knowledge and beliefs) their representational outputs are

insensitive to revision via experience. Experience provides specific inputs to modules, which yield mandatory representations of inputs. Certain experiential inputs may be necessary to trigger working of the module in the first place, but the processes by which the module arrives at its representations are mandatory rather than revisable.

Extending Fodor, several writers have argued that certain conceptual processes, not just perceptual ones, are modular (Karmiloff-Smith 1992; Sperber 1994) or supported by systems of cognitive modules (e.g., Baron-Cohen 1995; Leslie 1994). In these claims each module works independently, achieving its own special representations. Thus, for the most part cognitive modules are like Fodor's perceptual ones, except that "perceptual processes have, as input, information provided by sensory receptors, and as output, a conceptual representation categorizing the object perceived . . . conceptual processes have conceptual representations both as input and as output" (Sperber 1994: 40).

The claim that people ordinarily construct or possess folk theories (as distinct from scientific theories) is a controversial one. However, everyday thought may be considered theory-like in its resistance to counterevidence, ontological commitments, attention to domain-specific causal principles, and coherence of beliefs (Carey 1985; Gopnik and Wellman 1994). Like modules, folk theories are also domain-specific. Folk theories make use of domain-specific ontologies (e.g., a folk theory of psychology concerns mental entities such as beliefs and desires, whereas a folk theory of physics concerns physical entities such as objects and substances). Folk theories also entail domain-specific causal explanations (e.g., the law of gravity is not applied to mental states). However, in contrast to modules, which are generally assumed to be innately constrained, biologically determined, and invariant, theories are thought to undergo radical restructuring over time, and to be informed by knowledge and cultural beliefs. On this construal of domain-specificity, candidate domains include psychology (also known as theory of mind; Wellman 1990), physics (McCloskey, Washburn, and Felch 1983), and biology (Keil 1994); see Wellman and Gelman (1997).
